These proceedings of the Ninth International Conference on Permafrost (NICOP) extend the documented legacy of permafrost related research begun in 1963 when the first International Conference was held in West Lafayette, Indiana, USA. NICOP also marks the 25th anniversary of the Fourth International Conference on Permafrost that was convened in Fairbanks in July 1983. It is imperative that we continue this international and long-ranging dialogue of cooperation on permafrost, particularly during a period of overall global warming. At no time in the past has our overall interest level in permafrost been greater. The number of papers published in these proceedings substantiates this interest. In addition to climate change, development in regions of permafrost is contributing additional stress to this thermally sensitive environment. This recent increased growth is often associated with resource development such as oil and gas, and various mineral resources.

The papers presented in these proceedings are diverse in both time and space; they cover results from field and laboratory studies, remote sensing, analyses and modeling – or some combination of these. Both scientific and engineering aspects of various permafrost issues are presented, and are often intertwined with each other. We hope these proceedings provide one more positive step in our understanding of the permafrost environment that intrigues us as scientists and engineers.

Volume 2

Preface

Since the first International Permafrost Conference convened in 1963, we have sustained an international scientific and engineering collaborative effort until we now are immersed in this, the Ninth International Conference on Permafrost (NICOP). Considerable change has occurred over the past 45 years, resulting in heightened interest in the permafrost environment and understanding of its many aspects. Participation by engineers and scientists in advancing our knowledge of permafrost as a thermally impacted medium has continued to grow in the wake of both resource development and climate change.

The University of Alaska Fairbanks (America's Arctic University) is an excellent choice for the location of this conference. Permafrost is ubiquitous in Interior Alaska, and it influences many aspects of our society. Our local field trips are arranged around some of the most interesting phenomena here in the zone of discontinuous permafrost, including the world famous Permafrost Tunnel, the Trans Alaska Oil Pipeline, evidence of anthropogenic impacts on permafrost, and thermokarsting of warm permafrost. Fairbanks is also a good starting point for trips to other parts of Alaska, including the North Slope, Seward Peninsula, Denali National Park (Mount McKinley), and many other adventures. We have also taken this opportunity to offer courses related to the permafrost environment for high school and elementary teachers, advanced graduate students, and working professionals.

The University of Alaska Fairbanks hosted the Fourth International Conference on Permafrost in 1983. It was at this meeting that the International Permafrost Association (IPA) was formally established. IPA members are truly pleased with the strong international flavor of this year's conference, with approximately 30 countries participating. IPA's uninterrupted activities over the past 25 years are partially responsible for this concerted effort to expand our understanding of the permafrost environment, both spatially and temporally. It is also, however, abundantly clear that much of our current interest in this environment is driven by climate change.

Currently, many aspects of permafrost research are receiving considerable attention. These include carbon release into the atmosphere, discharge from catchments dominated with permafrost, the role of gas hydrates in cold environments, degrading permafrost and thermokarsting, infrastructure design in a changing environment, and the overarching issue of climate change on this thermally sensitive environment. It is essential that our scientific and engineering communities help our societies adapt to living and working on warming permafrost. Permafrost degradation will affect all aspects of life in the high latitudes and high elevations. We must anticipate the changes in ecology, hydrology, and infrastructure construction that will accompany degradation of permafrost with a warming climate. That is the challenge facing permafrost scientists and engineers. It is our hope that by sharing our knowledge and understanding, we may better serve our nations and people.

Enjoy the conference. We hope you will go home with increased knowledge and an invigorated appetite for expanding our understanding of the environment we call "permafrost."

—Douglas L. Kane
Water and Environmental Research Center, Institute of Northern Engineering

International Arctic Research Center

Acknowledgments

We, the organizers of the Ninth International Conference on Permafrost (NICOP), cannot sufficiently express our gratitude to those who have made NICOP both possible and successful. There are those who contributed financially by keeping the cost of the registration low, supporting young investigators, helping defer the cost of the proceedings, and sustaining many other behind-the-scenes activities. There are those who served on the numerous committees associated with this conference at the local, national, and international levels; we hope they found this exercise to be professionally rewarding. Finally, there are those who served as associate editors and reviewers of the more than 400 papers submitted. This conference is advertised as an International Conference; to be truly successful, much work must be done to overcome language barriers. While not always finding success in bringing a paper to publication, the associate editors and reviewers performed in a very commendable manner. Thank you all for your help.

Abstract

In the seasonally frozen ground regions in Gansu Province, Northwestern China, highway embankment and pavement have frequently been damaged due to the impacts of frost and salt heaving and thaw settlement, generally in the forms of pavement cracks and break-ups. Mechanisms and mitigative measures for these hazards have been puzzling geocryologists and road engineers. In this research repeated freeze-thaw experiments of saline soils sampled from the subgrade at highway segments with frequent and repeated damages, at periodically fluctuating temperatures, were conducted in order to investigate the relationship of freeze-thaw processes in saline foundation soils with the strengths and impacts of soil salinity on the stability of foundation soils. The experimental results showed that salinity and frost susceptibility had great impact on the deformation process in saline soils. The deformation of saline soil is accumulative within limited freeze-thaw cycles with sufficient water supply. Elevation of the embankment height, drainage, and salinity controls in subgrade and embankment fills were proposed to cost-effectively mitigate frost and salt heaving and subsequent thaw-weakening during highway design, construction, and maintenance periods in regions affected by seasonally frozen saline soils.

Keywords: frost action; frost heaving; highway foundations; saline soil; seasonally frozen ground; thaw-weakening.

Introduction

The area of salinized soils is 1.91 x 10^5 km^2, accounting for about 2.0% of the total land territory in China. It is distributed mainly in the arid, semi-arid, and cold regions. Gansu Province has a saline soil area of 1.16 x 10^4 km^2, one of the largest in China. The major centers for the distribution of saline soils, such as Dunhuang, Yumen, Jiuquan, Linze, Yongchang and Minqing, are located in the Hexi Corridor in Central and Western Gansu Province (Fig. 1) (Qiu et al. 1996, Xu et al. 1999). In addition, salts in the soil-water system can be partially crystallized and excluded, and migrate along the thermal, pressure, and moisture gradients.

Foundation soils can be significantly and differentially expanded from salt heaving, resulting in serious damages to roads and other buildings (Wu & Zhu, 2002). Studies on frost and salt heaving of saline soils have been intensively conducted both in laboratory tests and *in situ* observations in the field for many years. Xu et al. (1992) studied water and ion migration and its resultant deformation of soils in an experiment using the frozen Kaolin soil supplied with the NaCl solution. The result indicated that the deformation in the frozen Kaolin was mainly in the form of frost heaving. Qiu (1986) studied the processes of ion and water migration. He proposed that some ion types of salt for restraining frost heave. Fei et al. (1994) studied salt-heave characteristics of Xi'an Loess, and proposed that the salt-heave ratio was minimum for soils with 3% Na_2SO_4 and 1.8 g/cm^3 initial dry density. He further concluded that the salt heave of saline soil with Na_2SO_4 varied in a form of two parabolas with initial dry density and water content. Chen et al. (1988) suggested that the salt-heave ratio of silt with Na_2SO_4 changed exponentially with the cooling rate and the increasing overburden pressures. Xu et al. (1995, 1999) systemically studied frost and salt heave of soils, including changes of unfrozen water content, migration of moisture and ions, deformation due to salt heaving and its influencing factors, and coupled models for the prediction of frost and salt heaving. Wu & Zhu (2002) performed salt heave experiments of coarse-grained soil with Na_2SO_4 to analyze the processes of salt heave that affect the stability of building foundations. Results showed that the coarse-grained soil with a salt concentration layer could result in abrupt salt heaving that damaged engineering infrastructures. Liu et al. (2005)

Figure 1. Map of Gansu Province with main areas mentioned in paper.

carried out some experiments using soils with sulphates to measure the salt heave force and rate under a single factor and to study heave mechanisms. Other researchers mainly studied properties such as strength and deformation of saline soils, (Ogata et al. 1982, Sego et al. 1982), frost heave of saline soils (Chamberlian, 1983), the effect of salt enrichment on unfrozen water (Banin & Anderson, 1974), and water and ion migration in an open system (Ershov et al. 1989, 1991). In this paper, freeze-thaw experiments of typical soils, taken from the subgrade of highways where damages frequently occurred, have been conducted to study the characteristics of deformation processes due to the salt and frost heave and subsequent thaw weakening and settlement in Gansu Province. On the basis of this experimental study, some mitigative measures had been proposed to improve the stability of embankment and pavement soils in saline soil regions.

Experimental Process

Specimens for laboratory testing

Four soil specimens were studied in repeated freeze-thaw experiments in order to study deformation characteristics and processes caused by frost heave, salt expansion, and subsequent thaw settlement and weakening.

After careful field investigations on the damages of highway foundation soils in Gansu Province, northwestern China, three specimens of saline soils were sampled from road sections with severe damage in the embankment and pavement due to salt and frost heave. Sample No. 1 of silt was taken in Gaotai County along National Highway No. 109 (Fig. 1). Its field water content was 23.10% and salinity was very high. Salt crystals could be observed clearly. Numerous longitudinal and transverse cracks were found on the pavement where the specimen was taken. Sample No. 2 of silty clay was taken between Jiuquan to Jinta along National Highway No. 214. The climate is more arid in the area of Sample No. 2. The field water content was 5.18%. Sample No. 3 of fine silty sand was taken from the toe of the right side protection slope of National Highway No. 214 in the proximity of Jinta County, where visible white salt crystals

occur on the adjacent ground surface. Field water content was 9.53%. In addition, another soil specimen, Sample No. 4 of clay, was obtained in the middle of the Maqü to Luqü section along National Highway No. 213, at an elevation of about 3500 m and with a cold climate. It was tested as a reference specimen because of very low salinity (Table 1).

The basic parameters, such as liquid and plastic limits, plastic index, and salinity, of the four specimens were measured in the State Key Laboratory of Frozen Soil Engineering, CAREERI, Chinese Academy of Science (Table 1). The ions in the tested saline soils mainly include Cl^-, NO^{3-}, SO_4^{2-}, Na^+, Ca^{2+}, Mg^{2+}, K^+.

Sample preparation

Soil samples taken and sealed in the field were placed in polymethyl methacrylate tubes, layer by layer, and compacted to a certain density. Soils were converted to testing specimens. Cylinder specimens were 100 mm high with a diameter of 101 mm. They were consolidated for 24 hours at room temperature for uniform moisture distribution. Then the repeated freeze-thaw tests were carried out.

Laboratory equipment

Laboratory equipment for performing repeated freeze-thaw tests on the four soil specimens was developed by the State Key Laboratory of Frozen Soils Engineering (Fig. 2).

The polymethyl methacrylate tube was filled with a soil specimen. The temperatures at the top and bottom plates were controlled by cooling baths. The temperature at the bottom plate remained at +1°C. The exterior of the tube was insulated. The experiment system was put into an insulated box with a constant temperature at +1°C.

Every 30 minutes, the temperature at each vertical interval of 10 cm in the tested soil columns was measured by thermal-susceptible resistance sensors with a precision of ±0.2°C. The deformation in the soil columns was measured by a deformation sensor with a precision of ±0.01mm at the top of the soil columns. The temperature at the top plate varied according to a sinusoidal function as follows:

$$T = -2.5 + 7.5\sin(\frac{2\pi}{72}t) \tag{1}$$

Water was sucked up into the soil columns through the bottom plate due to the temperature difference. A freeze-thaw cycle is 72 hours. Saline soil Sample Nos. 1, 2, and 3 experienced three freeze-thaw cycles. Sample 4 was subject to only one freeze-thaw cycle because it had low salinity, and the frost susceptibility was measured and used as a reference. The temperatures at different depths, and deformation of soil samples were measured and recorded automatically when the freeze-thaw experiments were carried out.

Results and Discussions

The test results for Sample No. 1 indicate that the deformation at the top plate increased at a sinusoidal variation of the top plate temperatures with the elapse of time (Fig. 3). The temperature at the top plate was negative, and the upper part of the soil sample was frozen at the beginning of the experiment. The relevant deformation had a quickly increasing trend during the first several hours. Then the deformation increased slowly until about 30 hours had elapsed, when the temperature at top plate was positive. Subsequently, the heave rate of the soil sample increased more pronouncedly when the temperature at the top plate became negative again. In addition, when the temperature at the top plate was in the range of 0°C to 2°C, the heave rate of the soil sample was still reasonably high, due to the salt heaving. No thaw settlement was observed during the entire deformation process, due to the high salinity of the soil sample. From the above analyses and discussions, it can be concluded that the deformation of Sample No. 1 mainly included frost and salt heaving.

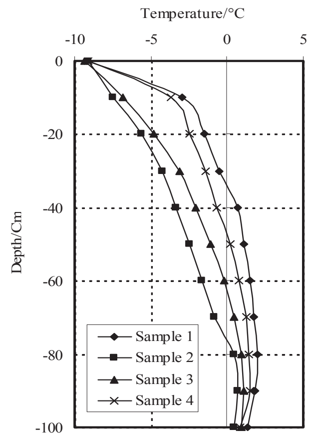

Figure 7. Temperature distribution curves in the tested soil columns when the top plate temperature reached -10°C, the minimum in the experiment.

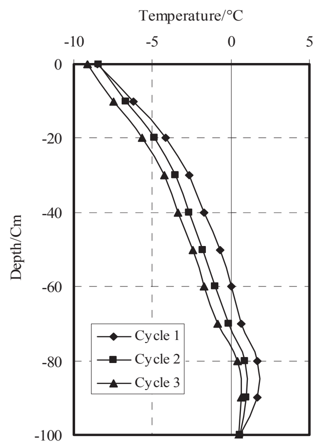

Figure 8. Temperature distribution curves of Sample No. 2 when the top plate temperature reached the minimum in different cycles.

Figure 4 is a diagram of the variation processes of the temperature and deformation at the top plate of Sample 2. The deformation of the soil sample gradually increased at the beginning when the temperature at the top plate was negative. A sudden decline of deformation of the soil sample occurred when the temperature at the top plate became positive, which mainly resulted from thaw settlement of the upper thawed soil. Slowly, the deformation kept almost steady, with only a slight decrease during the above-zero-temperature period. Subsequently, the deformation began to increase sharply when the temperature at the top plate was 2°C. It showed that salt heaving probably occurred. The deformation continued to rise sharply with the temperature becoming subzero and dropping continually. Meanwhile, it can be noted that the deformation was almost constant in the first few hours when temperatures dropped from 0°C to -2°C. That happened at each cycle. This indicates that there is a lag of deformation before cooling, due to insufficient time for deformation to occur. In the second cycle, the characteristics of the deformation process are similar to that of the first cycle. But the minimum amount of deformation of the soil sample corresponding to the positive temperature at the top plate was greater than that in the first cycle. It demonstrated

Table 2. Experimental results of four tested soil specimens.

Sample	Soil type	Salinity (%)	Deform-ation(mm)	Frozen depth(cm)	Water Uptake (ml)
No. 1	Silt	9.1	5	34	118
No. 2	Silty clay	2.79	7	76	89
No. 3	Silty sand	6.14	0.38	60	64
No. 4	Clay	0.15	3.6	47	45

that the deformation does not return to the initial position. There was a surplus heave deformation in Sample 2. The salt heave was not clear in the 2nd and 3rd cycles, probably because of a lack of salt after precipitation in the 1st cycle. From the above analyses and discussions, it can be seen that the deformation of Sample 2 was caused by frost heaving and thaw settlement, with possible salt heaving.

Figure 5 shows the variation processes of the temperature and the deformation at the top plate of Sample 3. The deformation of the soil sample began to increase when the temperature at the top plate was negative at the beginning. It was not clearer compared to that of Sample 2 (Fig. 4). When the top plate temperature became positive, the deformation was almost constant, with slight see-sawing decreases due to soil consolidation. When the temperature at the top plate decreased from a positive temperature to about -4.3°C, the deformation began to rise immediately and sharply. This showed that there was a longer lag of deformation compared to the temperature at the top plate, probably due to a high salinity (6.14%) and the soil type (silty sand), which are not favorable to soil freezing. Later, sudden settlement occurred in Sample 3 when the temperature increased to about -4.0°C. But it was still larger than that in the first cycle. This showed that the entire deformation was accumulative but smaller than Sample Nos. 1 and 2. It was difficult to determine the salt heave during the period of soil heave in Sample No. 3. So its deformation was mainly caused by frost heaving and thaw settlement, with possible salt heave, but the heave amount was smaller..

Sample No. 4, with low salinity, was tested for its frost-susceptibility. The deformation of the soil sample increased when the temperature at the top plate became negative at the beginning (Fig. 6). When the temperature reached the proximity of 0°C, sudden settlement of the soil sample occurred due to the thaw settlement of the upper part of the soil column. During the positive-temperature period at the top plate, the deformation kept stable. When the temperature decreased to about -0.6°C, the soil began to heave rapidly, until the temperature reached almost the minimum value of -9°C; then the increase of deformation slowed. However, even when the temperature rose within the subzero period, the frost heaving was still growing. This well confirmed that Sample No. 4 is a typical frost-susceptible soil.

Figure 7 shows the temperature distribution curves of the tested soil columns when the top plate temperature reached the minimum of -10°C during the 3rd cycle, except for Sample No. 4 in the 1st cycle. The frozen depth in Sample No. 2 was the maximum, while that of Sample No. 1 was the minimum. Sample No. 4, though subject to one freeze-thaw cycle, was frozen more deeply than Sample No. 1. Generally, the frozen depth in silty sand is greater than that in silty clay because of its greater thermal conductivity (Xu et al. 2001), but that in Sample No. 3 of silty sand was less than that in Sample No. 2. This indicates that salinity can effectively retard cold wave propagation.

Figure 8 shows the temperature distribution curves of Sample No. 2, as an example, when the top plate temperature reached the minimum of -10°C in different cycles. Note that the frozen depth rises with the increasing number of freeze-thaw cycles. The variation process of the frozen depth in Sample Nos. 1 and 3 is similar to that in Sample No. 2.

According to the above analyses and discussions based on the experimental results for four tested specimens, heave deformation is mainly influenced by soil type, salinity, freeze-thaw cycle numbers, and others. The heave deformation in Sample No. 2 of silty clay, with moderate salinity, is the maximum (Table 2). However, the heave deformation in Sample No. 3 of silty sand, with the greater salinity, is the minimum. Sample No. 4 expands to a higher level even after one cycle. The heave deformation in Sample No. 1, with the highest salinity, reached a higher level, and without thaw settlement. It can also be found that there are the different threshold values in salinity and freeze-thaw cycle for the different saline soils to lead to salt heave and salt hazards. To determine the threshold values need further investigations in detail.

Conclusions and Recommendations

According to the experiment results, analyses, and discussions mentioned above the following preliminary conclusions can be made:

(1) The deformation of saline soil is accumulative within limited freeze-thaw cycles with sufficient water supply, i.e., the minimum deformation increases gradually with the increasing number of freeze-thaw cycles.

(2) Salinity has great impact on the deformation process of saline soil. The deformation of soil with very high salinity was mainly caused by frost and salt heaving, without thaw settlement.

(3) Frost susceptibility strongly influences the deformation processes of saline soil. The heave deformation of non-frost susceptible saline soil, even with the higher salinity, is small.

(4) To determine the occurrence of salt heave is difficult for ordinal soils with moderate salinity because it happens together with frost heave.

(5) The heave deformation in saline soils is mainly influenced by soil type, salinity, freeze-thaw cycle number, water supply, and others. It is a complicated process with water, heat, and salt transfer subject to the repeated freeze-thaw cycles.

(6) Therefore, elevation of the embankment height from ground water table or surface standing water levels, subgrade and local drainage control, and stricter control of salinity of fills could be used to effectively mitigate frost and salt heaving, and subsequent thaw settlement and weakening for the design, construction, and maintenance of highway foundations in areas affected by saline soil.

Abstract

In this study, monthly average daily global radiation of 22 radiometric stations across the Tibetan Plateau were utilized to determine the coefficients of the monthly Angström–Prescott model for estimating global solar radiation from sunshine duration. Using the model, global solar radiation of another 116 meteorological stations across the Tibetan Plateau were estimated. Combined with frozen ground data measurement at 75 stations, global radiation effects on the maximum frozen depth of the active layer were discussed. The result showed that global radiation in the cold season (from October to February the next year) had much influence on maximum frozen depth of the active layer. The relationship between them in three typical stations showed a marked negative correlation. As a whole, the maximum frozen depth of the active layer in nearly 80% of investigation stations had the same relationship with the global solar radiation, while the others showed a positive correlation. This indicated that the maximum frozen depth of the active layer was the result of combined effects of several factors other than global radiation. Of these influencing factors, such as global solar radiation, local latitude, longitude, altitude, air temperature in cold season, relative humidity, accumulation of precipitation in cold season, etc., only local latitude, altitude, global solar radiation, and air temperature showed high correlation with frozen depth. Essentially, the influences of local latitude and altitude can be regarded as the effects of global radiation indirectly. As the local latitude and altitude influenced the distribution of global radiation, so the global radiation was an important affecting factor on the maximum frozen depth of the active layer.

Keywords: active layer depth; global radiation; relative sunshine duration; Tibetan Plateau.

Introduction

Solar radiation is a main source of the Earth's energy and the basic driving force of the physical and biological processes on the earth surface. The processes respond to the seasonal variations in solar radiation fluxes in a complex manner. The distribution of solar radiation around the world determines the planet's mean climate variation resulting from the thermal balance of the Earth–atmosphere system, and establishes atmospheric and oceanic circulation patterns (Souza, et al. 2005). Topographic conditions effect the distribution of solar radiation.

As for China, its regional topography is complex and its surface condition is varied. This is especially conspicuous in the Qinghai-Tibetan Plateau (TP) with higher altitude and complex terrain. The TP is one of the most complex geographical features in the world, with an average elevation about 4 km or more. Such land surface features make much difference in solar radiation among different regions across the TP and result in unequal surface heating by solar radiation (Ye & Gao 1979). Non-uniform distribution of solar energy on the land surface has much effect on climate over the TP and its surrounding area, and even on the global climate. In addition, the TP, which is a huge land mass standing in the mid-altitude troposphere with high altitude and complex terrain, lies in the transition zone between the tropical and sub-tropical and also in the heart zone of the famous monsoon region in the Northern Hemisphere; its dramatic heating and its strong continental strongly impact the Asian monsoon, global atmospheric circulation and global climate change (Ye & Gao 1979, Tao et al. 1999).

Moreover, the distribution of solar radiation across the TP has a decisive effect on a decision on the characteristics of plateau glaciers, permafrost, and vegetation distribution.

Furthermore, due to its unique geographic environment, the TP developed a large area of permafrost, which is the result of the climate change, and it also has feedback effect on climate. As an important component of cryosphere, which is an important driving force of global change and a connection for interaction of other layers in the climatic system, the presence and changes of the permafrost can affect the energy and water exchanges of the land-atmosphere system and further affect the formation and development of regional climate (Yao et al. 2002, Zhang 2002). The active layer at the upper part of the permafrost is thawed in summer and frozen in winter. Permafrost changes, leading to changes in water and heat exchange characteristics between land and atmosphere, first by changing the water-heat states of the active layer, thereby causing changes and anomaly of the atmospheric circulation system (Wang et al. 2003), then affecting the weather system. Changes of the maximum frozen depth of the active layer are key indicators of climatic warming (Pavolv 1994). Thus, the maximum frozen depth of the active layer has a close relation with the climate.

As a product of climate change, features of permafrost are by the impacts of climate change, and global radiation in the TP is an important influencing factor on Plateau climate. Global radiation is the major source of ground heat in the TP. Fluctuations in global radiation will cause a corresponding impact to permafrost and its active layer (Kou et al. 1981). Study of the relationship between global radiation and frozen/thawed depth of the active layer do much to help us better understand the impact mechanism of the permafrost and its active layer. Relevant research work has been launched in the TP region and has achieved some results. In the early 1980s, Kou et al. (1981) studied the relationship between global radiation and the thawed depth of the active layer using the data measured at Fenghoushan at the TP. In their view, thawed depth of the active layer in the permafrost region was caused by solar radiant heat arriving at the surface and down into the ground, and the statistical relationship between them was established. The studies of Cheng et al. (1983, 1984, 1992) showed that the characteristics of the surface solar radiation latitudinal variation were important reasons for the permafrost zone. The variation of global radiation determined the annual mean temperature at the bottom of the freezing and thawing depth of the active layer (Zhou et al. 2000). Ding et al. (2000) discussed the relationship between the accumulative soil temperature at 4 cm depth below the surface and the freezing/thawing depth of the active layer of the TP. Research showed that the formation of permafrost and seasonal permafrost had a relationship with surface radiation-heat exchange. The structure of the radiation-heat balance had a decisive role in the formation and dynamics of frozen ground. The surface energy budget and the changing of the surface-air temperature were decided by the net radiation, which depends mostly on global radiation, surface condition, and net long-wave radiation (Zhou et al. 2000).

Those works mentioned above provided a basis for the mechanism research of permafrost in the TP; however, restricted by natural condition and outlay, those studies were only based on a single site and with a short-term dataset (Zhou et al. 2000). The work was small considering the large-scale and long-term dataset of the TP. For the whole TP, further works need to be done.

In this work, global radiation was estimated across the TP; its influence on the maximum frozen depth of the active layer was discussed. By multiple regression analysis method, several effect factors for the maximum frozen depth of the active layer were analyzed too.

Material and Method

Data used in this paper include frozen depth, global solar radiation, monthly accumulative precipitation, monthly average and extreme air temperatures, relative humidity, and relative sunshine duration. Frozen depth data in the cold season were collected in 75 meteorological stations from 1961–1998. Datasets of precipitation, monthly average air temperature and extreme temperatures, relative humidity, and relative sunshine duration were collected in 138 stations in the TP and its adjacent regions. These data were measured by corresponding observation criteria.

As for radiant data, there were only 22 radiometric stations in the TP and its adjacent regions; other meteorological stations are without radiation measurements, so global radiations in those stations was estimated. The AngstrÖm–Prescott model (APM) is the most convenient and widely used correlation for estimating global solar radiation (Liu & Ji 1985, Chegaar & Chibani 2001, Almorox & Hontoria 2004, Almorox et al. 2005), which is expressed by

$$Q / I_0 = a + bS_1 \tag{1}$$

where Q and I_0 are, respectively, the monthly mean daily global radiation (MJ.m-2.d-1) and daily extraterrestrial radiation on a horizontal surface (MJ.m-2.d-1); S_1 is relative duration of sunshine (the ratio between the number of hours of sunshine duration to the total number of daylight hours); a and b are empirically coefficients. Using the measured data of monthly average daily global solar radiation on horizontal surfaces and sunshine hours from 22 radiometric stations across the TP, as given in Table 1, coefficients a and b can be determined by the method of least squares. As a result, the APM over the TP can be written as (Li, et al. 2007):

$$Q / I_0 = 0.213 + 0.5691 S_1 \tag{2}$$

The performance of APM was evaluated by calculating the following statistical error test such as mean bias error (MBE), mean absolute error (MAE), root mean square error (RMSE), and mean relative error (MRE). These tests are fundamental measures of accuracy (Driesse & Thevenard 2002, Almorox & Hontoria 2004, El-Metwally 2004, Almorox et al. 2005, Tymvios & Jacovides 2005, Menges et al. 2006, Bulut & Büyükalaca 2007). They are defined as below:

$$MBE = \frac{1}{n}\sum_{i=1}^{n}\left(Q_{i,obs} - Q_{i,est}\right) \tag{3}$$

$$MAE = \frac{1}{n}\sum_{i=1}^{n}\left|Q_{i,obs} - Q_{i,est}\right| \tag{4}$$

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(Q_{i,obs} - Q_{i,est}\right)^2} \tag{5}$$

$$MRE = \frac{1}{n}\sum_{i=1}^{n}\left|\frac{Q_{i,obs} - Q_{i,est}}{Q_{i,obs}}\right| \tag{6}$$

The indexes (obs) and (est) identify observed and estimated values, respectively. Results of the APM, applied to the whole dataset available with 7400 samples from 22 radiometric stations across the TP, are illustrated in Figure 1. It can be seen from Figure 1 that the scattering of the data points was small. And the values of MBE, MAE, RMSE for the whole dataset result in -0.06, 1.22, 1.64 MJ.m-2.d-1, respectively. The value of MRE is 7.6%. Such results indicate that the agreement between the measured and estimated values is marked. It demonstrates that APM was acceptable for estimating monthly global solar radiation from relative sunshine duration over the TP. With Equation 2, the monthly average daily global radiation on a horizontal surface (Q) in MJ.m-2.d-1 from January 1961 to December 2000 at 116 meteorological stations can be estimated. Finally, its monthly total can be obtained too.

For convenience of analysis, the statistical variable, accumulative anomaly for Q and FD is introduced. It is defined as

$$x_j = \sum_{i=1}^{j}\left(x_i - \bar{x}\right) \qquad (j \le n) \tag{7}$$

where x_j is the accumulative anomaly value of Q or FD from first year to the j year, $\bar{x}$ is the average value of the whole dataset, and n is the length of the dataset.

Results and Discussion

EOF (Empirical Orthogonal Function) analysis results showed that Yushu (33°01′N, 97°01′E, 3682.2 m), Lenghu (38°45′N, 93°20′E, 2770.0 m) and Delingha (37°22′N, 97°22′E, 2982.4 m) were typical sites (Xu, et al. 1990, Wang et al. 2003), so the influence of global radiation on the maximum frozen depth of the active layer in these three typical sites is discussed at first.

Figure 2 shows the influences of the accumulative anomalies of global radiation on the maximum frozen depth of the active layer in three typical stations at the TP. It can

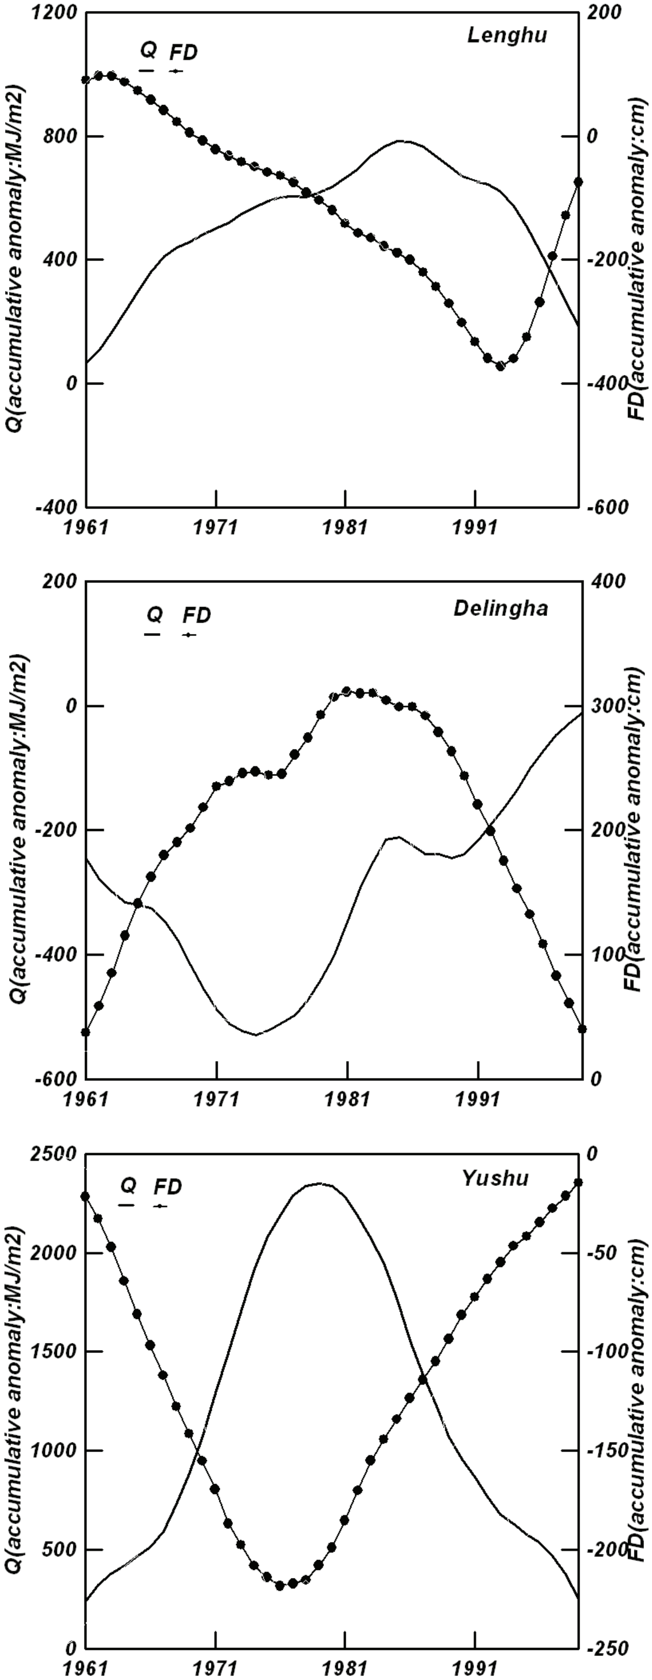

Figure 2. The influences of global radiation in three typical stations on the maximum frozen depth of the active layer.

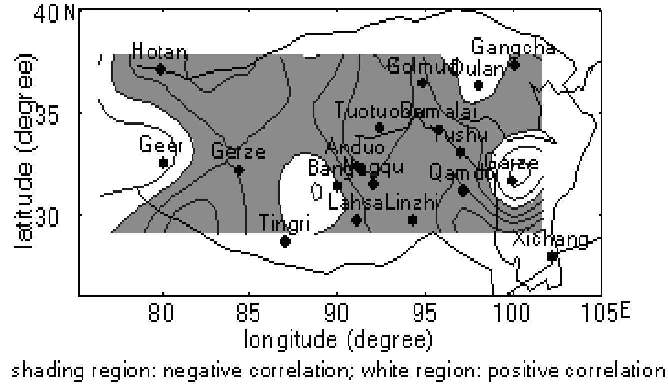

Figure 3. Distribution of the correlativity between global radiation and the maximum frozen depth of the active layer.

be seen from Figure 2 that the accumulative global radiation (Q) in cold season (from October to February of the next year) had much influence on FD. The relationship between them in three typical stations showed a marked negative correlation. How about the other stations across the TP? The relationships between global radiation and maximum frozen depth of the active layer in cold season across the TP for another 72 stations were also analyzed too. The results are illustrated in Figure 3.

Figure 3 shows the distribution of the correlativity between global radiation and maximum frozen depth of the active layer. In Figure 3, the shaded part stands for the negative correlation region, while the white part stands for the positive correlation region. As a whole, the maximum frozen depth of the active layer in nearly 80% of the investigation stations had the same relationship with global solar radiation as those typical stations, whereas the other 20% showed a positive correlation. It indicates that the maximum frozen depth of the active layer was influenced by other factors at the same time. In addition to global radiation, the maximum frozen depth of the active layer was the result of combined effects of other factors, such as soil water content, soil property, altitude and latitude, snowpack, vegetation, etc. But what is the importance among those factors mentioned above? Multiple regression analysis method was used here to answer the question. Factors such as global solar radiation, local latitude, longitude, altitude, average air temperature, relative humidity, and accumulation of precipitation in cold season were selected in the multiple regression analysis; among these factors only local latitude, altitude, global solar radiation and air temperature showed high correlation with frozen depth. The multiple regression equation could be written as

$$FD = -434.6 + 12.24\phi + 0.043H - 0.02Q - 6.74T_a \tag{8}$$

where Φ, H, Q, and Ta were the local latitude, altitude, global radiation, and air temperature at the station. The units of these variables were the same as those mentioned above.

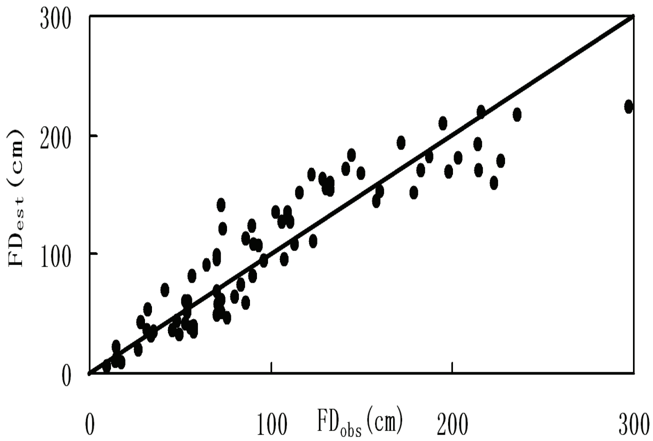

Figure 4. Comparison between the maximum frozen depth of the active layer values observed (FD_{obs}) and estimated (FD_{est}).

Global radiation was the amount from October to February of the next year. The air temperature, *Ta,* was the average value during the time range from October to February of the next year. The multiple correlation coefficient of Equation 8 was 0.90, the partial correlation coefficients for Φ, *H*, *Q* and *Ta* were 0.99, 0.98, 0.81, and 0.81, respectively. It indicated that the correlation between maximum frozen depth of the active layer and the four effective factors was good. The result between the observed and estimated frozen depth with Equation 8 is illustrated in Figure 4. It can be seen from Figure 4 that when the maximum frozen depth of the active layer is less than 300 cm, the agreement between the measured and computed values is good, and the scattering of the data points is small. It demonstrates that Equation 8 was acceptable for estimating the average of the maximum frozen depth of the active layer over the TP.

It can also be seen from Equation 8 that for the whole TP, the global ration showed a negative correlation with the maximum frozen depth of the active layer. The local latitude and altitude show positive correlation with the maximum frozen depth of the active layer. Essentially, the influences of local latitude and altitude can be regarded as the effects of global radiation indirectly. As the local latitude and altitude influence the distribution of global radiation, so the global radiation is an important affecting factor on the maximum frozen depth of the active layer.

Conclusions

From the above discussion, the following conclusions could be drawn:

(1) The APM was acceptable for the estimation of global solar radiation.
(2) Global radiation in the cold season greatly influenced the maximum frozen depth of the active layer. The relationship between them in three typical stations (Yushu, Lenghu, and Delingha) showed a marked negative correlation.
(3) For the whole TP, maximum frozen depth of the active layer in nearly 80% of all investigation stations had the same relationship with global solar radiation as the three typical stations; the others showed a positive correlation.
(4) The maximum frozen depth of the active layer was the result of combined effects of several factors except for global radiation. Among these influencing factors, local latitude, altitude, global solar radiation, and air temperature showed high correlation with the maximum frozen depth of the active layer.
(5) Global radiation was an important affecting factor on the maximum frozen depth of the active layer.

Due to a lack of data on soil properties of the TP, such as aspect was not considered in this work. Thus, further work needs to be done.

Tundra Soil-Water Content and Temperature Data in Support of Winter Tundra Travel

Michael R. Lilly

Geo-Watersheds Scientific, College Station, Texas
Douglas L. Kane
University of Alaska Fairbanks, Fairbanks, Alaska

Abstract

Unfrozen soil-water content was monitored in the active layer of tundra soil, using TDR sensors at several locations on the North Slope of Alaska and in the Brooks Range foothills. In addition, soil temperature was monitored to a depth of 1.5 m at these locations using thermistors. Particular attention was paid to soil water and temperature behavior during freezing and thawing conditions. The upper organic layer of soil often exhibited very wet conditions and showed much greater temporal variability of soil moisture than the lower mineral soil layers. Permafrost acts as a barrier to water flow, so soils usually are wet as they thaw in the spring. Soil surface roughness and vegetation under tundra conditions make accurate placement of sensors almost impossible. Minor discrepancies between soil water freezing and thawing behavior must be tolerated. However, an overall picture of the processes still emerges. Results of this study may be useful in improving tundra travel guidelines. Currently, tundra travel is allowed if the soil temperature in the upper foot of soil is colder than -5°C. Soil-water content is not considered in the current management approach, though it can be used to help better describe the temperatures at which soil freezing is complete. The measured soil-moisture data indicates most of the soil-water freezing occurs above -2°C. This information indicates the -5°C temperature condition is very conservative and a warmer temperature management point should be considered.

Keywords: measurements; permafrost; soil moisture; soil temperature; tundra travel.

Introduction

A project was established in 2006 to gather data for use in addressing various surface transportation issues in northern Alaska. This report examines some of the results obtained thus far with respect to winter tundra travel. Current guidelines limit tundra travel to periods when the soil temperature at a depth of 30 cm is less than -5°C with snow cover depth minimums depending upon the type of tundra (Bader 2005). This criterion is based on the results of a three-year study (Bader & Guimond, 2004) and may be conservative.

Soil-temperature and water-content data are used in this paper to examine the possibility of using a slightly relaxed criterion that could result in longer periods of allowed tundra travel. This is based strictly on the freeze-thaw behavior of soil water. No measurements of soil strength were obtained. The objective is to examine the behavior of soil temperature and water content in tundra soils during the processes of freezing and thawing.

Materials and Methods

Twelve stations were installed in the fall of 2006. Eight of the stations are located on the coastal plain; the remaining four are in the northern foothills of the Brooks Range. The stations used in this report are located east of the Sagavanirktok River (Fig. 1).

Soil-water content was monitored at each station with Campbell Scientific, Inc. CS616 TDR-type sensors at depths of 10, 20, and 40 cm. The depths at some sites varied slightly due to soil conditions. The soil-water content sensors were installed horizontally with minimal soil disturbance. Factory calibration was used to convert raw readings to volume fraction soil-water content. TDR-type sensors respond to the soil dielectric constant, and since ice has a dielectric constant similar to dry soil, the sensor effectively responds to changes in unfrozen soil-water content. Hourly readings of unfrozen soil-water content were recorded.

Soil temperature was monitored at each station with YSI thermistors mounted in a string, at intervals to provide temperatures at 0, 5, 10, 15, 20, 40, 60, 80, 100, 120, 135, and 150 cm below the soil surface. The soil temperature string was placed into a hole drilled into the soil, and the evacuated soil was used to back-fill the hole. Hourly readings of soil temperature were recorded.

Other measurements include air temperature, relative humidity, net radiation, wind speed and direction, snow depth, and summer rain. Sensor readings at each station were measured and recorded with a Campbell Scientific, Inc CR1000 datalogger. Data were transmitted hourly to a central processing facility with FreeWave radios. Solar panels and a battery bank were used to provide power for each station throughout the year.

Results and Discussion

Ice formation within soil pores increases the bearing strength of freezing soils. Extremely dry soils, such as found in the Dry Valleys of Antarctica, or dry gravel or organic soils exhibit no increase in bearing strength when frozen.

As soil water freezes, it acts as an impediment to the movement of soil particles, thus increasing the bearing strength of the soil. Water freezing in soil pores acts as if solid particles were growing in the pores. A graph of frozen soil-water content versus soil bearing strength in water- saturated soil would be a typical S-shaped curve. As soil water starts to freeze, little strength is added. At some point, the increase in strength with water content is dramatic. As the freezing process goes to completion, the curve levels off, and little strength is added during the last stages of freezing. The bearing strength of frozen soil is greater than the maximum of the strength of ice or of unfrozen soil.

Similarly, for unsaturated soils, higher water content up to some maximum, will result in higher strength when the soil freezes. Very low soil-water content does little to increase soil strength when the soil is frozen. As soil-water content increases, soil strength increases upon freezing.

Soil water does not completely freeze at temperatures below 0°C. As heat is removed from water, the temperature lowers until the freezing point is reached. At this point, the temperature remains constant until the liquid water solidifies, or changes to ice, at which time the temperature will once again start to drop. In soils, however, water does not all freeze at the same temperature. Some freezes at or near 0°C, while some freezes at much lower temperatures. No unique freezing point exists for soil water (Koopmans & Miller 1966). There are two reasons for this. One, soil water contains solutes or salts which lower the freezing point. As the soil water freezes, the salts become more concentrated due to exclusion from the ice. And two, the "structure" of soil water becomes increasingly ordered closer to soil particles. This changes the free energy of the soil water and lowers the freezing point. A similar phenomenon can be observed in capillary tubes (Edlefsen & Anderson 1943).

Increasing the solute concentration of soil water produces a minor effect compared to the "structuring" of the soil water near soil particles.

The water next to soil particles is the last to freeze, and will do so only at extremely low temperatures, due to its molecular interaction with the soil particles (Anderson et. al. 1973). Water is a polar molecule, and soil particles, especially clay and organic matter, have associated negative charges. Water molecules tend to align in an ordered fashion or "structure" next to soil particles. The effect decreases with distance from the soil particle. The ordered molecules are more difficult to freeze than those in bulk solution or free water. The amount of unfrozen water present depends principally upon temperature for a given soil material. Except for very low water contents, it is virtually independent of the total soil-water volume. The unfrozen-water content at a given temperature is mainly dependent on specific surface area of the soil. The amount of unfrozen water at a given temperature increases as the specific surface area of a soil increases.

Data are presented from station DBM4 Sag Ivishak Met, which was chosen as representative for this project. The

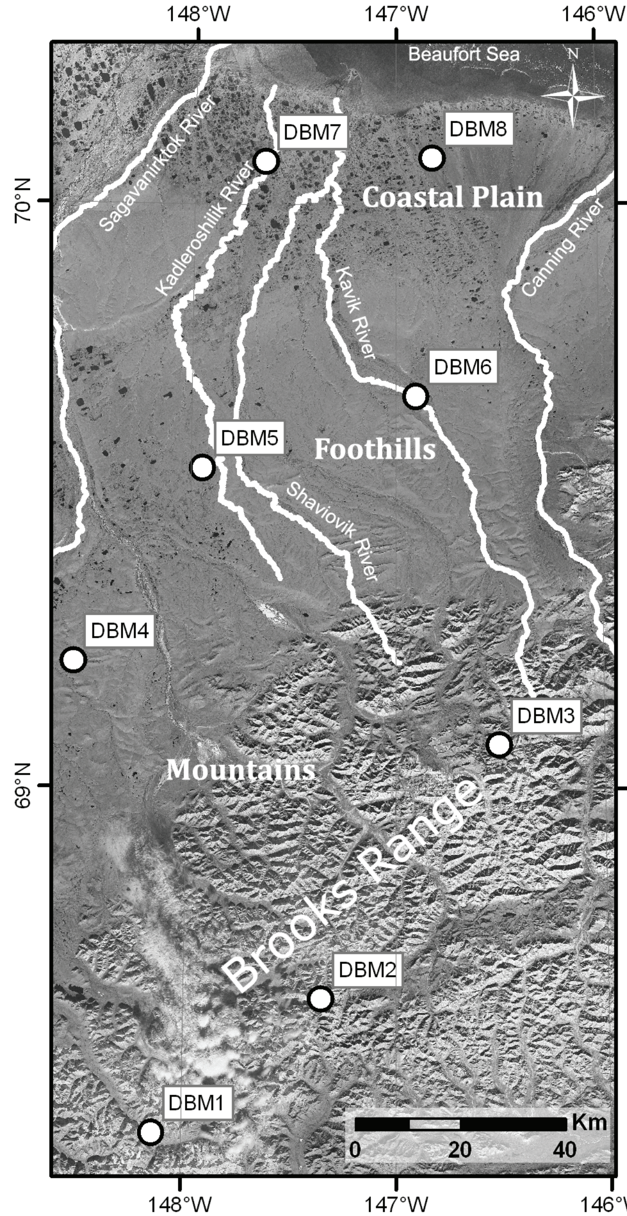

Figure 1. Study sites locations on the central North Slope, Alaska.

active layer thickness (Fig. 2) for this station, as determined by the point at which the maximum soil temperature line crosses the 0°C line, is approximately 60 cm for the period of measurement (October 1, 2006, to September 30, 2007). This is a fairly typical active layer thickness for the soils of this area. Active layer thickness varies from year to year depending on summer weather. The average soil temperature in the upper 150 cm was -4.15°C during the measurement period.

Other methods of active-layer strength determination may yield different results. Rod penetration is the most common method of determining active layer thickness. Problems with the rod penetration method include timing, presence of hard spots in the soil (ice lenses, rocks, compact areas, etc.), and operator consistency. It is also a labor-intensive method. An advantage of the penetration method is that it is usually

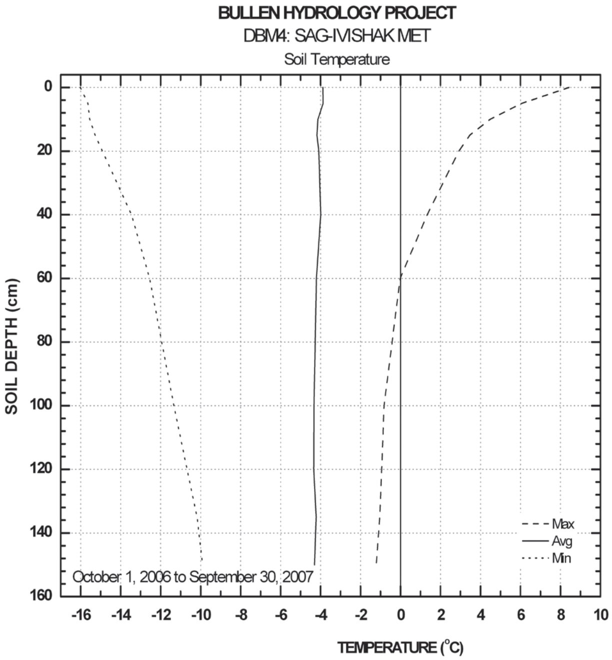

Figure 2. Average, maximum, and minimum soil temperature profiles for the DBM4 Sag Ivishak Met site.

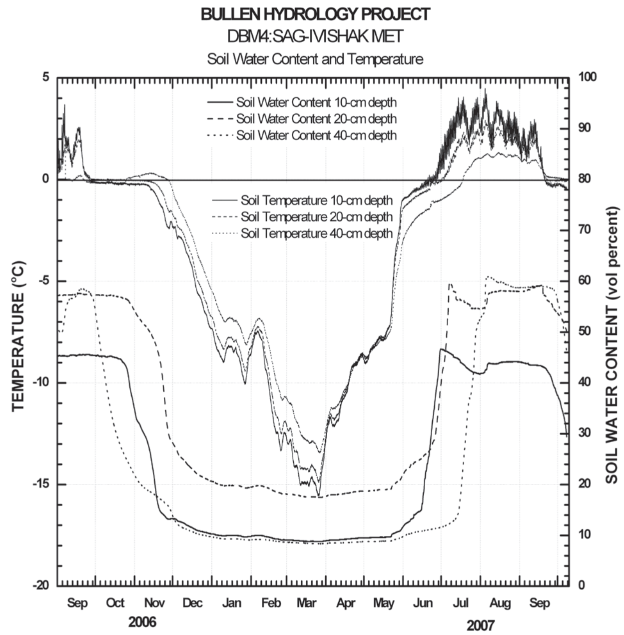

Figure 3. Soil-water content and temperature for the Sag-Ivishak (DBM4) meteorological station.

repeated over a relatively large area, resulting in an average, maximum, and minimum value for the area. One problem common to all methods is the location of the soil surface as a reference point for depth. This can be a very serious problem in tussock tundra.

Active layer thickness was generally a few centimeters less for the foothills stations than for those on the coastal plain. In addition, the soil at these sites remained frozen longer. Although soil temperatures vary among the stations, the relationship between soil temperature and soil water is consistent.

The soil-water content at the Sag Ivishak Met site was near saturation during the monitoring period from September 2006 to October 2007 (Fig. 2). This is typical of soils in this area. Often soils in northern Alaska are wetter in the spring and early summer, then dry out in the fall. During the summer, down-gradient drainage and evapotranspiration dry out the soils. The soil-water content at saturation in this soil is around 60% by volume. Normal mineral soils have a saturated-water content of around 40% to 45% by volume. The high-saturated water contents in the soils studied are attributed to high soil organic-matter content.

For greatest accuracy, the soil-water content sensors should be calibrated specifically to each soil, especially under conditions that depart from normal (Campbell Scientific, Inc. 2004). Although the absolute soil-water content may differ from that given by the factory calibration, the relative water contents and the behavior of phase change in relation to temperature should be accurate.

Freezing increases the complexity of the soil-water system. Water moves in response to various gradients, including thermal gradients. Water in soil moves from warm areas to cold areas. As water moves, in response to thermal gradients, it carries thermal energy or heat with it, thus modifying the thermal and hydraulic gradients.

Freezing of soil water changes its ionic concentration and thus its electrical properties, setting up new gradients and complicating water-content measurement based on electrical properties. The increase of solute concentration in soil water, due to solute expulsion from ice during freezing, can cause a minor decrease in the freezing point. This decrease is on the order of a few tenths of 1°C.

In spite of the complexity of determining soil-water content absolutely, much information may be extracted from the relative soil-water contents and the water-content curve shapes and positions.

Soil on Alaska's North Slope typically thaws from the top down, but freezes from both the top and bottom as shown in Fig. 3. These phenomena have been noted by others (Osterkamp & Romanovsky 1997, Romanovsky & Osterkamp 1997).

The unfrozen soil-water content curves indicate that water at the 40-cm depth began to freeze first, followed by that at the 10-cm depth. The water at the 20-cm depth was the last to freeze. As air temperature decreases and the days grow shorter in the fall, there is less heat transfer to the soil and it begins to freeze at the bottom of the active layer, just above the permafrost, depending on how cold the permafrost is. When the air temperature falls below freezing, water at the soil surface begins to freeze.

As the soil water freezes in the fall, the temperature remains near 0°C during the period of water-to-ice phase change. This phenomenon is often referred to as the zero curtain and is the result of the release of thermal energy during the phase change from water to ice.

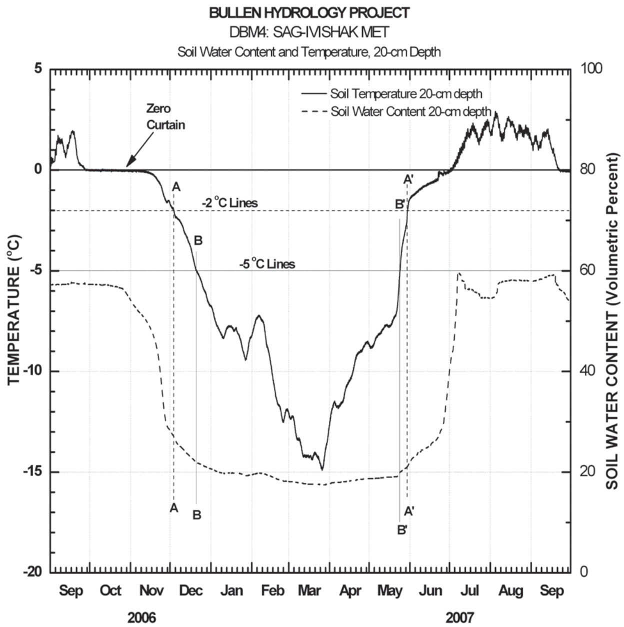

Figure 4. Soil temperature and water content for the 20-cm depth at Sag-Ivishak (DBM4) meteorological station.

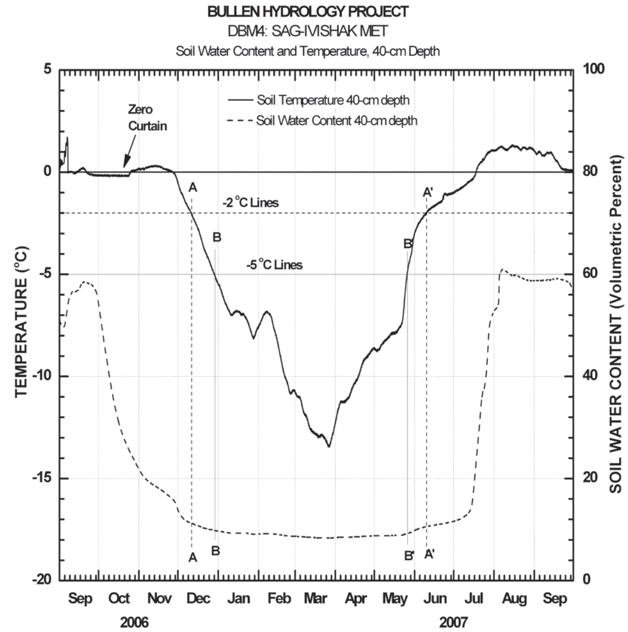

Figure 5. Soil temperature and water content for the 40-cm depth at Sag-Ivishak (DBM4) meteorological station.

The unfrozen-water content curve remains nearly constant during the initial period of the zero curtain. At some point, the soil water has lost most of its latent heat and rapid freezing occurs, as shown by the steep slopes of the curves in Figure 3. The unfrozen soil-water content curves then transition to a fairly constant unfrozen-water content, where very little further freezing occurs, even as the temperature markedly decreases. Sometimes this transition is rather abrupt, and sometimes it is more gradual.

Soil water at all sites studied thawed from the top down in the spring. In the spring, the days grow longer, air temperature increases, the snow begins to melt, and the soil thaws from the top down. Snowmelt water moves downward in response to gravity, warming the soil below.

Ice has a higher thermal conductivity than water, air, or soil. Thus ice is more efficient in transmitting thermal energy than water. This is another reason why soils thaw more quickly than they freeze.

In the spring, during thawing conditions, the soil temperature changes rapidly in response to liquid water moving into and through the soil. The temperature curve generally shows a slower rate of increase during the melting of the water at a particular depth. This is attributed to the latent heat required to thaw the ice. After the ice is thawed, the temperature resumes a rapid increase. The soil water generally thaws faster than it freezes. This may be attributed to the influence of liquid water moving through the soil, carrying thermal energy with it.

The phase-change period is shorter during the spring as the soil thaws and ice turns to liquid water. In addition, the temperature during this time usually is not constant at 0°C for any lengthy period of time. This may be attributed to meltwater carrying heat with it to underlying layers. During winter months, soils can desiccate and form thermal cracks. This increases the effective permeability of the soils, allowing more infiltration of water during snowmelt (Kane et. al. 2001).

Since no sensors were located at the 30-cm depth, data from 20 and 40 cm were used to approximate conditions there. Figures 4 and 5 show soil temperature and unfrozen-water content for the 20- and 40-cm depths, respectively.

Figures 4 and 5 show that soil water does not immediately begin to freeze at the onset of the zero curtain. Some time passes as the water is releasing latent heat while it starts to freeze. However, once started, the freezing process is relatively rapid.

Figure 5 shows a slight increase in soil temperature during the zero curtain during November. There is a corresponding decrease in the slope of the unfrozen-water content curve during this time. These features may be attributed to water moving into the soil layer at this point due to thermal gradients from the soil freezing above and below this depth. As the liquid water moves into this region, it carries heat or thermal energy with it, resulting in a slight increase in soil temperature.

Lines B and B' in Figures 4 and 5 indicate the time when the soil temperature drops below and rises above -5°C, respectively. During the time that the soil temperature is below -5°C, little additional unfrozen soil water will freeze even at soil temperatures well below -5°C. At these depths, the soil water is frozen to near its maximum level.

Lines A and A' show the conditions when the soil temperature is colder than -2°C. There is little difference in the frozen state of the soil water at these depths between -5°C and -2°C, particularly at the 40-cm depth. However, time that the soil is colder than -2°C is on the order of a month (Table 1), which is significant for tundra travel.

If we approximate the conditions at the 30-cm soil depth by the average of the 20- and 40-cm soil depths, Table 1

Table 1. Days soil temperature below certain levels for DBM4.

Soil temperature colder than	20-cm depth	40-cm depth	Avg of 20- and 40-cm depths
-1°C	195	209	202
-2°C	177	181	179
-3°C	169	165	167
-4°C	158	157	157
-5°C	154	148	151

shows that the soil was colder than 5°C during the winter of 2006–07 for approximately 151 days. During this time, the soil at the same depth was colder than -2°C for 179 days, four weeks longer. It was colder than -3°C for 167 days, 16 days longer. And the soil was colder than -4°C almost a week longer. Figures 3, 4, and 5 show steep curves for soil water freezing and thawing. When the soil reaches -2°C, the soil-liquid-water curve is near its minimum, and only minor freezing occurs at temperatures colder than this. Similar results were obtained for the foothills sites.

Again, no soil strength tests were performed, and the results indicate only the length of time that the soil was frozen at temperatures colder than indicated levels. However, it is known that the compressive (bearing) strength of the soils increases as the ice content increases.

Summary

Soil-water content and temperatures were monitored at twelve sites in northern Alaska from September 2006 through October 2007. Soil temperature and water behavior were observed during this time with particular attention paid to periods of freezing and thawing. Freezing started at the bottom of the active layer and proceeded from both the bottom and top of the active layer. During freezing, soil temperatures remained near zero while the soil water released its latent heat. This period is known as the zero curtain. At a point in the zero curtain, the soil water begins to freeze rapidly. When most of the water that was going to freeze had done so, a transition occurred to a nearly constant level of unfrozen soil-water content. Due to interaction with soil particles, soil water does not completely freeze. Soil temperatures colder than -2°C did not cause an appreciable increase in the amount of frozen soil water.

In the spring, the soils studied thawed from the top down. The thawing process was faster than freezing due to meltwater percolation. Also because of snowmelt, the soil-water content in the spring was at saturation. The difference in frozen soil-water content between -2°C and -5°C during the spring thaw was even less than it was in the fall during freezing.

A relaxation of the tundra travel guideline from a temperature of -5°C at a soil depth of 30 cm to a value between -2°C and -4°C could significantly increase the amount of time available for tundra travel. Further study needs to be undertaken to examine soil strength in the region between -2°C and -5°C before any changes in the guidelines are considered.

The Effect of Snow Cover on Permafrost Thermal Stability

Erwin L. Long
Arctic Foundations, Inc.
Edward Yarmak, Jr.
Arctic Foundations, Inc.

Abstract

The investigation to determine a cause for differential settlement of a tower foundation at Glennallen that had been stable for over 40 years led to the derivation of formulae that reflected Osterkamp's measurements for depth to base of permafrost in the area and included snow depths, temperatures, and quantity of thermosyphon cooling.

Keywords: Alaska; foundation; permafrost; snow depth; thermosyphon; warming.

Background

Two towers were constructed in 1960 on permafrost, using thermosyphon technology for passive subgrade cooling for the first time. The two Alaska Communications Systems (ACS) towers are both located in the vicinity of the Gulkana Airport. The Glennallen Tower is located approximately 4½ mi (7.2 km) southwest of the Gulkana Airport along the Glenn Highway, and the Aurora Tower is located approximately 21 mi (34 km) northeast of the Gulkana Airport and ½ mi (0.8 km) off the Tok Cutoff Highway. The locations of the tower sites are shown on Figure 1. Both sites are underlain by lakebed colodial clay silts which include coarser soils with cobbles and boulders dropped from glacial icebergs. The weather station at the Gulkana Airport has operated continuously since 1949. The construction of the Glennallen tower was begun one year after the construction of the Alaska Road Commission (ARC) complex on the west side of the ACS site. The ARC complex was constructed as if on a non-permafrost site, and the ARC recognized the existence of permafrost only after their water well froze up and considerable differential settlement of the structures in the complex occurred. The Aurora tower was constructed on virgin stunted black spruce terrain underlain with permafrost.

The Gulkana Airport is at an elevation of 1580 ft (482 m). The Aurora tower site is at 1890 ft (576 m), and the Glennallen tower site is at 1455 ft (443 m). Both towers are four-legged with post and pad type foundations. The individual tower leg foundations are composed of three 12-in (300 mm) XH pipe thermosyphons 24 ft (7.3 m) in length with the base plates 18 ft (5.5 m) below finished grade and are described in detail by Long (1963).

The Glennallen site was evaluated in 1981, and a new transmitter and equipment building was constructed on thermosyphon piling to the east of the tower. The new structure replaced the original building that was originally constructed on-grade and later refrigerated to minimize thaw settlement.

Both tower foundations were evaluated and soil temperatures measured in 1988. Soil temperatures were found to be warmer than anticipated in the original design. As a result, 170 ft^2 (15.8 m^2) finned condensers were added to two of the waveguide thermosyphon piles at the turf-covered Glennallen tower facility in 1989. Temperature measurements at the Aurora facility indicated a depth of thaw of over 20 ft (6.1 m) in the area surrounding the most southern tower leg foundation. To reverse the thawing found at Aurora, 510 ft^2 (47.4 m^2) finned condensers were added to the NW, SW, and SE foundations and 170 ft^2 (15.8 m^2) finned condensers were added to each of the waveguide foundations in 1989. Foundation temperatures seemed to be affected more by summer surface conditions than by the winter snow cover or the winter air temperature.

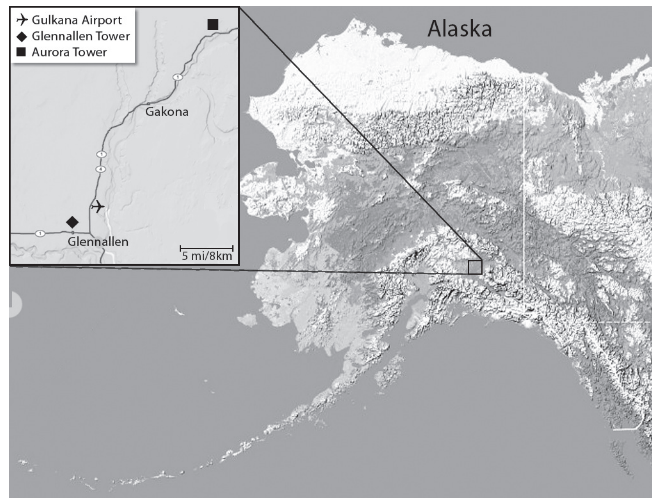

Figure 1. Location map.

In summer 2007, the foundations systems for each tower were inspected. Excessive settlement was found on two of the tower leg foundations at Glennallen. No settlement was found at Aurora. In order to prepare recommendations to stop the settlement at the Glennallen site, an in-depth evaluation was performed to determine the cause of the settlement. It was a goal to develop a method for better evaluation of permafrost stability with changing climate and to provide a means of pre-site evaluation.

Analysis

Osterkamp (2003) reported the depth to the base of permafrost at Gulkana for the period from 1985 to 2001. The depth to the base of permafrost is an excellent measure of the long-term thermal stability of permafrost. This measurement includes all the effects of climate change at a particular site.

Measured thermal conductivity of snow varies primarily with density and ranges from 0.02 btu/hr•ft•°F (0.034 W/M°K) to 0.29 btu/hr•ft•°F (0.503 W/M°K) for densities from 14.7 lb/ft^3 (0.236 g/cm^3) to 32.2 lb/ft^3 (0.515 g/cm^3) (Sturm et al. 2002). In comparison, a typical extruded polystyrene insulation used in civil construction has a thermal conductivity of approximately 0.02 btw/hr•ft•°F (0.03 W/M°K) (ASHRAE Fundamentals 2001). By the numbers, the insulating value of snow is very apparent. Of course, this is nothing new to the people who live in the Arctic and Subarctic, where a snow pile may be the difference between comfortable survival and freezing to death.

The authors have seen instances where snow drifting caused by man-made structures has insulated the ground to such a degree that the depth to the top of permafrost at the end of the thawing season increased from 5 ft (1.5 m) to 14 ft (4.3 m) in two years. An increase in the natural snow depth will have similar albeit more subtle consequences. In the region where the Glennallen and Aurora towers are located, a small change in the surface heat balance equals a large change in the foundation soil properties.

An empirical equation (Equation 1), which included snow depth, was developed to approximate the degree of surface freezing affecting the local permafrost. Weather data from the Gulkana Airport show an average accumulated snow depth of 26.6 in (676 mm) with an average Freezing Index of 4621 °F-days (2567 °C-days) and an average Thawing Index of 2970 °F-days (1650 °C-days) from 1960 through 2007. The end of December accumulated snow depth (DAS) was selected to approximate available seasonal surface snow conditions. Twenty inches (508 mm) was selected as an approximate mean snow depth at the end of December.

Accumulated degree days =

$$-\left(n_f\,{}^\circ d_f \,/\, \sqrt{\frac{DAS}{20}}\right) + \left(n_t\,{}^\circ d_t\right) \tag{1}$$

$°d_f$ = Degree days freezing (°F)
$°d_t$ = Degree days thawing (°F)
n_f = Winter air to surface temperature reference
n_t = Thawing air to surface reference
DAS = December accumulated snow depth (inches)
20 = Arbitrary snow depth reference (inches)

The results are shown as Figure 2 alongside a plot of the depth to the bottom surface of the permafrost presented by Osterkamp for Gulkana. Note that each plot fits the other well with a time offset to account for the depth to the base of the permafrost.

Equation 1 was then modified to represent the effect of the themosyphon cooling in a 70 ft (21 m) radius of the tower and building area. The work was done by trial and error so that the modified empirical equation would mimic the variation in the depth of the permafrost base over time.

The ground surface area being evaluated was selected as having a diameter approximately equal to the depth to the base of the permafrost. The magnitude of the supplemental cooling is a function of the thermosyphon radiator and is represented by its area (SF).

Accumulated degree days =

$$-\left(n_f\,{}^\circ d_f \,/\, \sqrt{\frac{DAS}{20}}\right) - \left({}^\circ d_f * \frac{SF}{A}\right) + \left(n_t\,{}^\circ d_t\right) \tag{2}$$

SF = Square feet of radiation surface
A = Square feet of 70-foot radius area

The plots of Equation 2 for each of the tower sites are shown in Figure 3. It is very apparent that 1976 was a pivotal year for the cooling of permafrost at Gulkana.

The permafrost cooling period from 1960 to 1976 reflects the greater Freezing Index (4935 °F-days (2742 °C-days)) and lesser Thawing Index (2906 °F-days (1614 °C-days)) with an average snow cover of 19.4 in (493 mm) at the end of December while the period from 1978 to 2007 reflects the lower Freezing Index (4416 °F-days (2453 °C-days)) and greater Thawing Index (3012 °F-days (1,673 °C-days)) combined with a heavier snow cover of 34.1 in (866 mm).

Figure 4 compares the Glennallen tower area accumulated degree-days with thermosyphon conditions with the conditions south and west of the tower. Figure 5 shows the Aurora tower area accumulated degree-days with thermosyphon conditions, compared with surrounding area conditions. The Glennallen tower area had a good surface turf cover, while Aurora had an exposed gravel surface which increased its summer thaw. Aurora had a greater thermosyphon heat removal capacity, which improved its frost conditions over Glennallen during years of heavy snow cover.

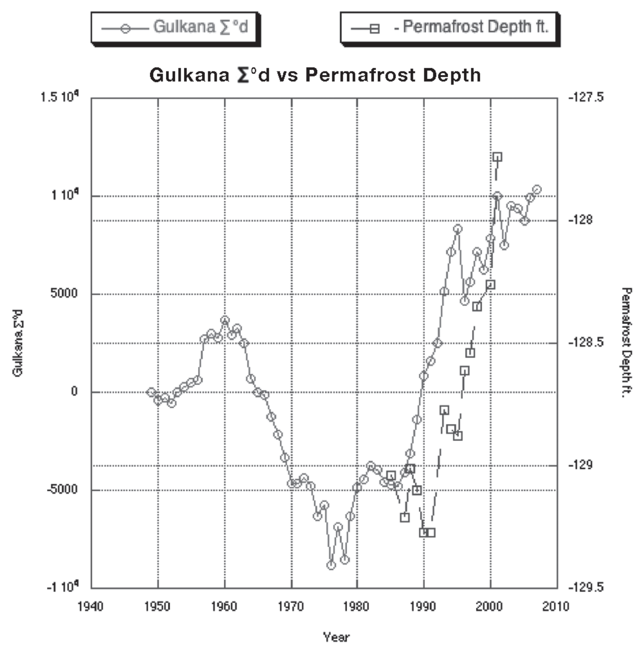

Figure 2. Equation 1 for Gakona airport

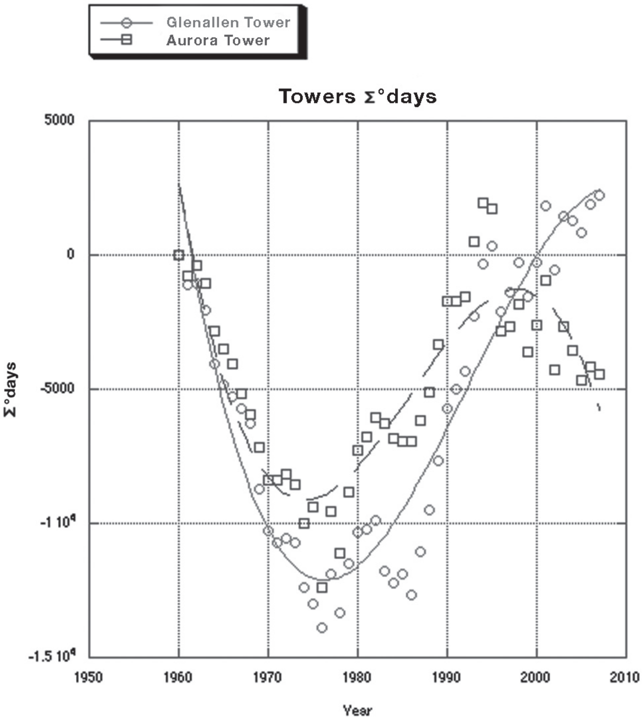

Figure 3. Equation 2 for Glennallen and Aurora towers.

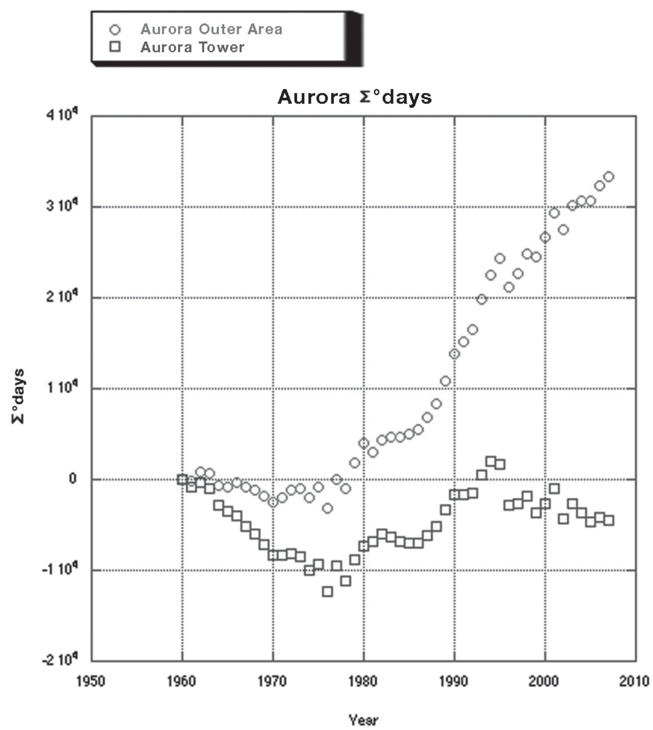

Figure 4. Glennallen tower thermosyphon effects.

With the prevalent colodial soil throughout the area, reduced temperatures will enhance ice lens formation as envisioned by Radd and Oevtle (1973), while warming will cause thawing and settlement (Nelson et al. 1983). By increasing the cooling capacity of the south and west foundations at Glennallen, ice lens formation and permafrost expansion below the foundation pads is expected to occur

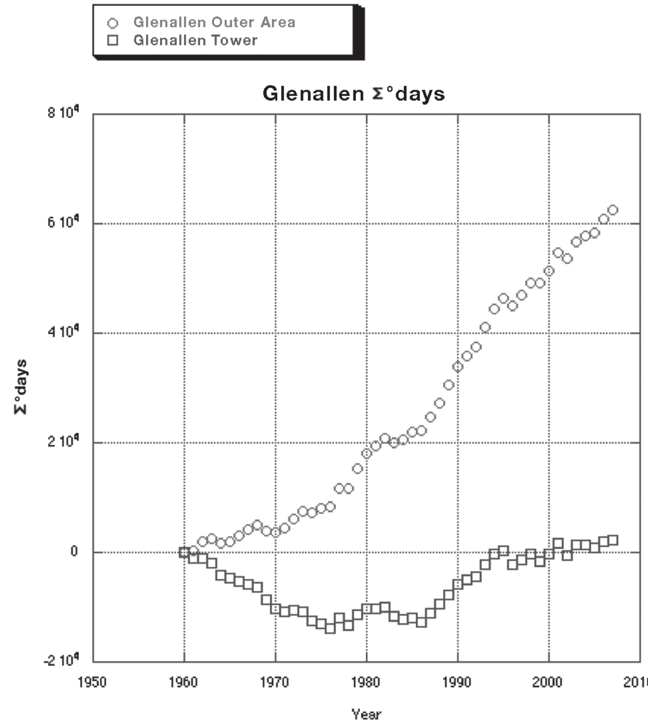

Figure 5. Aurora tower thermosyphon effects.

and help counteract the existing differential settlement and lateral thawing from the adjacent uncooled areas.

Conclusion

The data show that the greatest settlement occurred under the foundations with the least thermosyphon cooling capacity during periods of higher than normal snow cover. When analyzing the thermal conditions for a structure, the design should be area-wide and include snow conditions.

Recommendations

Increase the thermosyphon cooling of the foundations with the largest settlement at the Glennallen tower site.

Abstract

Despite the large area that fire covers, its recurrent nature, and its ecological role in this boreal region, it has been poorly studied. This research was conducted in naturally burnt sites (five) with different post-fire periods; 4, 5, 15, 25, and 50 years and intact (*Larix cajanderi*) forest sites (three) that were considered as control sites. Sampled soil profiles included the active layer and the upper permafrost (0–1.7 m). The effect of fire on the aboveground can be clearly observed, but what happens in the belowground is not well understood in fire-prone eastern Siberia. Irreversible landscape changes occurred when the ice-rich and salty permafrost reached a degradation threshold. The results of this study show that the active layer of burnt sites older than 25 years does not differ significantly with the active layer of intact forests. On the other hand, the "younger" burnt sites showed a deepening of the active layer. The degrading and aggrading processes of the permafrost are apparently followed by hydro-geochemical processes supported by the poorly drained soil conditions of the active layer. In the intact forest sites, the soil ion profile shows increasing concentration downwards, especially in the permafrost layer. During the years of permafrost thawing, ions moved upward into the upper soil layers. Once the water balance of the site is balanced by the appearance of birch (*Betula platyphilla*), soil moisture in the lower layers starts accumulating, and this movement downward brings the ions back to the lower layers where, due to high water content and lower soil temperatures, they become trapped again in permafrost (aggrading). This process takes approximately 20 years. In conclusion, fires in central Yakutia are at present assimilated by the forest ecosystem and the drastic changes it experiences initially are temporal. The conditions necessary for a permanent change in this boreal forest ecosystem is the increase in fire frequency which would not allow forest regeneration.

Keywords: active layer; forest fires; global warming; permafrost regions; salinization.

Introduction

Forest fires in central Yakutia are recurrent phenomena that determine regeneration, carbon storage and temporal changes in land cover. The trigger for fire can be natural (lightning) or human caused (human activity), but the condition necessary for severe fire expansion is dry weather (long rainless periods), high temperatures and low relative humidity. Forest fires are a large source of both carbon dioxide and methane emissions. However, they are both a temporary source of carbon dioxide and usually a biogenic one (Radionow et.al. 2006). Under special circumstances, which are a combination of factors such as fire intensity and climatic cycles (Shender et al. 1999), its occurrence in ice-rich and shallow permafrost burnt sites can develop into thermokarst depressions (Czudek & Demek 1970, Brouchkov et al. 2004, Agafonov et al. 2004) or as is more general, forest can return to its former state (as before the disturbance occurs).

Forest fires in eastern Siberia are not crown fires which are more devastating in their effect (Harden et al. 2000), but surface fires (Mouillot & Field 2005) because of low tree density and because of the pyrophytic properties of larch trees (Nikolov & Helmisaari 1993, Tvsetkov 2004). Changes above ground can alter the movement of water and salts present in the lower part of the active layer and upper permafrost (Lopez et al. 2007a). The organic matter in the top layer cools the active layer, and its disappearance after severe fires results in active layer deepening. Forest fires in Siberia have been cited as large scale disturbances that can contribute to permafrost degradation if the soil thermal regime is altered by climatic change (Kasischke et al. 1995, Zimov et al. 1996). However, to our knowledge no study has focused on the long-term effect on the belowground after forest fires in eastern Siberia (several years after the fire occurrence). If climatic warming increases fire frequency or intensity, the increase in annual thaw depths could result in active layer salinization within areas of salt-rich permafrost (Kokelj & Lewkowicz 1999, Lopez et al. 2007a). Thus, the objective of this study is to assess the process by which the forest ecosystem, especially belowground, recovers after a forest fire,

Materials and Methods

Site description

Neleger Experimental Station is located 30 km north-northwest from the city of Yakutsk (62º05′N, 129°45′) and belongs to the Yakutsk Permafrost Institute. Mean annual air temperature is -10 to -11°C; amplitude of monthly temperatures is about 62°C. Snow cover is 30–40 cm, but it has recently reached 60 cm. Icy deposits are located at depths from 1.5 m to about 3 m; they occur over more than half of the territory, have thicknesses of up to 20–25 m and are distributed in 18% or 76,000 km^2 of the territory of central Yakutia (Fedorov et al. 1991). The area consists of a group of Lena River terraces with elevations of 200–220 m a.s.l.; it is a region of continuous permafrost up to 400–500 m thick. Quaternary deposits are from a few meters to 200 m thick. The bedrock predominantly consists of limestones and argillites. Disturbances that occurred around 10,000 years ago, and still continue, have changed the landscape of this area to grassland (thermokarst depressions). Precipitation during the snow-free growing season is on average 110 mm, which is about half the annual precipitation, whereas the corresponding potential evaporation rate is 370 mm (Muller 1982). Soils in this region are classified as Gelisols; they are predominantly silty-clay-loam (SiCL) to silty-clay (SiC) in 70% of the territory and sandy-loam (SaL) in the remaining part.

Sampling

The sites selected were three intact forests (F1, F2 and F3) and five chronologically burnt forests (B1, 4 years; B2, 5 years; B3, 15 years; B4, 25 years; and B5, 50 years). The soil texture at all sites was silty-loam. Three 1.7 m-long soil profiles were sampled at each location in May 2006. The sampling took place when the soil profile was still frozen and required a boring machine. The frozen layer (permafrost) was measured in late September when the thawing front reached its maximum. The core samples were sectioned in 10-cm intervals, logged, double-bagged, and returned to a laboratory. Soil texture was determined by observation and feel.

Soil moisture and chemical analysis

Soil moisture was determined gravimetrically by drying to a constant weight at 105ºC for 24 hours. A different set of soil samples taken next to the samples used for soil moisture measurements, in each of the profiles, was air dried and then analyzed for pH in a supernatant suspension of 1:5 soil:deionized water mixture (pH meter HORIBA) and electric conductivity in a supernatant suspension of 1:5 soil:deionized water mixture (Page et al. 1982) (EC meter TOA CM-30V) for each sampling site. Electric conductivity of saturated paste (EC_e), used to evaluate saline and alkaline soils, was estimated using soil water 1:5 suspension measurements and following the relation obtained by Slavich & Petterson (1993) for each soil texture. One soil profile at each of the sites was subjected to ion content analysis: cations were measured by atomic absorption spectrophotometer (Hitachi Z5010) and anions by ion chromatograph (Dionex).

Results

Soil texture in the profile was predominantly silty-loam at all locations down to 1.5 to 1.6 m. At site F1, pure ice was found from 1.5 m. The ice found in that particular sampling is part of ice wedges that can be 8 m long. It is this ice that if melted could form pools and cause ground subsidence. Pure ice was not found in burnt sites during sampling, but layers with high ice content were found below the active layer. By principle ice wedges are distributed in areas were the soil is predominantly silty loam and they are absent in sandy loam soils.

Soil moisture

Soil moisture in the active layer sampled at the forest sites revealed different moisture conditions depending on the time elapsed after the fire occurrence. For the period when the sampling was conducted, a common pattern is observed for the forest sites: higher soil moisture in the upper part of the active layer (0 to 60 cm) with high soil moisture content (40 to 60%). This same pattern was observed in the B1, B2 and B3 site. In these three sites and in the forest sites, there exists a layer of lower soil moisture at the bottom of the active layer. In contrast, in sites B4 and B5 (25 and 50 years after fire occurrence), there is a built up of an ice-rich layer in the upper permafrost where soil moisture ranged from 0.4 to 0.6 cm^3.cm^{-3}). Soil moisture in the active layer at the “younger” burnt sites ranged from .2 to .4 cm^3.cm^{-3} at the surface of the mineral soil layer (below 10 cm). At approximately 120 cm depth at all burnt as well as intact forest sites, soil moisture increased, signaling the boundary zone or “shielding layer” between the active layer and area where ice-rich permafrost concentrates (Shur 1988). In the burnt sites the active layer depth ranged from approximately 130 to 160 cm depending on the time elapsed after the fire event (Fig.1). In each site, vegetation differs in biomass with grasses and fireweed

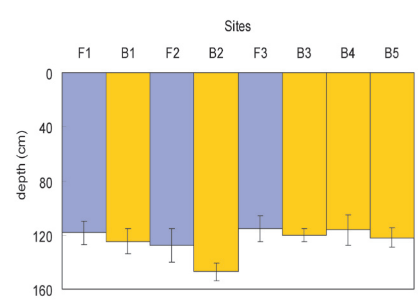

Figure 1. Soil thawing depth at the intact forest (F) and burnt (B) sites.

covering the recently burnt sites (B1 and B2) while birch dominates the sites burnt 15, 25 and 50 years ago (B3, B4 and B5). The size and age of trees differs accordingly but the most important characteristic is the vegetation succession. In B3, for instance, fireweed is non-existent and in B4 birch becomes dominant and its canopy covers the burnt site, while in the B5 site, larch trees are already present, although not still dominant.

Soil pH, EC_e and chemistry

Soil surface (0 to 15 cm) pH varies at the forest sites from 5.5 to 6.2 and then increases rapidly downwards. In the more recently burnt sites B1, B3 and B4, low pH values in the surface layer were observed, whereas pH in B2 and B5 were around 7. Regardless of the site, intact or burnt forest, pH shows a similar value of 8 from 50 cm downward. Despite significant differences observed in the total ion composition of the soil profile, no change was observed in the pH between the active layer and permafrost.

Electrical conductivity of the soil profile showed low values in the active layer (0.81±0.24) and high in the permafrost layer (1.0 to 3.0 $mS.cm^{-1}$) of the intact forest sites. In the burnt sites, EC_e is over 1.0 $mS.cm^{-1}$ and shows an increase in salt concentration in the active layer as compared to the intact forest site (Fig.2). Nevertheless, it is important to point out that EC_e in the B4 and B5 sites are similar to those in the intact forest. In general, the increase in salinity (using EC_e as a proxy) for the burnt sites in the active layer (1.03±0.19) is low in comparison to grasslands soil, for example. The most abundant ions in the active layer and upper permafrost are Cl^-, SO_4^{2-} and Na^+ (Lopez et al. 2007a). Of all these ions, it is the Na^+ that appears more mobile than the other two. As it was observed in the EC_e profile, ion concentration increases in the active layer as a result of fire disturbance. Na^+ moved upward in the B1, B2 and B3 sites, whereas in the B4 and B5 sites this was not observed and the concentration of Na^+ is similar to that in the active layer of the intact forest site. Cl^- appears to have decreased from the upper permafrost except for site B4, where the concentration in the permafrost was remarkably high. It was in the B2 and B3 sites that the increase of SO_4^{2-} was observed, while a decrease in the upper permafrost indicates that it was the source of this ion. Again, a remarkable concentration of SO_4^{2-} was observed in the upper permafrost layer of the B4 site as it was the case with Na^+.

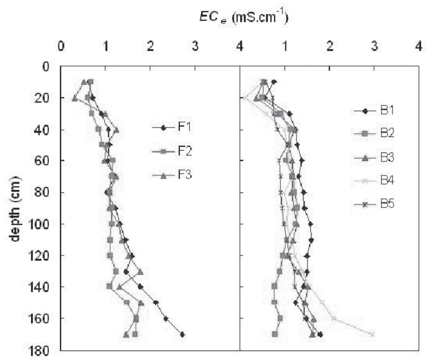

Figure 2. Electric conductivity in the intact forest (F) and burnt (B) sites. Each values are the mean of three samplings.

Discussion

Contrary to what has been suggested in previous studies, forest fires do not cause physical or chemical changes in the long-term that might bring changes in the landscape or specifically hinder the re-establishment of trees. These results, of course, do not suggest that thermokarst formations in the past were not triggered by forest fires. The conditions under which fires occurred at present differ from those during the early Holocene in which the landscape looks much different today than it did approximately 10,000 years ago. The thermokarst depressions intermingled within the forest and called "alas" are actually a drainage zone for the melting snow in early spring and the extreme precipitation events in summer (when the thawing layer is shallow and the storage capacity is low) that are characteristic in central Yakutia (Lopez et al. 2007b). Alas sites, where trees are not able to grow because of high salt content in the root zone (Desyatkin 1993, Lopez et al. 2007a) were caused by global climate changes that most probably triggered forest fires among several other climatic responses (Payette & Delwaide 2000). The results of this study suggest that at present, forests assimilate fires provided they keep the same frequency of occurrence to which they have been exposed during the Holocene. Unfortunately, fire frequency studies have been limited in Siberia, and other causes (political, social or economical) for fire have not been correctly addressed,

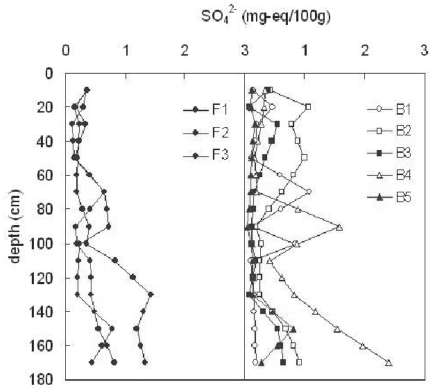

Figure 5. SO_4^{2-} profile in the soil profile (0-1.7 m) in the intact forest (F) and burnt (B) sites.

while global warming has been the most reasonable "pundit" to blame.

Soil moisture increased immediately in the active layer after clear-cut (Iwahana et al. 2005) sites in the same area whereas the cause for immediate increase of soil moisture in the active layer. In this experiment the same was not observed in the site more recently burnt (4 years) or in the other sites, suggesting that vegetation that appeared after severe forest fires (*Chamerion angustifolium*) transpired (2.6 mm d^{-1}, unpublished data) more than the vegetation that appears after clear-cuts. This transpiration rate is similar to the larch forest average transpiration of ~ 3 mm d^{-1} (Dolman et al. 2004, Ohta et al. 2001) in central Yakutia. After fires, the active layer is known to deepen in the first years and later recover to its former depth (Mackay 1995) following re-vegetation of the forest soil and thickening of the organic matter layer, factors that play an important role in keeping a thin active layer. Despite the spatiality of the sampling sites, recovery of the active layer has been also observed in this study. The difference of the above vegetation at each of the sites is thought to exert a strong influence on the water balance of the active layer, and thus cause movement of water that carries ions within its stream. The denser cover of birch trees 15 years after the fire occurrence is probably responsible for cooling of the active layer, as it can be observed from the active layer depth at each of the sites for the year when the experiment was conducted. The role of understory vegetation and the re-building of the organic mat cannot be set aside since they play an important role in keeping soil temperatures low in the soil (Harden et al. 2006). In the older burnt sites (25 years and 50 years) the depth of the active layer was found at around 110 cm depth which is similar to intact forest (Sawamoto et al. 2000). The B2 site had the deepest active layer (160 cm) in 2006. One of the explanation why B1 did not deepened as well could be that the fire in this latter site was light (not stand- replacing fire), and for that reason temperatures in this site were kept lower than in B2. As it has been observed in this study, deepening of the active layer has the potential to make soluble salts available for transport into the upper soil layers of the active layer. Elevated amounts of soluble salts in the root zone especially can affect negatively larch forest establishment because salinity affects plant growth and species diversity.

Between forest and thermokarst depressions in central Yakutia there is usually a belt of birch that marks a buffer zone where soil salt concentration is slightly higher than in the forest but lower than in the grassland soils (Lopez et al. 2007a). This spatial gradient of vegetation adaptability to soil conditions could be the explanation for chronological vegetation succession in fire-prone forest of eastern Siberia. According to information provided by local people, larch forest takes approximately 100 years to fully regenerate in this region.

The results of this study suggest that climate change, already observed in the form of increasing temperatures and increased precipitation in central Yakutia, have the potential to affect the boreal forest through forest fires but this will only happen if, prompted by higher summer temperatures, fire frequency increases prompted by higher summer temperatures, increases. Forest fires play a regeneration role that has been part of this boreal forest for centuries (Ivanova 1996) and has scarcely triggered thermokarst formations (Brouchkov et al. 2004). There should also be strong consideration of winter temperature and precipitation trends, since growing season hydrology and permafrost stability which is affected by winter conditions are strongly linked to the size and frequency of forest fires during the growing season (Ivanova. 1996, Harden et al. 2000) during the growing season.

Conclusions

The effects of forest fires in the boreal forest of central Yakutia are not permanent but are part of a regeneration cycle for the forest in this region. The steps leading to forest degradation (active layer continuous deepening, thawing of ice deposits, formation of pools on the forest soil, etc.) were not observed in the burnt sites in this study. On the contrary, forest fires appear as a temporal phenomenon that revitalizes the forest without affecting its stability.

Abstract

The structure of the upper layers of permafrost and their interaction with cryosols was studied. Cryogenic processes are widely distributed on loamy watersheds of North Jakutia's lowlands, where the active layer is relatively shallow. The upper layer of permafrost here is very complicated and its genesis is connected with the Holocene environmental conditions and pedogenic processes of that time. The authors propose the term "soil-cryogenic complex" that includes the soil profile, transient layer, and intermediate layer of permafrost. The role of the above-permafrost horizon of cryosols in forming structure, properties, and spatial differences of the transient layer was analyzed. Widely distributed lateral transition and accumulation of coarse organic matter between the elements of tundra microrelief were obtained.

Keywords: above-permafrost horizon; active layer; intermediate layer; lateral redistribution; soil organics; transition layer.

Introduction

In case of shallow thickness of the active layer (AL) (1 m and less), permafrost plays a great role in pedogenesis and determines the wide complex of signs and properties of cryosols. It is a significant physical and geochemical barrier that prevents vertical matter migration and determines its lateral redistribution (Shur 1988, Gubin 1994, Alekseev et al. 2003). The relatively high dynamics of AL thickness cause the formation of the complex structure of permafrost upper layers that reflect spatio-temporal interactions with pedogenesis.

Depending on climatic fluctuations, weather conditions, soil cover, and vegetation genesis, this zone of contact can appear as a component of the AL or as a component of permafrost (Shur & Jorgenson 1998, Shur et al. 2005).

The transient layer (TL) (the layer which thaws in the warmest conditions) and the intermediate layer (IL) (the layer of maximal Holocene thaw) are the upper layers of permafrost within this zone (Shur 1975, Shur 1988). The main properties and diagnostic signs of the TL, such as its thickness and the seasonal and long-term dynamics of being in a frozen or thawed state, are the significant factors that influence pedogenesis. It is well-known that the majority of pedogenic fieldwork in high-latitude areas is conducted in the summer, when the AL has not reached its maximum yet and the real above-permafrost soil horizon is still frozen. True thickness of the AL and the morphological structure of soils can be obtained only at the end of September–beginning of October, when surface freezing begins and snow cover becomes stable.

Methods

The moundy soil complex and TL were analyzed on loamy watershed sites of the Khomus-Yuriakh River (Indigirka lowland; 70°00′N, 153°36′E) and Sukharnaya River (Kolyma lowland; 69°30′N, 152°00′E). The basic deposits here are Late Pleistocene silty loams with the features of synlithogenic pedogenesis and with ice complex (yedoma formation). The IL thickness here is about 1–1.5 m. The vegetation cover is represented with moss-sedge-cotton-grass on the Indigirka site and with moss-sage-dryas on the Kolyma site. The mean gradients of the watershed slopes are about 2–3°. The Kolyma site has the features of steppe because of low thickness of snow cover and better drainage.

The structure of soils and the TL were analyzed at the beginning of autumn, when the AL had reached its relative maximum. On the Kolyma site, two trenches were dug through all microrelief elements (2 and 5 m long, 40 cm wide). The structure of soils, their horizon thickness, the AL thickness, and the TL structure (upper 20 cm) were studied. Near the trenches numerous additional soil pits ($n = 15$) were dug to obtain the variety of morphological properties of soils under the mounds of different height and types of vegetation and under the cracks of different depth.

On the Indigirka site, it was necessary to find two experimental, square sites because of more complete soil structure. The first (basic) site is on watershed (250 x 250 cm), and the second (additional) is on the top of a gentle slope (200 x 80 cm; 150 m from the first site; slope gradient, 3°). All of the microrelief elements were within these sites: low, middle, and high mounds with different vegetation, sedge-cotton-grass tussocks. Choosing the proper site, the maximal difference between mounds and crack surface was a concern. The majority of elements within the sites was similar; surface structure, size of mounds and cracks, soil and vegetation cover, and quantity of patchy mounds. The main difference was in relatively more ponding of the second (slope) site which was reflected in a greater distribution of tussocks.

On the first site (watershed), soil and permafrost surfaces were graded. The highest point of a site was taken as “zero,” with the precision of 1 cm and an interval of measure of 5 cm; 2500 measurements of each parameter were made. Measurements of soil horizon thickness (organogenic and above-permafrost) and the TL structure were made with an interval of 10 cm in 10 trenches, 25 cm wide.

After clearance of the site bottom, the lateral structure of the TL was analyzed. There are three main components of it: ice, ice-ground, and frozen coarse organics. Its ice saturation was estimated, and the cryogenic texture was obtained. Morphological analysis of soil profiles was made on the example of the most representative side of the trench, where samples were also taken. According to this data, schemes of soil and permafrost surface, TL structure, and vegetation-cover structure were made.

Additional soil pits (n = 15) were dug near the experimental sites and the TL structure was also studied to a depth of about 20 cm. The AL thickness was measured under the different types of mounds and cracks (n = 130).

The same measurements were made on the second site (slope), but the interval of measurements was 10 cm.

Results and Discussion

Comparison of the soil and permafrost surface schemes of the first Indigirka site (watershed) showed that the microelevations of the TL surface are under mounds and are represented by ice. The authors suggest that such structure of the TL surface can be determined by the previous history of soil-surface genesis, and propose the following model of ice formation.

At the earlier stages of nanorelief genesis (patchy mound with sparse vegetation), the AL thickness was more than under cracks. While thawed, water has accumulated here, and then with seasonal freezing, has turned to ice. This accumulation had a progressive tendency caused by ice forming on the one hand and by vegetation and organogenic horizon forming that has decreased the heat flux on the other hand. Heat absorption differences between ice, ice-ground, and frozen coarse organics determined different speeds of thaw, TL surface genesis, and structure formation (Mackay 1983).

The results of comparing soil surface and TL microrelief schemes of the second Indigirka site are a little bit different. Their topography is well expressed too, but the micro-depression zones of the TL surface are mainly distributed under the centers of mounds, and are presented by ice-grounds or coarse organics. The micro-elevations are under cracks filled with peat. Ice distribution in the TL is related to circumferential parts of mounds, and ice underlies 5–10 cm deeper than the TL surface. The same situation in the soil and the TL structure was obtained in numerous additional pits (n = 8) in microrelief and appears to be authentic for this region of the Indigirka lowland.

Another component of the above-permafrost horizon (AH) and TL formation was obtained in numerous soil pits and trenches. When the AL thickness reaches its relative maximum, the lower parts of soil profiles are over-saturated with water. The microdepressions of the TL surface microrelief become the channels, where the inrush of water is obtained. The scheme of possible fluxes, which was created by a method of relief plastic (Stepanov 2006) on data basis, coincided with the situation obtained in the field. Such water redistribution determines the coarse organic matter redistribution and discharge (Shuster et al, 2003, Mergelov 2006). The material is denuded from the microelevations of the TL surface and accumulates in the microdepressions. The obtained data show that the mean slope gradient is about 2–5°, and the maximal is 12–15° or even 20°. Such an active migration of small portions of wet peat along the microslopes can be forwarded by thaw of ice-ground with the reticulated cryotexture, which is distributed in negative microrelief forms.

The authors suppose that the difference in spatial structure of the TL and the AH is determined by the processes which occur in the lower parts of the soil profile and by the interaction of microrelief elements.

On the Indigirka site, in the majority of cryosols under mounds, the organogenic AH is forming. It consists of peat mixed with mineral material. Organic carbon content here is 4.7% (n = 6). These indexes are a little bit higher in the TL, but then they decrease with depth. Both horizons are spatially different. Zones which are extremely rich with organics are obtained here (23.4%). There are also flux-like zones in which the organic material is mixed with the mineral one (3.2%). As for the mean samples of coarse organic material, total organic carbon content is 10.1% for the first experimental site (n = 10) and 8.9% for the second (n = 6). The mean thickness of the AH is 7–12 cm, and the total thickness of this horizon with the TL is 25–32 cm. This data coincide with that of another author (Hinkel 2005).

The mean thickness of the peat (or duff) horizon is not more than 7–13 cm, and the quantity of organic carbon here is about 9%. So in some cases, the store of organic carbon in the system here (AH + TL) is even more than in the upper parts of soil profiles (except of peat soils in nanopolygonal cracks).

The given data allow us to single out the organogenic AH of Indigirka tundra soils that differs from similar horizons with cryoturbated organic material of the Kolyma lowland (Karavaeva 1969, Gubin 1994), other regions of North Jakutia (Elovskaya et al. 1979), and East European tundra (Ignatenko 1979). Soils with such an unusual lower horizon and TL were obtained earlier (in the 1980s–1990s) on watersheds of typical tundra in the Alazeya-Kolyma region. Distribution of such soils is limited, and the main requisition is the existence of cracks filled with peat that reach the surface of permafrost. So the possibility of such a system forming is determined by contemporary and previous (Holocene) conditions (AL thickness, processes of frost heaving and peat forming, etc.).

Conclusions

An analysis of loamy watershed deposits and cryosols of North Jakutia lowlands shows the existence of a complex system of layers with different properties on the border between the AL and permafrost. Its genesis and structure are determined by the bioclimatic situation of the Holocene. The authors propose to single out this system as a "soil-cryogenic complex." Its structure is the following: soil profile: TL (a layer which thaws in the warmest conditions) and IL (a layer of maximal Holocene thaw). The border between the AH and TL is the arena of active pedogenesis, where its most specific features are reflected. The spatio-temporal differences of this system show the mechanisms of soil-cover genesis and the interactions between its elements. Such well-expressed permafrost microrelief determines the wide lateral redistribution, migration, and accumulation of coarse organic matter within this complex.

Acknowledgments

The authors thank Yuri Shur for the inspiration for this work and for genuine interest in it.

Abstract

Erosion along Alaska's Beaufort Sea Coast introduces substantial quantities of largely undecomposed organic matter into the Arctic Ocean annually. Three bluff exposures along the northern coastline of Barter Island revealed organic materials extending 1.5 meters below the surface. Peat deposits (12–80 cm thick) are in sediments that extend to 1.8 meters and overlay sands and gravels, under which are alluvial-marine sediments. The bluff exposures are composed of 10–20% ice wedges and moisture content of the soil ranged 2–80%. Total carbon content in the active layer averaged 10% and 14% in the frozen soil. Total nitrogen was less than 2% throughout the soil profiles. Soil pH and electrical conductivity show a relationship between mineral soils at depth and increased values.

Keywords: Arctic Alaska; coastal erosion; cryogenesis; cryoturbation; gelisols, patterned ground soils.

Introduction

Coastal erosion is a growing concern in northern Alaska. The apparent accelerated rate of erosion along the Beaufort Sea coast of Alaska (Brown et al. 2003) may have major implications for life and development along the coast. Several coastal Native Alaska villages are battling against increasing storm intensity and frequency (McCabe et al. 2001), a continuing loss in duration of the protective sea ice (Fetterer 2002, IPCC 2007), and increasing summer temperatures (Jorgenson et al. 2006). All of these are causing increased erosion and permafrost degradation. In Kaktovik, located on Barter Island, the current airport and an old landfill site are rapidly eroding into the sea (Robinson 2004). Erosion along the arctic coastline of northern Alaska has also been hypothesized to be a significant influence on global climate change due to the input of carbon-rich peat soils into the ocean and carbon dioxide to the atmosphere (Jorgenson et al. 2005). The result may be a positive feedback to an Arctic warming cycle.

On polygonal terrain along the coast, soil physical structure and chemical properties are strongly related to ice wedge polygon development (Shur and Jorgenson 2007). This interactive-formative process may span a period of five to eight thousand years. Soil stratifications and physical structures are mixed and warped, by cryoturbation, at the boundary of ice wedges due to freeze-thaw cycles and ice wedge formation and reformation (Bockheim 2007). This situation complicates the examination of soil morphology and characterization of the active layer and renders the systematic interpretation of permafrost soils a challenge.

In the past, tundra soils have been a significant carbon sink because primary production has been greater than the slow decomposition rate of organic matter in cold and frozen permafrost soils (Hobbie et al. 2000, Ovenden 1990). As a consequence, it is estimated that tundra soils have accumulated an estimated 25–33% of the world's soil carbon (Oechel and Vourlitis 1995). Soils along the Arctic coastline contain large quantities of mostly poorly decomposed organic materials (Ovenden 1990, Ping et al. 1997). As the coast erodes, there is a change in the thermal regime of the soil and the ice wedges degrade. Moisture content decreases while temperatures increase, and as a result the active layer thickens.

Likewise, warming temperatures can cause large scale permafrost and ice wedge degradation (Jorgenson et al. 2006) which can in turn cause substantial changes in surface hydrology (Hinzman 2005). In the last several decades, temperatures have been on the rise in the Northern Hemisphere, most notably in the Arctic and Sub-Arctic (IPCC 2007), and there is evidence that this warming trend will continue unabated (Chapman and Walsh 1993, Serreze et al. 2001). The current warming trend in the arctic is evidenced by increased erosion of the northern coast of Alaska (Semiletov 1999, Brown et al. 2003), permafrost degradation (Jorgenson and Kreig 1988, Jorgenson et al. 2001), and decreased extent and duration of sea ice and hydrological changes (Morrison et al. 2000).

The ability to make predictions about changes in the soil depends on an understanding of what alterations are taking place and what interactions may occur between various soil properties. To understand the complex changes that may occur due to erosion of coastal soils, a detailed study of soil morphology, as well as chemical and physical soil processes is required. In this study we examine properties of the soils that are eroding along the coastine exposures near Kaktovic Alaska in order to better understand the processes occurring and materials being transferred to nearshore waters.

Methods

Sites for intensive investigation were selected on the northern shore of Barter Island, west of the village of Kaktovik. Three bluffs sites were selected for excavation and sampling (GPS: 70.13393N, -143.65578W, 70.13393N, -143.65245W, and 70.1345N, -143.66083W). Polygons

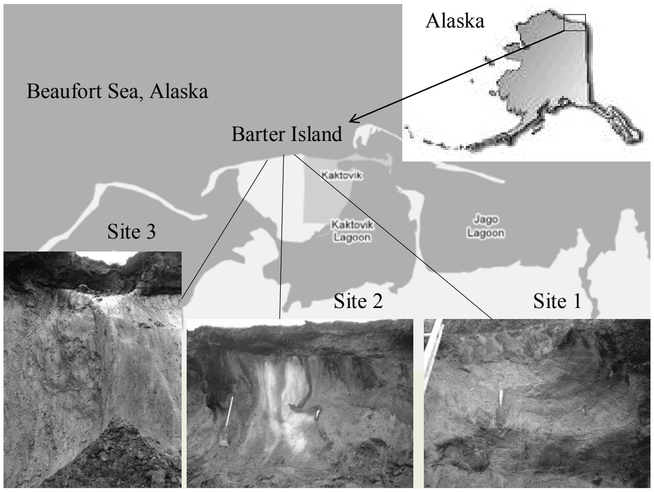

Figure 1. Site location and profile photos.

west of Kaktovik are very large and flat, measuring 12–20 m in diameter, indicating large ice wedge formation. Exposed ice wedges at the eroding bluff are indeed large, reaching 3–3.5 m in width. The large ice wedges and dense surface polygonal net in this area are consistent with high bluff alluvial-marine sediment landforms. Most of the vegetation cover along the northern Barter Island coastal bluff is sedge with some willow and small amounts of Dryas found on frost boils. Bluff exposures at three points located approximately 100 m apart (Fig. 1) were cleaned from the surface to a depth of 1.5 meters. Following removal of slumped and refrozen material, the soil layers were identified (Schoeneberger et al., 1998), dimensional samples were cut from the active layer, and dimensional core drilled with a SIPRE corer to a maximum depth of 1.5 m. All samples were kept frozen until time of analysis at the UAF-AFES Plant and Soils Laboratory at the Palmer Research Center. Soil bulk density and water contents were determined by weight difference of dimensional samples upon drying at 100°C. Total organic C (TOC) and N were determined using a LECO CHN analyzer and organic matter (%OM) by loss on ignition at 450°C. Exposure sediment, water, TOC, and N stocks were determined using the exposure description and analysis by the method of Kimble et al. (1993) to account for cryoturbation. Temperatures from near the surface soil and right above the permafrost table were measured with a thermometer.

Results and Discussion

Temperature

Soil temperatures in the first week of August, 2006, at the ground surface, measured from 5–7°C, and just above the permafrost 2–5°C. Surface temperatures are likely to vary based on weather conditions present.

Cryogenic features

Active layers along the northern coast of Barter Island averaged lower volumetric water at 38% compared to the permafrost which averaged 53% volumetric ice (Table 1).

Table 1. Soil properties for eroding shoreline at Barter Island, Alaska.

Property	Bluff Exposure 1	2	3
Bank height above water (m)	18	18	18
Mean thaw depth (cm)	45	36	54
Cumulative organic thickness (cm)	77	63	87
Maximum organic depth (cm)	133	78	127
Total amount of wedge ice volume (%)	21	20	18
Total organic carbon store in top 1m, excluding ice wedges, volumetric extrapolation from sample, (kg C/m²)	32	41	34

The high water content in active layers is positively related to organic matter which has high water holding capacity.

The high water (ice) content in permafrost is due to segregation of ice. The upper active layer is dryer than the permafrost due to exposure to warmer temperatures, drainage at the bluff face, and lateral movement to lower-lying thermo-erosion troughs nearby. In addition to buried organic layers holding water, ice lenses ranging in thickness from 1mm to 20mm were present in the permafrost cores. Vertically aligned ice bubbles in these ice lenses indicate that each lens is a former freezing front. In early winter, the thawed portion of the soil refreezes at two fronts: from the surface and from the underlying permafrost. Water in the active layer migrates toward these freezing fronts and low-lying water will migrate toward the lower freezing front. This vertical movement is evidenced in the bubble alignment. All three cores showed evidence of refreezing in the first 3 cm from a deeper thaw in a previous summer.

Ice wedge volume on Barter Island is higher compared to other portions of the Beaufort Sea coast. The high bluffs provide protection from direct ocean wave impact and erosion. Because of the volume of the large ice wedges, extensive cryoturbation is evident. As the ice wedges develop and expand, they squeeze the inter-laying soils, bending and distorting soil horizons, and altering bulk density and thus, moisture-holding capacity. This evidence of cryoturbation is strongest near the ice wedges and less in the center areas of polygons. Barter Island experiences short, cool summers and very cold winter temperatures. The severe cold can cause the surface soil layers to crack vertically. The combination of material falling or washing into these cracks, and the distortion imposed on soil layers by expanding ice wedges creates the cryoturbated features (Fig. 1).

Morphological properties

Depending on where the permafrost core is drilled in relation to the location of the ice wedges, great differences in soil stratigraphy are observed. For example, in the core at Site 1, a peat-filled crack extended from 125 to 133 cm below the surface, and vertically oriented layers of peat and sediments were found at a depth of 80–125 cm. The vertical

Table 2. Soil properties by horizon.

*AL=active layer; Pf=permafrost.

stratigraphy and high ice volume (50–70%) indicates that this core resides in close proximity to an ice wedge. Similar conditions existed at Site 3. The first attempt to drill a core at Site 2 resulted in a high ice volume sample with vertically oriented peat horizons, appearing as if cracks in the soil surface had filled with water, distorting the soil stratigraphy. At 97cm, gravel was encountered, drilling stopped, and a second, successful drilling, just 0.5m from the original site, resulted in the core used for analysis. The core at Site 2 had nearly horizontal soil layers with abrupt wavy boundaries. Layers of muck (sapric) alternated with mineral sediments, most likely deposited by eolian or alluvial processes. Organic-rich materials with lower ice volume (pore ice at 30%) were found from 50–70cm and below that marine-alluvial sand deposits were encountered.

All three sites followed similar general horizonation in the active layer. A thick organic layer (12–19cm) lay over silt, which lay over a more decomposed organic layer. Mixing of these layers due to cryoturbation was present in some cases, but the origin of the horizons could still be distinguished by texture (muck for organic materials and silt loam for Bg or Bw horizons). Organic matter was found cryoturbated deep into the permafrost to a depth of 133 cm. None of the bluff cores exhibited clear horizontal layering as the result of strong cryoturbation.

Redoximorphic features were observed in the root channels of the Bg and Bw horizons in the active layer (Fe-concentration 7.5 YR 5/8, matrix 2.5 Y 4/1). The saturated conditions created a reducing environment in which root channels become the source of oxygen in the redox process. Organic acids produced in the surface organic layers lower the pH and iron is reduced from Fe(III) to Fe(II). The reduced iron is water soluble and carried with water movement to the lower mineral layers. Roots extending into the mineral horizons exude oxygen where microbial activity facilitates oxidation and precipitation of the iron Fe(III) oxides resulting in the presence of reddish-brown soil mottling.

Soil physical properties

Thaw depth varied slightly among the 3 sites (45, 36, and 54 cm) most likely due to micro-topographical differences. Thaw depths are smallest in polygon troughs and deeper at the center of the polygon, and deeper again on the rim. Polygon troughs were generally avoided for pit excavation and coring, as they tend to have ice wedges (pure massive ice) below the surface. Thaw depths were not measured according to micro-topographical features, but in relationship to bluff excavations. Thaw depths of 25–50 cm are typical at bluff exposures along the Beaufort Sea coast, but varies somewhat based on annual climate at a particular site.

Soil textures at these locations were found to be fairly consistent. Muck layers (Oa) were found in the top 10–20 cm at all sites, followed by a silt loam horizon (Bg or Bw, 10–40 cm) and then a muck or muck/silt loam horizon (Oa/Bgjj) starting at 38 cm and extending to 100 cm in one site. Cores 2 and 3 had a Cf horizon of alluvial-marine sand at 79 and 140 cm respectively. This pattern of vertically stratified organics, mineral, organics, mixed organic/mineral, and sand gives a glimpse into the formation of the soils at the coast. The surface organic layer has likely been developing for many hundreds of years. The underlying thick silt layer is an indicator of a long-term event of eolian or alluvial deposit, which was preceded by a period of plant growth similar to current conditions. Cryoturbation has largely erased similar historical pattern in the permafrost layers, but the underlying sand layers are remnants from the end of the last ice age.

Chemical properties

Surface organic horizons and buried organic layers contained the highest quantity of organic carbon (OC) averaging 19.1% and 12.0%, respectively, and the silt dominant layers contained 7.6% OC on average. The total nitrogen (N) averaged 1% with no clear correlation between the values and the soil type, mineral or organic. This may be due in part to the difficulty in separating the mineral and organic components in cryoturbated layers. The pH at each site tended to increase with depth, as did the EC, especially in the mineral horizons. Additionally, there is an inverse relationship between the TOC%, pH and EC, which reflects the strong influence of the organic matter on soil properties. Organic acids produced by the OM decrease the pH values, but also act as a buffer, neutralizing the salt effects. Thus, the EC was lower in organic-rich layers, but higher in the mineral soil. The higher pH values found in deeper, mineral soils are due to the calcareous nature of the parent materials (Ca-rich deposits from the Brooks Range). At bluff Site 1, the EC values are significantly higher between 38–146 cm. This may be due to one of two reasons. One theory is that these soils represent an old surface, a thaw lake that had at one time been flooded with seawater. Another possibility is that the neighboring area, which was treated with bio-solids for 13 years, affected surrounding soils. The high salt content of the waste may have migrated and moved deep under the surface through frost cracks and cryoturbation.

Conclusions

Soils along the high bluffs of Barter Island are characterized by high ice volume, both in size of ice wedges and segregated ice within the depth measured. Cold temperature and the wet tundra on the coastal plain contribute to such ice formation. Cryoturbation was found in all exposed bluff faces and permafrost cores drilled inland. All active layers exhibited a similar pattern of horizonation: thick surface organic layer over a mineral B horizon, with a cryoturbated O horizon underneath. Redoximorphic features exhibited in pore linings and masses were common in the mineral B horizons. All profiles contained high organic carbon and increasing pH with depth.

Additional research is currently underway on the soil properties of similar soils inland from the bluff, those not impacted by erosion, in an effort to add to the understanding of the impacts of coastal erosion on soil properties.

Global Land Use Change and Its Specificity in Permafrost-Affected Regions: Consequences for Cryosols

Dmitry I. Lyuri
Institute of Geography, Russian Academy of Science, Moscow, Russia

Sergey V. Goryachkin
Institute of Geography, Russian Academy of Science, Moscow, Russia

Abstract

The most specific land use change in high latitudes is the dynamics of agricultural lands. Contrary to the global zonal trend (northward increase of agricultural land abandoning), there was the growth of agricultural areas in cold and permafrost-affected regions both of Eurasia and North America. But since the 1990s the dynamics of agricultural land became divergent in different parts of the North. Due to the system economic crisis in Russia, the area of agricultural lands in permafrost-affected regions shrank greatly; however, in Alaska and Norway, farmlands continued to grow. It proves that increasing of agricultural lands of the North is mostly related to social and economic reasons, but not to climate change. Consequences for cryosols induced by both socio-economic and climate changes are mostly similar. They provoke the deepening of the active layer, development of thermokarst, and change of organic matter quality (degradation of peat and increase of soil humus content).

Keywords: agricultural lands; cryosols; global change; land use; permafrost; socio-economic change.

Introduction

Global climate change and the following landscape and ecosystem transformations are the most popular topics in geosciences including geocryology and soil science. However, global change overwhelms not only climate, but also socio-economic processes as well. The shift of oil and gas mining to the north is a very well-known trend in the world. Socio-economic processes in the North usually have their specificity (Forbes 1999), but their influence on the trends of land use change in high latitudes is not the focus of recent studies. Less is known about the main trends of permafrost-affected landscapes and ecosystems change due to alteration of land use in the North, and only last year, the scientific community began to pay attention (Gutman 2007). As for permafrost and soils, something is known about how they are changed under such transformations of vegetation as clear-cutting (Iwahana et al. 2005) and forest fires (Yoshikawa et al. 2003, Lopez et al. 2006). Much less is known on the agricultural transformation of northern soils. However, the last decades were very crucial to agricultural lands of the world as the intensification of relevant technologies and the rise of productivity resulted in a drastic decrease of arable lands in many countries. Almost nothing is known about what the situation with the dynamics of agricultural areas is in northern (perma)frost-affected regions of the world.

The goal of this paper is to assess the main processes of land use change (primarily agricultural) in northern regions in comparison with the global trend and the consequences for (perma)frost-affected soils—cryosols. Analyses of national and world statistics, literature, and field observations are the main methods in the study.

Change of Agricultural Land Use

Global trends of agricultural land use

Contrary to the slow growth of total agricultural areas in the world, more than 80 countries demonstrate the stable decrease of them. From 1961 to 2002, about 2.3 mln km^2 were abandoned from agricultural use, mostly in Russia, Australia, the USA, and West Europe. Six types of abandonment of agricultural lands were distinguished (Lyuri et al. 2006). The first four types are associated with countries, where decreasing of agricultural lands is a result of agricultural intensification. *US-type*: the decrease of agricultural area as a result of agricultural intensification with the increase of agricultural production. Twenty-one countries (US, UK, West Europe, Australia, India, Thailand, etc.) have this type of agricultural lands dynamic, and they abandon about 1.0 mln km^2 of agricultural area (43.5% of the world value) (Fig. 1).

Japan-type: the decrease of agricultural area as a result of agricultural intensification with the decrease of agricultural production (the course for food import). Two countries, Japan

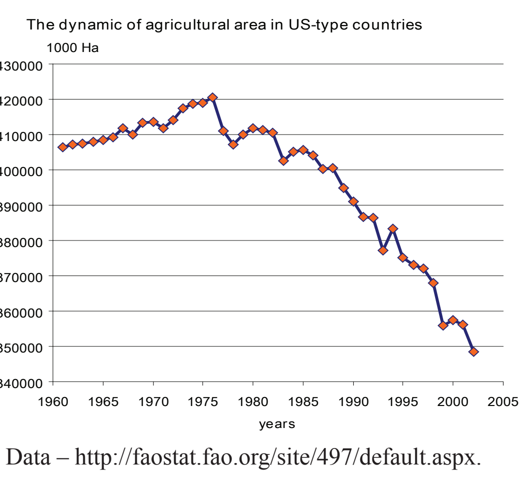

Figure 1. Data – http://faostat.fao.org/site/497/default.aspx.

and South Korea, abandoned 0.02 mln km^2 of agricultural area (<1% of the world value). *France-type*: the decrease of agricultural area as a result of agricultural intensification, then its increasing during last years with increasing of agricultural production (the course for food export). Six countries abandoned 0.1 mln km^2 of agricultural area (4%). *Hungary-type (transitional)*: the decrease of agricultural area as a result of agricultural intensification, then its decline as a result of deep economical crises. Nine countries (Poland, Hungary, and other countries of East Europe) abandoned 0.07 mln km^2 of agricultural area (3%).

Two other types of agricultural land abandonment are associated with countries where agricultural lands decrease as the result of crises, wars, revolutions, and other non-agricultural processes.

Russian-type: the enlargement of agricultural area, then its falling as a result of deep economical crises with the rise and then decrease of agricultural production. Seventeen countries (Russia, other countries of the former USSR, Bulgaria, and Romania) abandoned 0.85 mln km^2 of agricultural area (37.0% of the world value). *Miscellaneous-type*: the decrease of agricultural area with no relation to agricultural productivity and production. Twenty-one countries (Bangladesh, Cameroon, Lesotho, Nigeria, Swaziland, etc.) abandoned 0.25 mln km^2 of agricultural area (10.9%).

Abandoned agricultural area is substituted by two kinds of lands: (1) by settlements, infrastructure, industry, etc., and (2) by fallows. In the last case, fallows are usually a process of replacement by natural ecosystems.

Land use change in Russia and its northern regions

The dynamics of the areas of agricultural lands both in Russia as a whole and in its northern (perma)frost-affected regions is very specific. We have analyzed it separately for two essentially different periods: (1) for non-crisis 1960-1980, and (2) for the 1990s – system economic crisis in the country and afterwards. Figure 2 shows that the growth of the cropland areas has practically finished from the beginning of the 1960s for the whole territory of Russia. Cropland area expansion occurred only in the most southern regions; however, in boreal and temperate zones, it was stable or even diminishing.

The reverse situation took place in northern permafrost-affected areas. The intensive increase of the cropland area began from 1960-1970 and continued until the beginning of the crisis of 1990 (Fig. 3).

Similar patterns, but more complicated and controversial for northern territories, are characteristic for dynamics of arable lands and agricultural areas (Figs. 4, 5). Thus, the dynamics of the cultivated areas in permafrost-affected regions of Russia in the favorable 1960s-1980s was more similar to that of the most southern parts of the country, but not to adjoining boreal and temperate regions.

In the 1990s the system crisis had embraced all of the country, and in all regions of Russia there was a significant reduction of agricultural areas, including arable lands and crops (Figs. 6, 7).

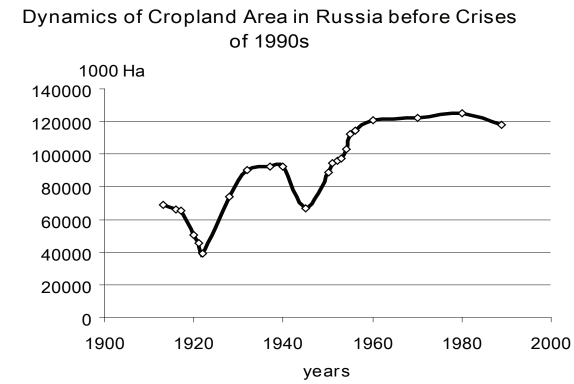

Figure 2. Data – State Committee 1985-1998.

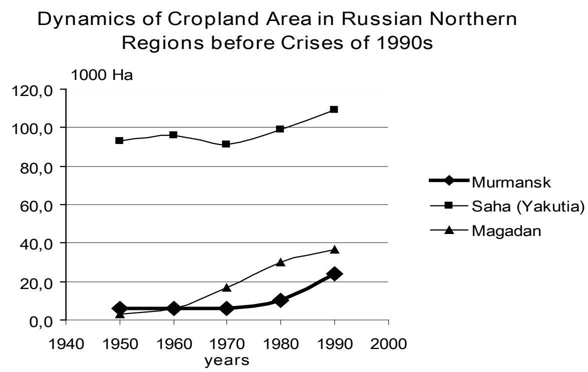

Figure 3. Data – State Committee 1985-1998.

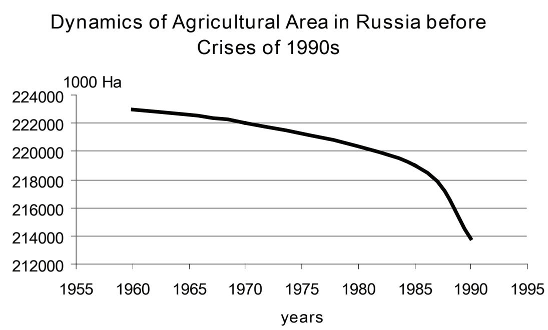

Figure 4. Data – State Committee 1985-1998.

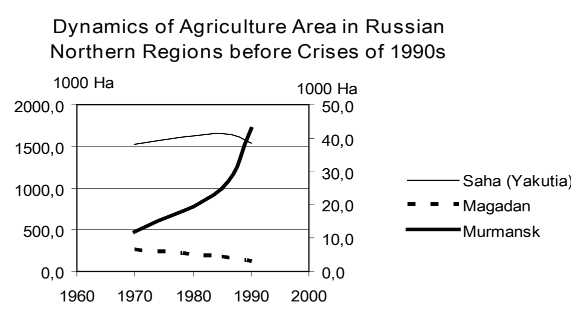

Figure 5. Left Y-axis is for Saha; right one, for others.. Data – State Committee 1985-1998.

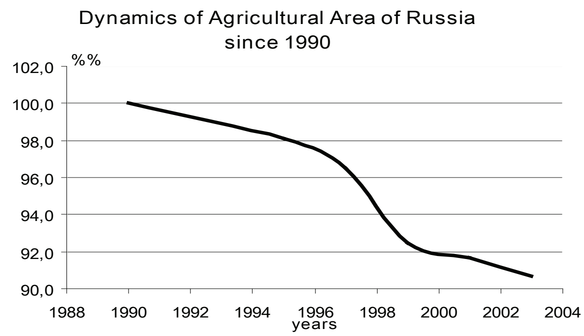

Figure 6. Data – State Committee 1985-1998, 2006.

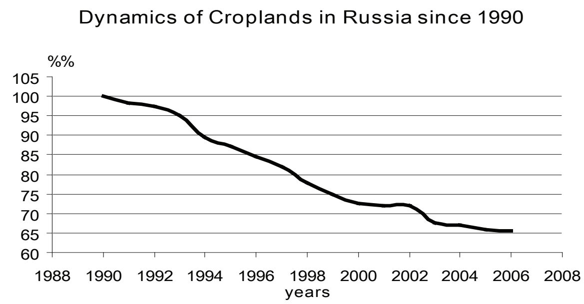

Figure 7. Data –State Committee 1985-1998, 2006.

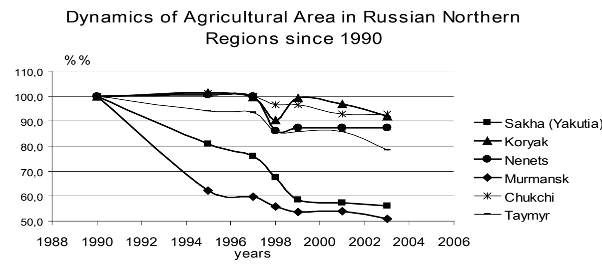

Figure 8. Data – State Committee 1985-1998, 2006.

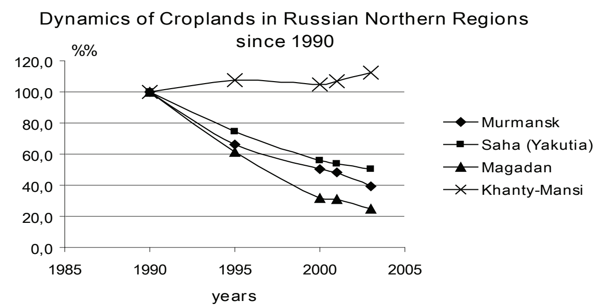

Figure 9. Data – State Committee 1985-1998, 2006.

Analogous processes took place in permafrost-affected regions of the country, though the unique subject of Russian Federation (Khanty-Mansi autonomous district), with some increase in the areas of croplands in crisis time, occurred namely in this zone. In all other northern regions, the agricultural areas were reduced, though this process had various rates. However, by the end of the 1990s in the majority of permafrost-affected regions the shrinkage of agricultural areas has practically stopped, and they were approximately stabilized. It is observed in the Murmansk area, Saha (Yakutia) (which has the greatest area of the agricultural lands in the permafrost-affected zone), in Nenets and Chukchi autonomous districts (Figs. 8, 9).

Such agricultural land stabilization has occurred more than in half of analyzed permafrost-affected regions. It is remarkable, but a similar effect of the termination of the shrinkage of agricultural areas takes place only in the most southern regions of the country, and in the boreal and temperate areas the process of croplands decrease proceeds with former intensity. Thus, the agricultural lands of permafrost-affected regions have reacted to the system crisis of the 1990s in a very specific form: Their dynamics even in these crisis years was more similar to dynamics in the most southern agriculturally productive areas of the country.

The effect of stabilization in cold regions, which in the south is related to the optimum for conducting agriculture by natural and demographic conditions, should be explained by other reasons. First, it is caused by the remoteness of these areas from the basic agricultural regions of the country; it makes the transportation of the foodstuffs here very expensive and focuses local producers and consumers on home resources. Secondly, it can be explained by the significant percentage in the population of local indigenous people for which the traditional agriculture is the core and even the only source of existence that forces them to stabilize the situation at a certain acceptable level as soon as possible. Besides that, a traditional economy is "economically isolated" and much more independent to financial cataclysms, legal problems, and other aspects of a system crisis than the modern economy.

Land use change in the north of Russia, US, and Europe

However, in spite of all specificity of the agriculture of permafrost-affected regions the general decrease of the agricultural areas in the north of Russia was very significant. So, arable lands of Russian northern regions in the period from 1990 until 2003 have decreased by 1.5 times (from 230,000 to 150,000 Ha) and reached practically the value of 1970 (Fig. 9).

However, the dynamics of Russian arable lands has a very severe pressure of economic crises. In this case it is very interesting what type of dynamics of agricultural lands was in other non-crisis permafrost-affected regions of the Northern Hemisphere. It was found out that in Alaska, the constant increase of the area of arable lands took place in the 1974-2004 period. It has extended practically in 5 times (Fig. 11). This Alaskan agricultural situation is principally contrary to the rest of the US, as the stable reduction of agricultural lands took place in the country at that time.

In another northern region—Norway—the other type of arable land dynamics takes place (Fig. 12). The expansion of arable lands from the middle of the 1990s was replaced by stabilization, and the last years, by insignificant reduction (approximately 3%). It essentially distinguishes Norway from all other countries of Western Europe, where from 1960-1980, there is a reduction of arable areas.

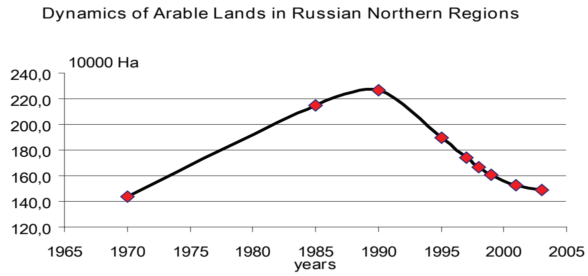

Figure 10. Data – State Committee 1985-1998, 2006.

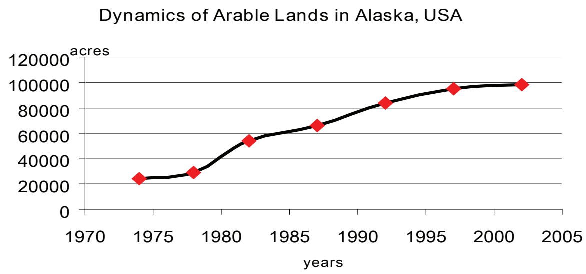

Figure 11. Data – USDA 2003.

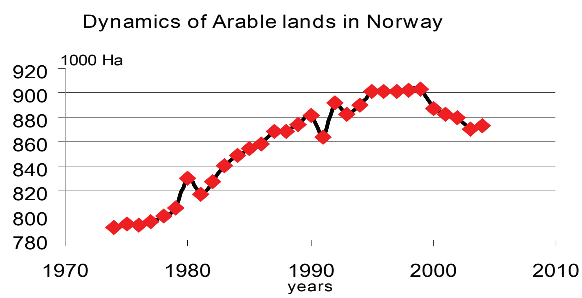

Figure 12. Data – http://faostat.fao.org/site/497/default.aspx.

Thus, the dynamics of arable lands in different cold regions of the Northern Hemisphere is essentially diverse. We see "growth-fall" in Russia, "growth" in Alaska and "growth-stabilization" in Norway. That allows the assumption that it is mainly defined by social and economic, but not by natural (changes of a climate) factors. Besides that, the dynamics of agricultural lands in permafrost-affected areas in different parts of the Northern Hemisphere are absolutely not similar to the mainland and neighbors: Alaska is different from the USA, and Norway, to all other countries of Western Europe. The Russian north is more likely similar to the Russian agriculturally productive south, than to the adjacent boreal and temperate regions.

Consequences of Land Use Change for Cryosols

Previous materials elucidated in the paper showed that agricultural use of soils in permafrost-affected regions of the world is growing or, at least, a stable factor of soil change. So, the influence of this type of land use on polar soils should be known as well as the other ones.

Figure 13. Total destruction of agricultural field after use of permafrost-affected soils for a cropland. Central Saha (Yakutia). Remnants of ploughed horizon proved the former tillage of these soils.

Our field studies in Central Saha (Yakutia) showed that the tillage of loamy soils resulted in occurrence of a humus horizon with a sharp lower boundary, as it is characteristic for all arable soils of the world. However, a specific tillage-induced feature is the lowering of the permafrost table often beneath 2 m (so after agricultural development, these permafrost-affected soils do not fit the criteria of Cryosols (WRB) and Gelisols (Soil Taxonomy) anymore).

But the most dangerous phenomena taking place after involvement of some permafrost-affected soils in agriculture is the total destruction of soil surface because of catastrophic development of thermokarst and thawing of underground ice wedges (Fig. 13).

Our data are in full correspondence with materials of Gavriliev (2004) who experimentally showed that after 12 years of agricultural use in Central Saha (Yakutia), ice wedges can thaw from a depth of 1.8 m to 3.2 m, and thermokarst holes can develop depths from 0 to 0.95 m.

The other data on tundra soils involved in agriculture from another part of the Eurasian cryosol area—northeast European Russia—also showed that they are characterized by development of sod and humus horizon instead of peaty litter and by occurrence of more contrast temperature regime with deep thawing of mineral horizons (Archegova et al. 2004).

Agriculture-induced soil change in permafrost areas has both similarity and difference with other types of land use and anthropogenic influence. As well as reindeer overgrazing, clear-cutting, and forest fires, it leads to active layer deepening (Broll 2000, Iwahana et al. 2005, Lopez et al. 2006). However, manure amendments for agriculture lead to an increase of carbon store in cryosols contrary to other types of land use. Anthropogenic change of cryosols has mostly the same trend as induced by global climate change, at least in some regions of the cryopedosphere—active layer increase (Mazhitova et al. 2004).

Conclusions

Agricultural land use change in permafrost-affected regions is very specific and has other trends than boreal and temperate regions of the world. Cold regions have different types of dynamic: (1) growth in Alaska, US, (2) growth and stabilization in Norway, and (3) growth and fall in Russia due to economic crises of the 1990s. Land use change is caused by socio-economic but not by climatic reasons. The local agricultural economy of remote northern areas is much smaller and more independent than that of central productive regions; that is why it will be saved by local communities, especially by indigenous people.

The consequences for cryosols induced by both socio-economic and climate changes are mostly similar. They provoke the deepening of the active layer, development of thermokarst, and change of organic matter quality (degradation of peat and increase of soil humus content).

Control of Asymmetrical Subgrade Temperature with Crushed-Rock Embankments Along the Permafrost Region of the Qinghai-Tibet Railway

Wei Ma, Luxin Zhang, Qingbai Wu

State Key Laboratory of Frozen Soil Engineering, Cold and Arid Regions Environmental and Engineering Research Institute, 320 Donggang West Road, Lanzhou, 730000, China

Abstract

On the basis of in situ tests of embankments with different crushed rock structures, this paper studied methods for controlling asymmetrical subgrade temperature. It is found that these methods can slowly change the ground temperature regime, but cannot completely adjust the asymmetrical subgrade temperature. Small changes in thickness and grain size of crushed rock had only a limited effect on controlling asymmetrical temperature regime. Compared with the ground temperature regime under different structures of crushed rock slope protection of the same height, it is found that the ground temperature under the south shoulder of an embankment with full crushed rock coverage is lower than that under an embankment with partial coverage, and that the ground temperature under the north shoulder of an embankment with partial coverage is lower than that of a slope with full coverage. It is suggested, therefore, that the south-facing slope be fully covered with crushed rock with thicker structures, while the north-facing slope be partially covered with crushed rock and thinner structures.

Keywords: crushed rock structure embankment; permafrost region; Qinghai-Tibet Railway; south- and north-facing slope of the embankment; temperature regime.

Introduction

Using an active cooling embankment to protect the underlying permafrost, a lot of engineering measures were successfully applied in permafrost engineering construction, especially in the Qinghai-Tibet Railway (QTR) (Rooney 1997, Georing et al. 1996, 2000, 2001, 2003, Ma et al. 2002, Cheng 2003). For instance, they include crushed rock embankments, embankments with crushed rock slope protection, embankments with thermo-siphons and permafrost bridges etc. Their cooling effects have been studied (Georing et al, 1996, 2000, 2001, 2003, Wu et al. 2006, Sun et al. 2004). These measures have ensured that the QTR successfully passes through the warm permafrost regions with high ice contents. Long-term monitoring data along the QTR showed that these measures have different cooling effects in permafrost regions with different ground temperatures (Wu et al. 2005, Ma et al. 2006). In particular, no matter what embankment structure was used, there was a thermal difference between the south- and north-facing slopes of the embankment, an asymmetrical temperature regime was formed under the embankment -- the ground temperature under the south side shoulder is higher than that under the north side shoulder (Sun et al. 2004, Wu et al. 2005). This kind of temperature distribution can cause the potential instability of the embankment. It is therefore necessary to adjust the asymmetrical temperature distribution under embankments by using special measures.

Along QTR, on the basis of in situ tests and temperature monitoring of embankments with different crushed rock structures (3 embankments with the slopes fully covered by crushed rock, 3 embankments with the slopes partially covered with crushed rock with different grain sizes and 1 embankment with the slope partially covered with the filling soil of the embankment), this paper analyzed and compared the changes in the ground temperature regime under the embankment with different structures. Observations should provide fundamental data for preventing and fixing of the potential damage to embankments.

Test Sections and Schemes

The test site is in the Wudaoliang area along the QTR, which is a plateau with lacustrine deposits and thick ground ice area covered by 5%–6% vegetation, altitude of 4500–4700 m. The mean annual air temperature is -5.6°C and the mean annual range of air temperature is 22.3°C. The mean annual precipitation is 264.8 mm and the maximum snow depth is 14 cm.

DK1082+350–DK1082+500 was the test section of embankments with the slopes fully covered with crushed rock with different thicknesses; DK1082+650–DK1082+850 was the test section of embankments with the slopes partially covered by crushed rock with different grain size and an embankment with the slope partially covered with soil. Their details are shown in Table 1.

The original embankment in the test section is a common soil embankment built in 2002. The width of the track surface is 7.1 m, the height of embankment is 2.0–2.8 m and the gradient of embankment is 1:1.5. The widths of the south- and north-facing partial slope protection using soil are 3 m and 2 m.

For the requirements of the tests, we changed the original design. In the section DK1082+350–DK1082+500, we only fully covered crushed rock with different thickness on the slope of the original embankment (shown in Fig. 1). In the sections of DK1082+650–DK1082+750 and DK1082+800–DK1082+850, we use a partial coverage of crushed rock with

Table 1. Test schemes.

QTR kilometer post	T_{cp}* / °C	Mean height of embankment/m	Structure size of Slope protection of embankment	Structure type of embankment
DK1082+350-DK1082+400	-2.35	2.51	Thickness of the south/north-faced slope: 1.0 m/0.6 m ; Crushed rock size: 10 cm	Embankments with the slopes fully covered by crushed rock
DK1082+400-DK1082+450	-2.35	2.65	Thickness of the south/north-faced slope: 1.3 m/0.8 m; Crushed rock size: 10 cm	
DK1082+450-DK1082+500	-2.35	2.79	Thickness of the south/north-faced slope: 1.6 m/1.0 m ; Crushed rock size: 10cm	
DK1082+650-DK1082+700	-2.35	2.35	Width of the south/north-faced slope: 6.0/4.0 m Crushed rock size: 20 cm; Thickness: 1.5 m	Embankments with the slopes partially covered by crushed rock

DK1082+800-DK1082+850	-2.35	2.76	Width of the south/north-faced slope: 5.0/3.0 m; Crushed rock size: 10 cm Thickness: 1.5 m	
DK1082+750-DK1082+800	-2.35	2.11	Width of the south/north-faced slope: 5.0/3.0 m; Thickness: 1.5 m	Embankment with the slope partially covered by soil

* T_{cp} is mean annual ground temperature at depth of 15 m from the original ground level down (shown in Fig. 4).

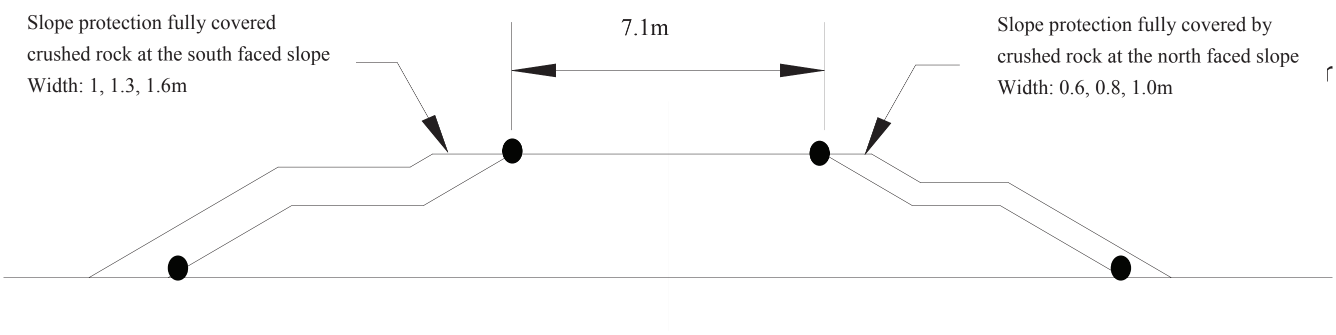

Figure 1. The cross section sketch map of embankment with the slope protection fully covered by crushed rock in DK1082+350–DK1082+500.

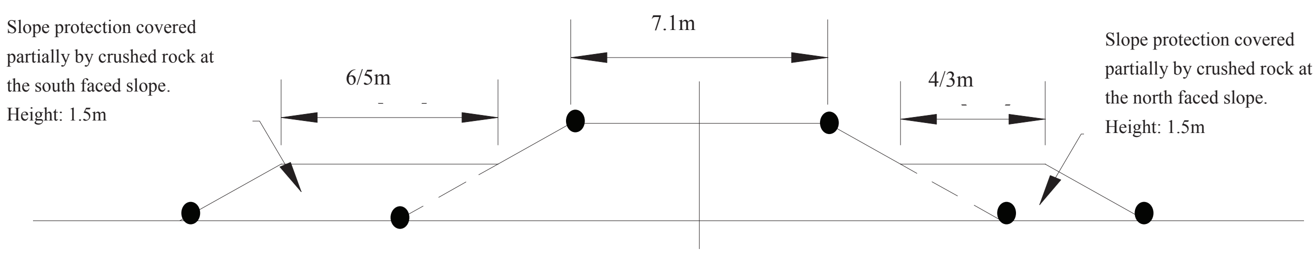

Figure 2. The cross section sketch map of embankment with the slope protection partially covered by crushed rock in DK1082+650–DK1082+850.

different widths and grain sizes to replace the original slope protection partially covered by soil (shown in Fig. 2). In the section of DK1082+750–DK1082+800, we only widened the original soil slope protection to 5.0/3.0m (shown in Table 1). Per test section, the length is 50 m, a lot of tests indicated that they are long enough to eliminate the thermal boundary effects from adjacent embankment sections (Wu et al. 2006, Sun et al. 2004, Ma et al. 2006).

DK1082+375, DK1082+425, DK1082+475, DK1082+675, DK1082+725, DK1082+775, and DK1082+825 respectively were chosen as monitoring profiles of ground temperature. In DK1082+375, DK1082+425, and DK1082+475, four boreholes were installed in each profile–on the south and north shoulder of the embankments and at the

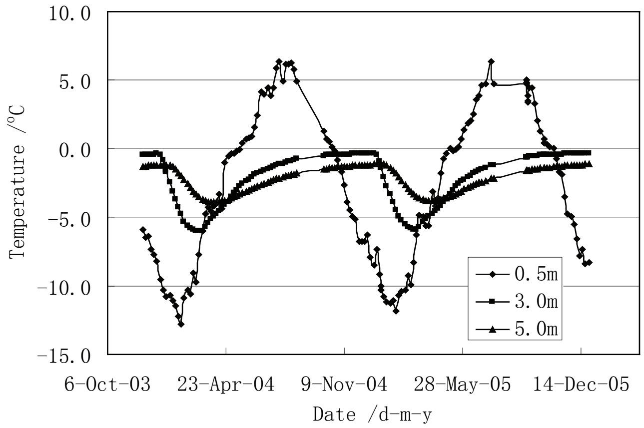

Figure 3. Ground temperature changes vs. time at different depths in the natural borehole (DK1082+600).

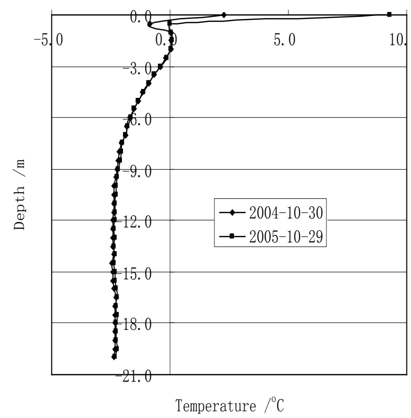

Figure 4. Ground temperature changes with depth when the thawing depth reached the maximum in the natural borehole (DK1082+600).

south and north toe for embankments with partial slope protection using soil (shown in Fig. 2 marked by "●"). In DK1082+675, DK1082+725, DK1082+775, DK1082+825, six boreholes were installed in each profile–the south and north shoulder and toe of embankment, the south and north toe of slopes partially covered by crushed rock, respectively (shown in Fig. 3 marked by "•"). Also a reference borehole 20 m deep was installed 20m away from the north slope toe of embankment at DK1082+600 to measure the natural ground temperatures.

A galvanized iron pipe was placed in each borehole. A thermometric string (the thermocouples placed at 0.5 m intervals) was installed in each pipe to record the temperatures at different depths.

The thermocouples were manufactured by the State Key Laboratory of Frozen Soil Engineering, Cold and Arid Regions Environmental and Engineering Research Institute, CAS, and the precision is ±0.05ºC. All data were collected using a Datataker 500 from Oct. 2003 to Dec. 2005.

Results and Analysis

Natural ground temperature changes

Figures 3 and 4 show the ground temperature changes with time at different depths and with depth when the thawing depth reached a maximum in the natural borehole. It is found that the permafrost table was at 2.0 m and the mean annual ground temperature was -2.35°C. It was also found there were little or no changes in the permafrost table or in the mean annual ground temperature. The air temperature therefore had very little effect on ground temperatures during the experimental years at the test site. So, we will not consider the effect of air temperature on temperature regime of embankment in following discussion.

Ground temperature changes under embankment with the slope protection partially covered by soil

Figure 5 shows the ground temperature changes with time at different depths and locations beneath the embankments. Compared with the slope shoulders and toes of embankment, it is found that the ground temperatures at the south shoulder and toe of the embankment were above -2°C and clearly higher than these under the north shoulder and toe. With increasing time, the minimum ground temperature at 0.4 m keeps slight increase, and under 0.4 m, they decrease slightly, and the decreasing range of ground temperature was about 0.2°C–0.3°C. Under the north shoulder of the embankment, the ground temperatures were about 1°C to -5.3°C. In the course of time, they decreased considerably, and the decreasing range of ground temperature is about 0.5°C to 1.1°C. Such developments would cause larger and larger ground temperature difference between the south and north slopes of the embankment and increase the potential instability of the embankment. So, this method can be put away first.

Ground temperature changes under the embankment with the slope protection fully covered by crushed rock

Figure 6 shows the typical ground temperature changes with time at different depths and positions under the embankments at DK1082+375. It can be seen that with the slope fully covered with crushed rock, the ground temperatures under embankment decrease noticeably, but the rate of decrease of ground temperature under the south side shoulder was less than that under the north side shoulder ground temperature difference, particularly under the toe of embankment. With increasing thickness of the crushed rock layer, the ground temperature difference decreases gradually under the south and north shoulders. Compared with embankments DK1082+425 and DK1082+475, the embankment structure with the thicknesses on the south/north-faced slopes of 1.6 m/1.0 m (DK1082+475) is better than the others. The difference exists mainly in the change of minimum ground temperature. The maximum ground temperature has no obvious relationship with thickness of the crushed rock layer. For the embankments with the thicknesses of crushed rock layer of 0.6 m and 1.0 m (DK1082+375), 0.8 m and 1.3 m (DK1082+425), 1.0 m and 1.6 m (DK1082+475), respectively, the differences in the minimum ground temperature at different depths under the south and north side shoulders were 1.29°C to 2.68°C, 0.98°C to 1.98°C, 0.90°C to 1.89°C, respectively. In addition,

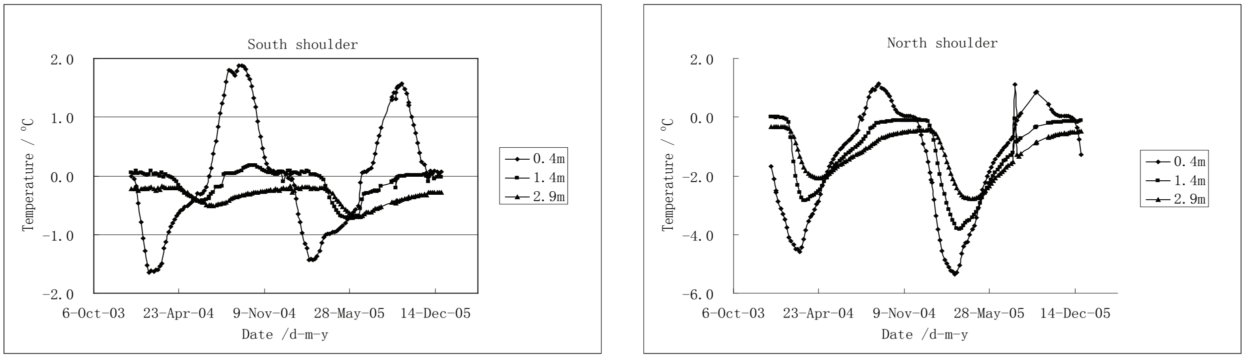

Figure 5 Ground temperature changes vs. time at different depths under embankment with the slope protection partially covered by soil (DK1082+775).

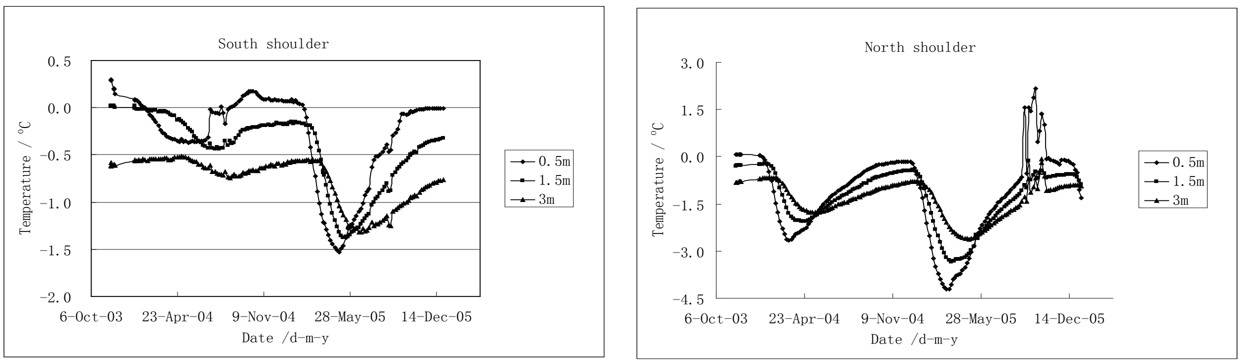

Figure 6. Ground temperature changes vs. time at different depths under the embankment with the slope protection fully covered by crushed rock (DK1082+375).

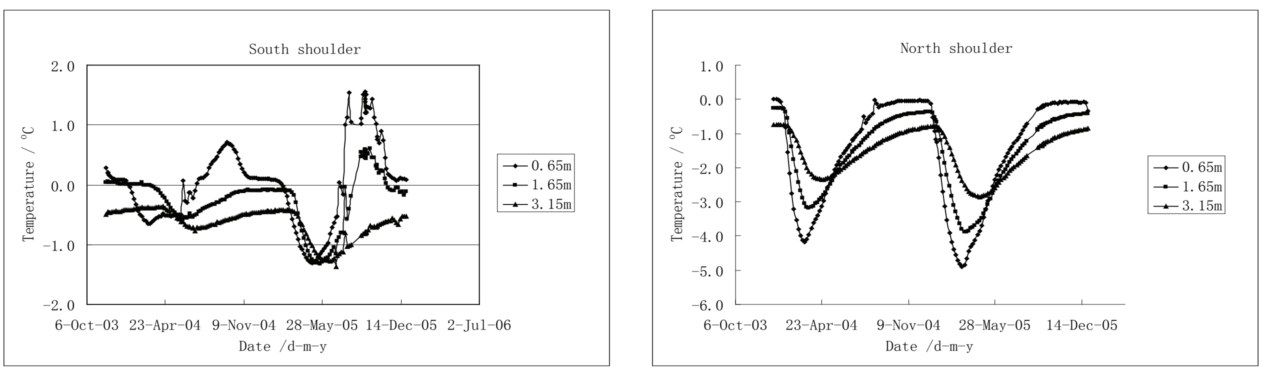

Figure 7. Ground temperature changes vs. time at different depths under the embankment with the slope protection partially covered by crushed rock (DK1082+675).

it is found that the minimum ground temperature in shallow layers under embankment had larger ground temperature differences than that in deeper layers.

Ground temperature changes under embankments with the slope protections partially covered by crushed rock

Figure 7 shows typical ground temperature changes with time at different depths and positions under the embankments at DK1082+675. It can be seen that with the slope partially covered by crushed rock, the ground temperature under the embankment decreased noticeably. Compared with minimum ground temperature, it was found that the rate of decrease of ground temperature under the south shoulder was larger than that under the north shoulder. The same was true for the south and north toes. However, a ground temperature difference still exists between the south-and north-facing slope of the embankment, particularly under the shoulders of the embankment. The ground temperature difference under the south and north shoulder and toe decreased gradually with time. Comparing with the ground temperature change under the shoulders and toes at DK1082+675, +725, +825, found that adjustment of the asymmetrical thermal regime under the embankment structure is best with the widths of the south/north-faced slopes of 4.0 m/6.0 m, using the crushed rock size of 30 cm (DK1082+725). Second best is the embankment with the widths of the south/north-faced slopes of 4.0m/6.0m and the crushed rock size of 20 cm (DK1082+675). The embankment with the widths

Table 2. Maximum thaw depth at the south and north shoulders of embankments.

Monitoring profile	Location	Height of embankment /m	Maximum thawing depth in 2003 /m	Maximum thawing depth in 2004 /m	Maximum thawing depth in 2005 /m	Structure type of embankment
DK1082+375	South shoulder	2.49	4.0	3.51	2.93	Embankments with the slopes fully covered by crushed rock
	North shoulder	2.53	3.25	2.48	2.46	
DK1082+425	South shoulder	2.59	4.0	3.41	3.82	
	North shoulder	2.71	3.6	3.33	3.29	
DK1082+475	South shoulder	2.76	4.0	3.66	3.36	
	North shoulder	2.81	3.5	2.62	3.00	
DK1082+675	South shoulder	2.28	4.1	3.62	3.43	Embankments with the slopes partially covered by crushed rock
	North shoulder	2.42	3.2	2.89	2.87	
DK1082+725	South shoulder	2.13	3.6	3.47	3.18	
	North shoulder	2.36	3.5	3.32	2.90	
DK1082+825	South shoulder	2.80	5.1	4.77	4.42	
	North shoulder	2.72	3.8	3.5	3.35	
DK1082+775	South shoulder	2.04	4.1	3.85	3.54	Embankment with the slope partially covered by soil
	North shoulder	2.17	3.8	3.54	2.96	

of the south/north-faced slopes of 3.0 m/5.0 m and the crushed rock size of 10 cm is the worst (DK1082+825). The difference of the minimum ground temperature at different depths under the south and north toe was 1.11°C to 1.27°C, 1.6°C to 2.26°C, 1.94°C to 3.2°C, respectively. In addition, the minimum ground temperature in shallow layers under embankment has larger ground temperature differences than that at deep layers.

Discussion and Suggestions

In general, choice of good embankment structure must consider both the ground temperature difference and the maximum thawing depth (permafrost table) between the south- and north-facing slopes of the embankments.

On the basis of observations, it is seen that except for the embankments with slope protection partially covered with soil, the other embankment structures achieved a certain adjustment of the asymmetrical thermal regime.

Compared with the thickness and size change of crushed rock, it is found that with full coverage using crushed rock, the ground temperature difference decreased gradually with increasing thickness of the crushed rock layer. For the slopes partially covered with crushed rock, the adjusting effect of the asymmetrical temperature distribution using larger grain sizes is better than the others. But, a small change in the thickness or grain size cannot completely adjust the asymmetrical temperature distribution in this test. Based on ground temperatures under the south and north shoulders, the ground temperature with full coverage with crushed rock under the south shoulder was lower than that using partial coverage with crushed rock, and the ground temperature of the partial coverage with crushed rock under the north shoulder is lower than that using coverage with crushed rock. For integrated effect of ground temperature regime, the asymmetrical temperature distribution adjustment using full coverage with crushed rock was better than partial coverage with crushed rock.

Table 2 shows the changes in the maximum thawing depth under the south and north shoulders for different monitoring profiles. Except for the monitoring profiles of DK1082+425 (south shoulder), DK1082+475 (north shoulder), and DK1082+825 (north shoulder) where the maximum thawing depth decreased from 2003 to 2004 and increased from 2004 to 2005, the others decreased from 2003 to 2005. Through in-situ investigation, we found that abnormal change of the maximum thawing depth in DK1082+425 (south shoulder), DK1082+475 (north shoulder), and DK1082+825 (north shoulder) were caused by rainwater massed at the slope toe of the embankment. The maximum thawing depth for full coverage with crushed rock under the south shoulder is less than that of using partial coverage with crushed rock, and the maximum thawing depth for partial coverage with crushed rock under the north shoulder is less than that of using full coverage. Compared with the difference of the maximum

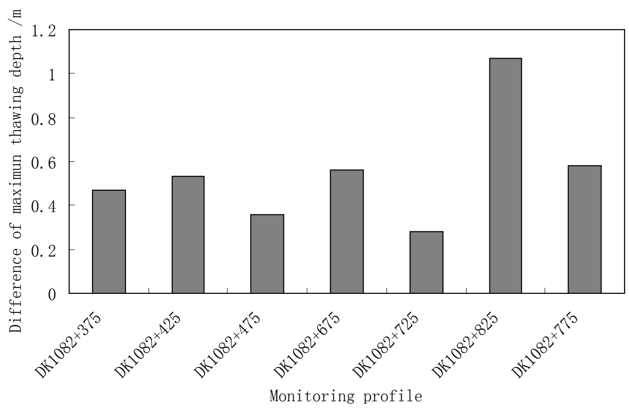

Figure 8. Difference of the maximum thawing depth between the south and north shoulder for different monitoring profiles in 2005.

thawing depth between the south and north shoulders in 2005, the differences at DK1082+475 and DK1082+725 are still less than the others, they are 0.36 m and 0.28 m, respectively (shown in Fig.8).

In other words, the better embankment structures for adjusting asymmetrical permafrost table were the embankments with slope protection using partial coverage with crushed rock with widths of the south/north-faced slope of 4.0 m/6.0 m and a crushed rock size of 30 cm (DK1082+725), as well as embankments with slope protection using full coverage with crushed rock and thickness of the south/north-facing slopes of 1.0 m/1.6m and the crushed rock size of 10 cm (DK1082+475).

Based on the above discussions, we can say that under the conditions of our test sections, these methods can slowly change the ground temperature regime but cannot absolutely adjust the asymmetrical temperature distribution under the embankments. In these testing programs the small change in thickness and grain size of the crushed rock had only a limited effect on adjusting and controlling the asymmetrical temperature regime. After integrated considering of the difference of ground temperature and the maximum thawing depth under the north shoulders and toes of the embankment, as well as economical cost, we suggest that the south-faced slope is better fully covered by crushed rock with wider and thicker structure. For the north-facing slope partial coverage with crushed rock that is narrower and thinner is better.

The above conclusions were drawn only based on three years of data and the lower temperature permafrost region; the effect of the warming climate was not considered. At present, we want to re-monitor these test sections and set up some new monitoring profiles in the higher temperature permafrost regions along the QTR and the Qinghai-Tibet Highway, and hope some new results can be found.

Abstract

It is well known that frost heave occurs in zones of thawed and non-anchored frost-susceptible soils under the effect of buried chilled gas pipelines. This phenomenon is due (related) to the specific stress-strained state of freezing soils. Simulation results revealed the following special features of the process: peak linear heave load increases with a decrease in permeability and with an increase in soil freezing rate; peak linear heave load increases in the following succession: sand–sandy loam–loam–clay; and peak linear heave load varies with time and achieves maximum values during the first year of operation of a gas pipeline. Appropriate thermal insulation can eliminate frost heave entirely. The technical decisions providing engineering protection are developed on the basis of soil thermal behavior simulations and strain calculations. These decisions will ensure the stability of the planned pipeline embedding during the whole operation period.

Keywords: buried pipeline; discontinuous permafrost; freezing rate; frost heave; heave load; stress-strained state; permeability.

Introduction

It is well known that frost heave occurs in zones of thawed (under ponds, lakes, bogs) non-anchored frozen soils under the effect of chilled gas pipelines. This phenomenon is related to the specific stress-strained state of freezing soils. Estimation of the displacement of a buried pipeline as a result of frost heave has been a problem because of the lack of appropriate theoretical analysis.

The phenomenon of the frost heave of chilled pipelines in unfrozen soils has been studied since the 1980s. The first approximate theoretical analysis of this phenomenon was undertaken by Grechishchev (1994). Experimental studies of the frost heave of chilled buried pipelines under natural conditions were carried out in France (Williams, 1986, 1989) and Alaska (Akagawa et al. 2004, Kanie et al. 2004).

The calculation of the theoretical peak heave force has remained the pri chilled pipeline on the surrounding soils, the theoretical peak frost heave force applied to a chilled pipeline, and the stress-strain state of the pipeline were evaluated.

Computation procedure was as follows. First, the anticipated thermal behavior of soil was estimated. Based on the obtained thermal behavior parameters (soil freezing above the pipe, soil freezing under the pipe, peak annual freezing rate under the pipe), maximum possible frost heave force applied to the chilled pipeline was estimated. Finally, the obtained linear pull-out force values were applied to the pipeline to estimate its stress-strained state.

Anticipated changes in the thermal conditions of soils underlying the pipeline during construction and operation periods were estimated using the specially developed PROGNOZ software (RSN 67-87), providing a possibility to make allowances for geological and geocryological section heterogeneity, soil physical and thermal properties, and the anthropogenic thermal effects. Mathematical simulation in this software is achieved by enthalpy finite-difference method on an explicit two-layer grid. Simulation was two-dimensional.

The applied calculation method (10) provided a possibility to estimate the values of normal heave forces applied to gas pipe or the confining force to be applied to the pipe to ensure its stability.

Software package Mathcad 2001 was developed for the numerical solution of model equations.

The stress-strained state of the gas pipeline was estimated using the Cosmos Works software based on the finite-element method. Normal frost heave force value was assumed to be equal to estimated heave load (shut-off pressure). Also, gas pipeline actual operating pressure and the subsoil and transmitted gas temperatures were assigned.

Initial Data

By way of a case study, given below are computation results for Olekmisk conditions. The pipeline diameter is 1400 mm, the pipe center depth is 1.5 m, and the operating pressure is assumed to be 10 MPa.

The frost heave of a buried chilled gas pipeline was estimated for the case of discontinuous permafrost with a roof foundering of 10 m and average annual soil temperature of minus 0.1°C at the annual zero amplitude depth. Calculations

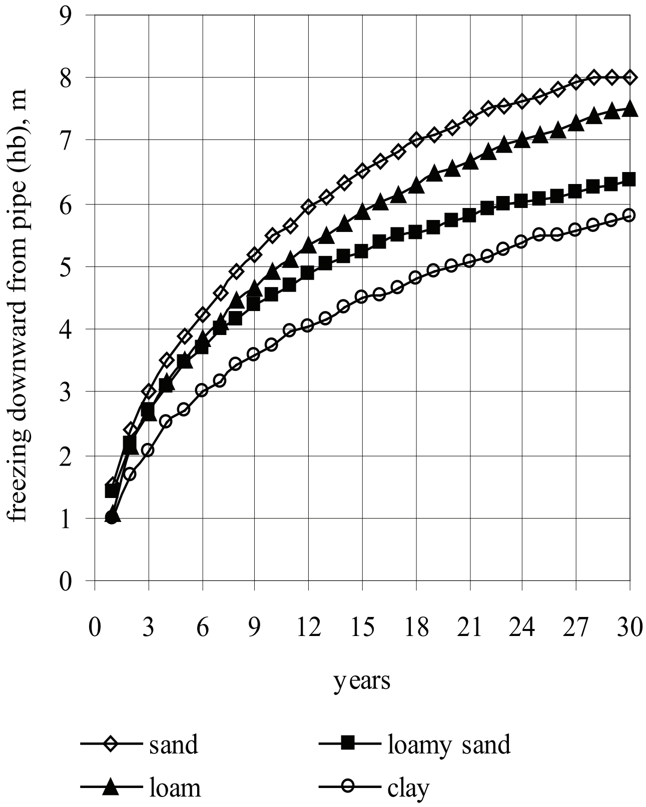

Figure 1. Change of depth freezing downwards from a chilled gas pipeline with time.

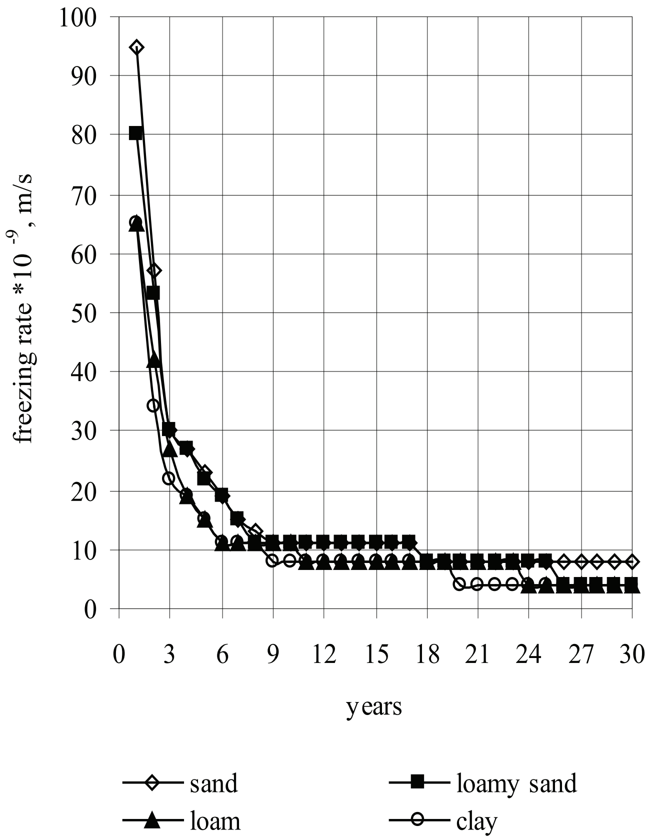

Figure 2. Change of freezing rate with time.

were performed for sand, loamy sand, loam and clay soils.

Calculations for the pipe-soil boundary were made for transmitted gas temperature varying in time from minus 7.5°C in winter to minus 2°C in summer. The following cases were studied: pipe without thermal covering and pipe with a thermal covering with a thermal resistance to heat transfer of 3.6 W/m^2×°C (with reference to clay soil).

Results

Thermal behavior calculation results are illustrated by Figure 1 and 2. The obtained data suggest that freezing depth (Fig. 1) and rate (Fig. 2) increase in the following succession: clay–loam–sandy loam–sand.

Peak linear heave load as a function of freezing rate is shown in Figure 3. As obvious from the figure, peak linear load value varies with time and is the highest during the first year of the gas pipeline operation period.

Data shown in Figure 3 also demonstrate the increase in peak linear heave load with an increasing soil freezing rate.

Peak heaving load as a function of soil permeability is shown in Figure 4. Analysis of data shown in Figure 4 suggests that the effect of soil permeability on linear heave load value is significant. Linear load value increases with a decrease in permeability.

Analysis of calculation results (Figs. 3 and 4) suggests that peak linear heave load increases in the following succession: sand–sandy loam–loam–clay.

The stress-strained state of pipeline under the estimated peak heaving load was estimated. Pipeline heave buckling (displacement), in this case, may be as large as 0.5 m.

Heat isolation restricts subsoil freezing. Heat isolation with a thermal resistance to heat transfer of 3.6 W/m^2×°C eliminates soil freezing under the pipeline completely. It follows that it is possible to select isolation thickness sufficient for the complete elimination of pipeline heave buckling.

Based on calculation results, engineering solutions can be worked out for stabilizing the planned chilled buried pipeline position: application of a heat insulation cover with a thickness determined by special calculations; application of ice-and-soil supports or chemically stabilized soils with screw-in anchors, to which pipeline is fastened by special heavy-duty belts. The calculated linear heave load values shall be borne by these anchors.

Conclusions

1. Simulation data analysis has revealed the following tendencies of the process: Peak linear heave load grows with a decrease in permeability and with an increase in soil freezing rate; peak linear heave load increases in the following succession: sand–sandy loam–loam–clay; and peak linear heave load varies with time and achieves maximum values during the first year of a gas pipeline operation period.

2. Integrated predictive estimation of the thermal and

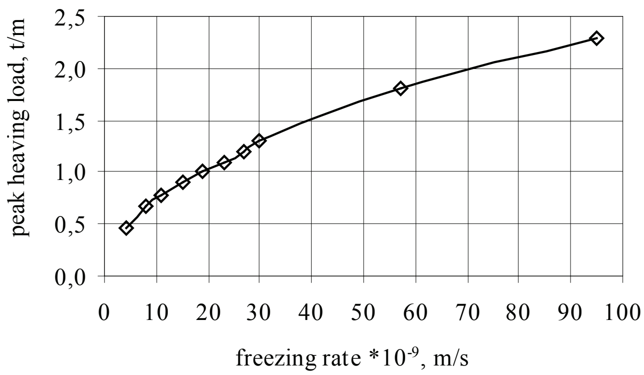

Figure 3. Variation of peak heaving load and freezing rate.

strain behavior of soils at the early stage of project designing provides the opportunity to identify and recommend the optimum temperatures of the piped product to minimize the thermal effect on the subsoil. At later stages of project designing (project design, detailed engineering), engineering protection solutions are developed on the basis of thermal behavior modeling and strain computation to ensure the stabilization of the planned pipeline position during the whole operation period.

Analysis of Discharge Characteristics in a Region of Continuous Permafrost: Yana Basin in Siberia

Ipshita Majhi
WERC, University of Alaska Fairbanks
Daqing Yang
WERC, University of Alaska Fairbanks

Abstract

Yana basin was analyzed to understand the hydrology of the catchment, since it is situated in a continuous permafrost region with minimal human impact. The discharge analysis revealed the typical permafrost laid hydrograph with peak summer flood in June and minimum flow from November to April. Temperature and precipitation did not show any significant trend over 70 years. Statistical analysis showed a mixed trend for the stations examined, but there is no significant trend observed for winter months. There is a relationship between snow water equivalent and discharge, but further examination is needed to document the relation. Overall, a better understanding of hydrology was gained through this analysis.

Keywords: hydrology; permafrost; snow water equivalent; Yana.

Introduction

Rivers provide a vital link by integrating, spatially as well as temporally, atmospheric and land surface processes at catchment level, thereby providing a mechanism to detect climate change (Déry et al. 2005).

Significant changes have been observed in the large arctic river basins. For instance, Ye et al. (2003) and Yang et al. (2004) found Lena and Yenisei River discharges increase during the winter months and shift in peak discharge timing in Siberia mostly due to reservoir regulation. Small coastal rivers with no regulation and scarce population density provide an ideal medium to understand the effect of climatic variation on streamflow.

The emphasis of this research is to gain a better understanding of various parameters which affect the unregulated Yana River basin in Eastern Siberia. The basin was chosen for this analysis, since it is a non-regulated mid sized watershed, and streamflow response to snowmelt is direct without reservoir interference or other anthropogenic activities. This analysis will enhance our knowledge of discharge response to changes in precipitation, temperature and snow cover.

Study area, data, and method

The Yana basin is one of the large rivers in northeast Asia with a basin area of 238,000 km^2. The river flows north for 879 km, passing through subarctic and arctic region, and finally discharges into the Laptev Sea at 72°N .The Yana River lies between the East Siberian lowland and the Verkhoyano range. In the lowlands the elevation does not exceed 150 m. The climate in this region is continental. Precipitation ranges from 200–400 mm/year in the lowlands to 400–500 mm/year on the ridges. Continuous permafrost with infrequent taliks as well as widely developed taliks occurs everywhere.

Hydrological observations in the Siberian regions, such as discharge, stream water temperature, river-ice thickness, and dates of river freeze-up and break-up, have been carried out since the mid 1930s by the Russian Hydro Meteorological Services (Shiklomanov et al. 2000). The discharge data are now available from the R-Arctic Net (v.3.)-(www.r-arcticnet.sr.unh.edu/main.html) online.

In addition, subbasin mean monthly temperature and precipitation were obtained from University of New Hampshire (http://rims.unh.edu) along with the Special Sensor Microwave/Imager (SSM/I), remote sensing snow water equivalent data (SWE). As part of our preliminary analysis we defined the natural climatic variation through temperature and precipitation interannual variability, mean, standard deviation, and linear trend. Second, we analyzed monthly and annual discharge records along the main stream to quantify discharge change. Third, we compared snow water equivalent, precipitation, temperature, and discharge as a function of time to assess their relationship.

Result and Discussion

Climate-hydrology

Annual temperature during 1930–2000 ranged from -16°C to -12°C; the cold temperature is characteristic of a region with continuous permafrost (Fig. 1). The basin is characterized by a long cold season of eight months, with temperatures ranging from -10°C in September to around -2.5°C in May. The brief warm season has a temperature range of 9°C in June to 3°C in August, with July being the warmest month (mean temperature of 13°C). The coldest month is January with a mean monthly temperature of -40°C.

Mean annual precipitation over the basin ranges from 145 mm to 300 mm, with an average value of 220 mm (Fig. 1). There is minimal precipitation ranging around 5 mm in January, February, and March. Peak precipitation is in the months of July and August with an average rain depth of 45 mm. Monthly mean value of precipitation for September,

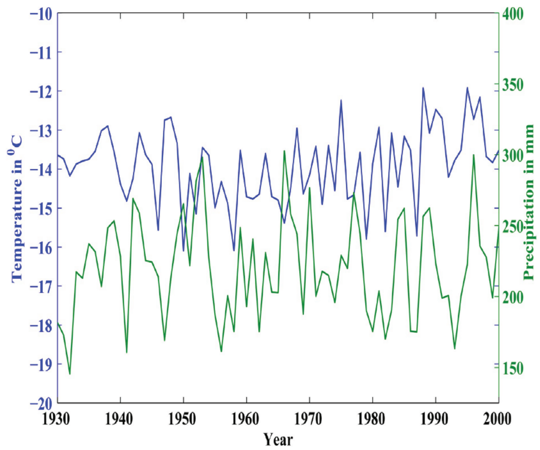

Figure 1. Interannual variability for temperature and precipitation at Yana basin from 1930–2004.

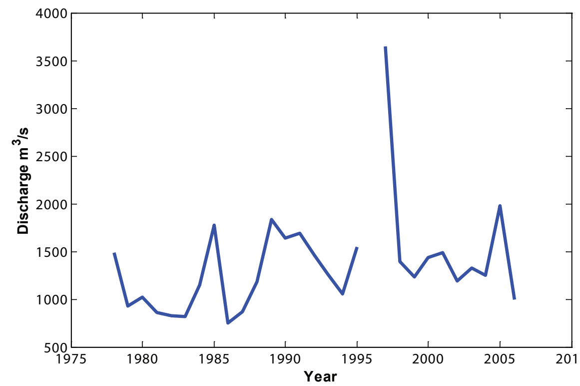

Figure 2. Interannual variability for discharge at Yana basin from 1976–2006.

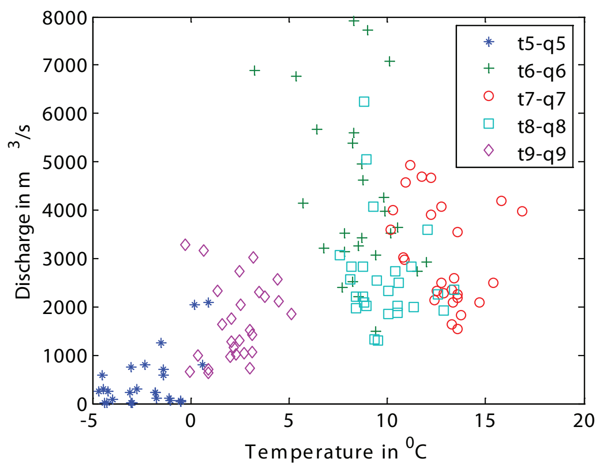

Figure 3. Discharge (*q*) and temperature (*t*) comparison from May to September with no lag.

October, November, and December are 25 mm, 15 mm, 10 mm, and 7 mm.

Temperature and precipitation interannual variability (standard deviation) did not show any significant upward trend from 1930–2000. The highs and lows of precipitation and temperature show consistency, indicating with higher annual temperature there is higher annual precipitation. To understand the basin hydrology, annual flow, monthly flow and variation (standard deviation) and trend are analyzed

It was found that basin discharge is typical of continuous permafrost region (Kane 1997) with peak flow in June and low flow dominating from October to April. Trend analysis shows mixed results for all the stations, but negligible or no change is observed during the cold season from October to April.

Discharge, temperature, precipitation, and Special Sensor Microwave/Imager (SSMI) SWE analysis

The discharge regime at the outlet shows interannual variation from 1600 m^3/s to 800 m^3/s with a tendency towards decreasing trend from 1988–2000 (Fig. 2). The variation in monthly streamflow is generally small for the cold season (October to April) and large in summer months, mainly due to floods associated with snowmelt and storm activities.

Correlation between temperature and discharge was examined to understand the effect of higher or lower temperature fluctuation on mean discharge. Statistical analysis of annual mean discharge at the basin outlet and temperature annual mean showed a positive correlation (R = 0.30). There is no consistent relationship for warm and cold season for zero time lag, which could be due to no flow for most of the cold season in the Yana basin (Fig. 3). The only statistically significant month was May with a strong positive correlation (R = 0.48). Yang et al. (2002), observed a similar relationship for Lena basin, emphasizing that higher temperature in May will lead to larger snowmelt floods. This relationship shows that during transition period, as the watershed warms up, snow cover disappears and evaporation starts to dominate (Yang et al. 2002). Since this is a smaller basin compared to other large Siberian rivers, even one month lag does not show any significant relationship except a high positive correlation between November to December (R = 0.47); that is, higher temperature in November leads to more discharge in December.

Statistical analysis for correlation between precipitation and discharge showed a positive relationship for interannual comparison (R = 0.24), indicating that some years with higher precipitation showed higher average discharge. The winter months of January (R = 0.43) and March (R = -0.32) showed a negative relationship for zero lag, and other months from October to April showed no significant relationship. This could be because cold months are characterized by snow cover accumulation, and discharge is mostly base flow or no flow (Yang et al. 2002).

Discharge and SWE follow an inverse relationship, with the advent of snowmelt at about day 86 (last week of March), and it finally disappears at day 150 day around the last week of May on average (Fig. 5). The discharge subsequently peaks on day 160. This is typical of arctic regions underlain with continuous permafrost. The time series of discharge and snow water equivalent emphasizes the inverse relationship. High value of snow water equivalent does not always lead to high peak discharge; this could be due to different ablation

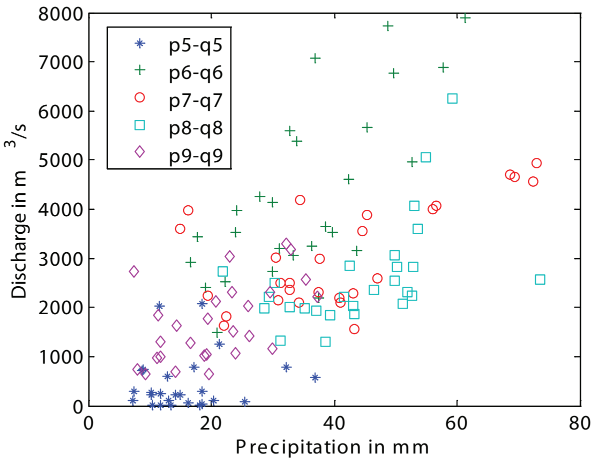

Figure 4. Discharge(q) and precipitation (p) comparison from May to September with no lag.

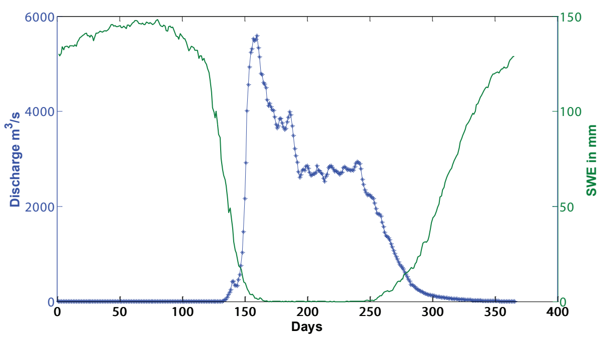

Figure 5. Daily mean discharge and SWE relationship.

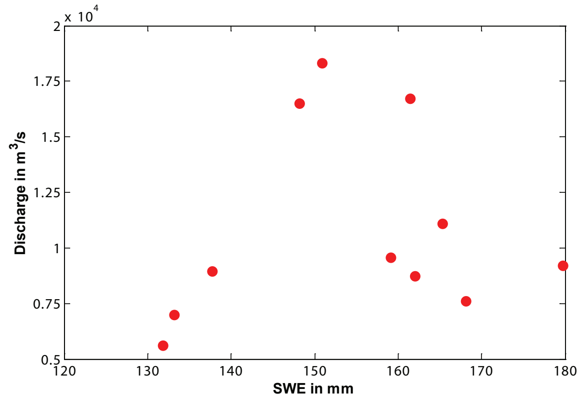

Figure 6. Daily maximum discharge and SWE relationship.

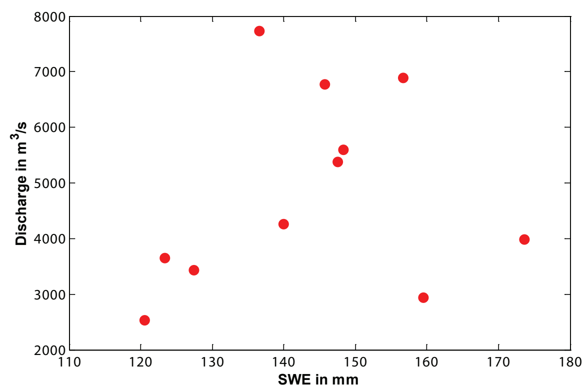

Figure 7 Monthly maximum discharge and SWE relationship.

rates, which are variable from year to year. We calculated the ablation rate around mid May to the first week of June and it varies from as low as 2 mm/day to as high as 16 mm/day at the start of snowmelt; the rates change with increase in temperature.

Highest daily value of SWE and discharge are compared, and their relationship (Fig. 6) follows a Gaussian curve. Increase in discharge is associated with increase in snow water equivalent (SWE), but there are some discrepancies for some years.

There is a lot of missing data for some years, and the mean value could be shifted to the month of August resulting in a lower peak. On looking at mean monthly maximum discharge in June and mean maximum SWE in March, the relationship is more linear with two outliers at the high end of SWE, which is similar to the daily maximum SWE and discharge relationship. The result indicates that on average, a year of higher precipitation in winter will lead to higher peak discharge.

The dates for maximum snow and discharge for each year are analyzed (Fig. 7), and no major change or shift is found in the timing of peak discharge and maximum snow water equivalent.

Conclusion

Significant changes have been observed in the large arctic river basins. For instance, Ye et al. (2003) and Yang et al. (2004) found Lena and Yenisei River discharges increase during the winter months and shift in peak discharge timing in Siberia mostly due to reservoir regulation. In our study of the Kolyma basin, we also found significant increase in winter discharge by as much as 522%-3157% downstream of the dam from December to April (Majhi et al. in press). Our results indicate that the Yana basin does not show any significant change in discharge.

Temperature and precipitation interannual variability (standard deviation) did not show any significant upward trend from 1930–2000. The peaks and lows of precipitation and temperature show consistency, indicating with higher annual temperature there is higher annual precipitation. Most of the precipitation falls in the summer months from June to September. Temperature shows a basin high of around 15°C in summer and a low of -40°C in January. Basin discharge is typical of continuous permafrost region with peak flow in June and low flow dominating from October to April. Trend analysis shows mixed results for all the stations, but negligible or no change is observed during the cold season from October to April.

The only statistically significant month for temperature and discharge was May with a strong positive correlation . Yang et al (2002), observed a similar relationship for the Lena basin, emphasizing that higher temperature in May will lead to larger snowmelt floods. Correlation between precipitation and discharge showed a positive relationship for interannual comparison, indicating that some years with higher precipitation showed higher average discharge. The winter months of January and March showed a negative relationship for zero lag, and other months from October to April showed no significant relationship, while there was significant relationship from June to September for no lag. This could be due to quick response of discharge to rain events, since the Yana is comparatively a medium-sized basin.

Overall there is a need to better understand discharge dynamics to further the hydrological cycle and its implications. Monitoring snow pack variability for the arctic region has implications in the context of global change, since it is fundamental to estimate the change in freshwater flux. Moreover, changes in snow depth and timing alter the surface albedo, resulting in feedbacks at both regional and global scale. The analysis reported may be very useful in improving the snow and discharge relationship in hydrological models.

Abstract

To understand better the formation and history of petroleum gas hydrates in terrestrial permafrost regions, we have performed numerical temperature profile modeling in response to surface forcing due to both the glacial-interglacial history and future climate change, where atmospheric CO_2 has doubled due to climate change. The models are constrained by heat flow from deep wells, thermal conductivity, latent heat, and the observed permafrost and gas hydrate thicknesses. The models consider the pressure–depth dependence of ice and gas hydrate thawing points over the entire gas hydrate and permafrost intervals, in contrast to previous models that considered only a thin layer using a constant dissociation temperature. In areas of thick permafrost, results show that a thinned gas hydrate layer persisted through previous interglacials, and that future warming before the "natural" end of the current interglacial will not destabilize the gas hydrate layer significantly. Therefore, present changes in temperature gradient reflect transient conditions, and they should not be used to derive thermal conductivity in permafrost regions using a constant heat flow assumption. We also find that the ratio of temperature gradients within and below the permafrost has very little to do with the thermal conductivity ratio of the permafrost, although this is less appropriate in the sub-permafrost layers due to the buffering effects of overlying ice-bearing permafrost. Models with unfrozen-frozen thermal conductivities of 2.4–3.6 W/(m.K), and with an unfrozen-frozen conductivity ratio of 2.1–3.4 W/(m.K), (that is, very similar conductivity ratios 1:1.5 and 1:1.6) give dramatically different thermal gradient ratios 1:5.4 and 1:2.9, respectively.

Keywords: climate change; gas hydrate; latent heat; permafrost.

Introduction

To understand better the formation and history of petroleum gas hydrates (GHs) in terrestrial permafrost regions, we have performed numerical modeling of the surface forcing due to both glacial-interglacial history and future climate change. Persistent GH layers in a terrestrial environment of thick permafrost in cold regions sequester methane and impede its migration into the atmosphere. The Mallik site in the Mackenzie Delta (MD) is an excellent example of such GH deposits (Dallimore & Collett 2005, Smith & Judge 1995, Judge et al. 1994, Judge & Majorowicz 1992). We examine this hypothesis by modeling terrestrial MD GH thickness variations below an ice-bearing permafrost (IBP) layer in response to past and future surface temperature changes, using a 1D thermal model that assumes no water or gas flow. Past surface forcing uses a detailed Holocene glacial-interglacial history compiled from other sources (Taylor et al. 2005). We also consider the implications of a warmer future based on a doubling of atmospheric CO_2 resulting in a local mean surface temperature increase of 2°C/100 yrs.

Method

Solving the transient heat conduction equation gives the temporally dependent subsurface temperature change in response to surface forcing:

$$C_v \, \partial T/\partial t = \partial[K(\partial T/\partial z)]/\partial z + A \qquad (1)$$

where T is the temperature, K is the thermal conductivity, C_v is the volumetric heat capacity, A is the rate of heat generation per unit volume, z is the depth, and t is the time in a one-dimensional layered geothermal model. We employed a computer code to simulated temporal subsurface temperature changes in response to surface forcing (Safanda et al. 2004). Within the model, Equation 1 is solved numerically by an implicit finite-difference method similar to that described by Galushkin (1997). The upper boundary condition is the temporally varying surface temperature, and the lower boundary condition is a constant heat flow density at 15 km depth. The depth grid steps are: 2, 5, 10, 50, 100, 250, and 500 m deep; model layers are defined between: 0–100, 100–1500, 1500–2000, 2000–2500, 2500–5000, 5000–10,000, and 10,000–15,000 m deep. Time steps vary between 0.5 yr to 50 yr, depending on the amplitude of surface temperature changes.

The finite-difference scheme of Equation 1 on the depth and time grids, together with the upper and lower boundary conditions, leads to a system of difference equations for unknown values T_{k-1}^{n+1}, T_k^{n+1}, T_{k+1}^{n+1} (where the subscript k and the superscript n denote a value at the k-depth step and the n-th time step) within a tri-diagonal matrix, which was solved by the forward method (Peaceman & Rachford 1955).

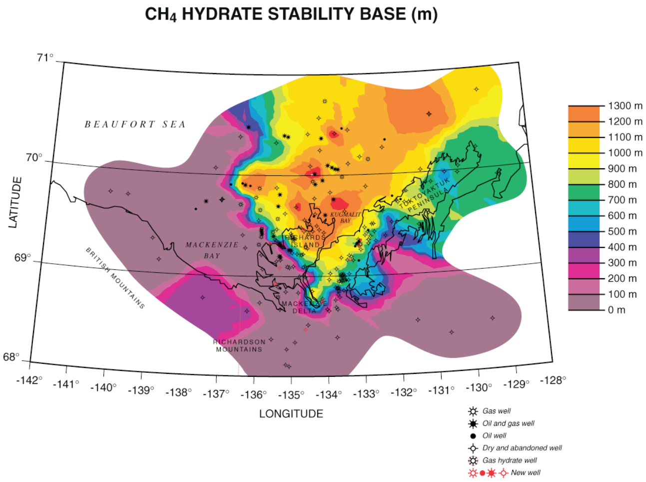

Figure 1. Depth to GH base of Type I stability in the BMB based on the interpretation of measured temperature logs, bottom hole temperature data (Fig. 2) and T-z calculations (modified from Majorowicz and Hannigan 2000) that are constrained additionally by both deep heat flow and base of the IBP. Modelling undertaken here is for northern Richards Island (near centre of figure).

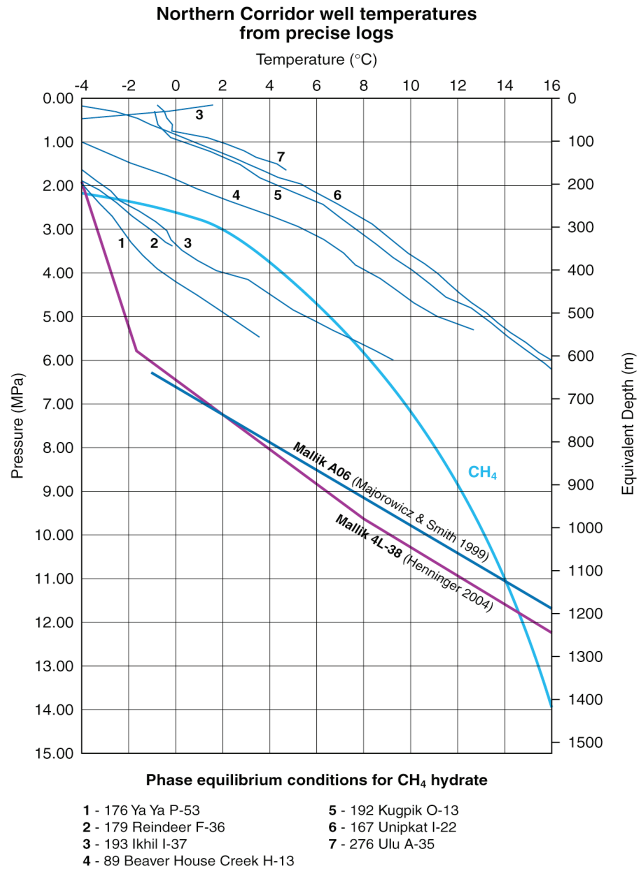

Figure 2. Example of temperature-depth profiles vs. the equilibrium GH stability curve. Examples of precise logs observed in wells years after the end of the drilling disturbance are from Taylor et al. (1982).

To estimate effective thermal conductivity values and volumetric heat capacity, it was necessary to consider the respective geometric and arithmetic averages of the constituent values for the rock matrix, water, ice, and GH in proportion to their volumetric fractions (Galushkin 1997, Nixon 1986). A consumption or release of the latent heat, L, in water/ice (334 kJ.kg^{-1}) and GH (430 kJ.kg^{-1}) accompanying either thawing or freezing was included. The effects of interstitial ice and GH were accounted for using apparent heat capacity (Carslaw & Jaeger 1959), when the volumetric heat capacity is increased in the depth sections of the model where the thawing and freezing occurs; that is, where the temperature is within the thawing range between the temperature of solidus T_S, and liquidus, T_L, at the actual simulation time step.

The liquidus and solidus temperatures of water/ice and GH are depth and hydrostatic pressure dependent (Galushkin 1997) and solidus temperatures were 0.2°C lower than liquidus temperatures. A contribution to the heat capacity from the latent heat = $\rho\Phi L/(T_L\text{-}T_S)$ was considered, where ρ is the density of either ice or GH, and Φ is a fraction of the total volume occupied by these phases. In the IBP zone, we infer the 30% rock matrix porosity to be fully occupied by water at temperatures above T_L, and by ice at temperatures below T_S. Within the GH stability zone, the GH saturation in matrix porosity was inferred to be 60%. For the model to be tractable, the model IBP and GH stability zones are assumed not to overlap, which follows common observation in the study area that GHs are not generally found within the IBP (Dallimore & Collett 2005). The salt concentration 9 g/L was considered constant with depth, and the p-T phase curves were adjusted to this value.

Numerical code performance was tested by comparing model results against the analytical solidification problem solution (Carslaw & Jaeger 1959), where the molten half-space at liquidus temperature, 1300°C, is in contact with a solid half-space at zero temperature and releases the latent heat of 477 kJkg^{-1} in the temperature range 1100°C–1300°C. Comparison of the differences between the numerical and analytical temperature profiles found them to be within about 20°C. If we assume that the magnitude of the difference is proportional to the temperature range, that is, to the contrast at the contact of the molten and solid half-spaces, the error expected for the IBP and GH numerical simulations should be about 100 times smaller (i.e., tenths of a °C) because of the scale of both the temperature range and surface temperature variations that are used in our simulations. A similar error range was estimated by halving the time and/or depth steps.

Our model uses deep heat flow, thermal conductivity, present IBP and Type I GH thicknesses, and a surface melting temperature (-0.576°C) that considers groundwater salinities (9 g/L). It employs latent heat effects throughout the IBP and GH layers, which improves upon previous models (e.g., Taylor et al. 2005). The models are constrained by deep heat flow from bottom hole temperatures in deep wells (Majorowicz et al. 1990) and thermal conductivity, latent heat, present IBP thickness, and present Type I GH thicknesses (Henniges et al. 2005). The models consider the pressure–depth dependence of ice assuming hydrostatic (e.g., Lachenbruch et al. 1982) and GH thawing points over

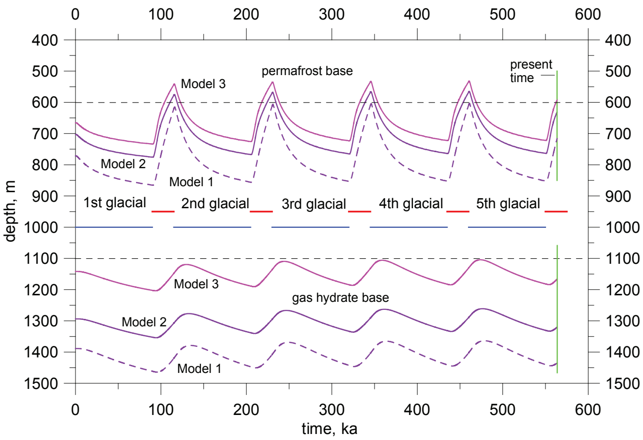

Figure 3. Simple test results of glacial-interglacial surface forcing upon permafrost and GH (Models 1–3 are described in the text). (Time scale shown is 600 ka. Dotted lines show the present base of permafrost and GH. Glacial-interglacial timing and temperature magnitudes are based on Muller & MacDonald (2000) and Taylor et al. (2005).

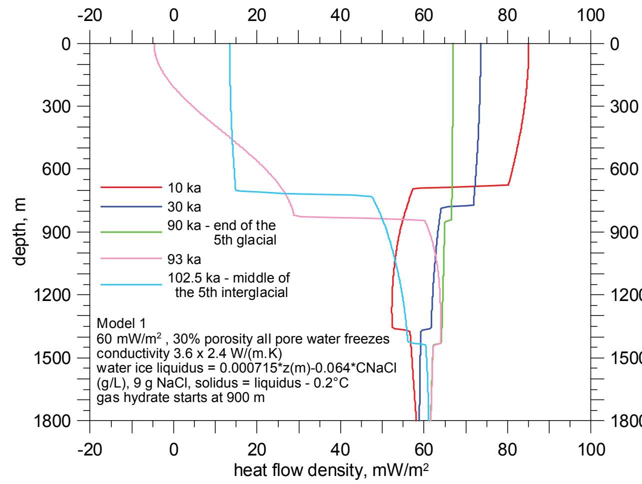

Figure 4. The heat flow and depth profiles for different phases of the glacial cycle for Model 1.

the entire expected extent of the IBP and GH layers (Sloan 1998). Previously published models have considered only a thin layer using a constant dissociation temperature (Taylor et al. 2005).

Current Gas Hydrate Stability Zone

The GH stability zone is currently widespread both in the onshore and offshore BMB, especially to the east of Mackenzie Bay (Fig. 1). There the GH stability zone base reaches 1.5 km deep, where the IBP is thick and the heat flow is low (Figs. 1, 2).

Modeling Results

We have simulated the downward propagation of the surface warming and cooling attending the cyclical glacial and interglacial models for a Richards Island location (Fig. 1). The dependence of the thermal conductivity on water/ice content and the specific heat of the rock section on the porosity and the proportion of interstitial water and ice are important. Accounting for the effect of the latent heat necessary to thaw the interstitial ice in the IBP layer is crucial for matching observations at realistic time rates. In the absence of this heat sink provided by thawing ice in the IBP, the subsurface warming would proceed much faster.

Models of the past history of permafrost and GH layers

Individual computational models use the characteristics of IBP and GH formation and dissipation as functions of temperature history, constrained by present temperature observations and current IBP and GH layer thicknesses. The surface climate history for the end of the Wisconsinan and Holocene is after Fig. 3b in Taylor et al. (2005); Pleistocene surface history of glacials and interglacials is after Muller and MacDonald (2000). Forward modeling of the past history for the IBP and GH layers on Richard's Island in the vicinity of the Mallik well (Dallimore et al. 1999, Dallimore & Collett 2005) can be calibrated against present-day observed IBP and GH zones, which have bases at about 600 m and about 1100 m, respectively.

The numerical solution of the transient heat conduction equation (eq. 1) was applied to model time vs. temperature, depth, IBP characteristics using latent heat effects (Galushkin 1997). This new model employs the pressure–depth dependence of ice and GH thawing points and considers latent heat effects in subsurface heat transport modeling and their impact on paleo-temperature reconstructions across the entire GH layer and not just its boundaries. All models account for latent heat by means of the apparent specific heat, which is a standard treatment. The model also considers diffusive heat flow related to surface-subsurface coupling.

Figure 3 shows three models of the surface temperature forcing effect on IBP and GHs, which currently have observed bases at about 600 m and about 1160–1170 m, respectively:

Model 1 is a simple test of glacial-interglacial forcing upon IBP and GH layers, where the GH zone is constrained to be 900 m deep or deeper. Results show that the model base of IBP and GH is much deeper than the currently observed values, despite a high heat flow value of 60 mW/m^2 (Majorowicz et al. 1990, Henniges et al. 2005). We infer that the frozen IBP conductivity, 3.6 W/(m.K), is lower than that used in this model, which is based on a measured GH layer conductivity of 2.4 W/(m.K), where the pore space of 30% is filled with water and adjusted using the geometric mean to the pore space filled with water ice. We considered glacial-interglacial cycle lengths of 115 ka, of which 90 ka are glacial and 25 ka are interglacial. The present day is 13.5 ka after the last glacial interval. In Model 1, the mean temperature during glacial intervals was -17°C (Allen et al. 1988) and the mean temperature during interglacials was -4°C, which is slightly higher than the present -6.5°C at the Mallik site.

Model 2, like Model 1, considers the climatic history proposed by Taylor et al. (2005, Fig. 3b). We note that in

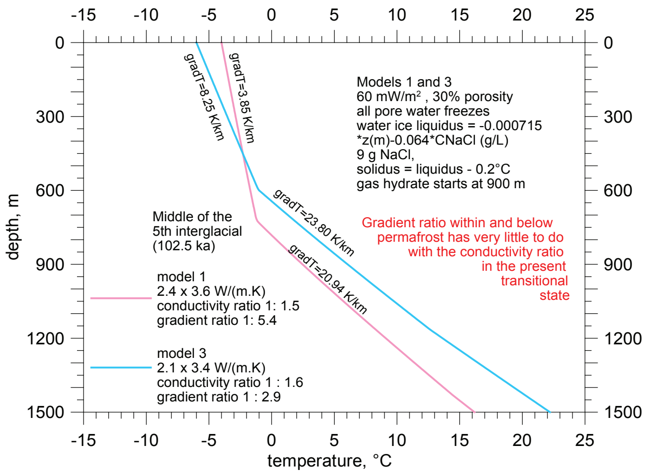

Figure 5. Thermal gradient for the frozen-unfrozen system vs. thermal conductivity ratio (Models 1 vs. 3).

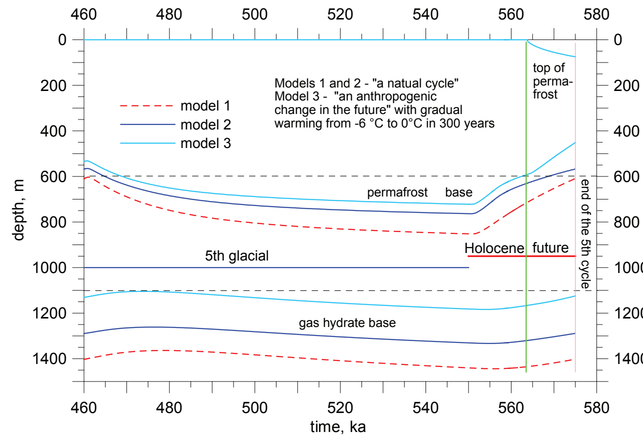

Figure 6. Consequences of the global climate change model that considers 6°C gradual warming projected 300 years into the future. Present time is marked by a green line.

Model 2 the base of both the IBP and the GH layers occurs ~100 m shallower than that calculated by Model 1, mainly due to higher average temperatures during glacial intervals (-15°C, rather than -17°C). In Model 2 the predicted current base of IBP, 13.5 ka after the onset of Holocene warming, is 657 m (-1.04°C) while the base of the GH layer is 1262 m (13.45°C), both of which are slightly too deep for observed values (Fig. 3).

Model 3 is a model that employs a surface warming like that of Model 2. However, Model 3 employs a frozen-thawed conductivity varying from 3.4 (frozen) to 2.1 (unfrozen) W/(m·K) compared with 3.6 (frozen) to 2.4 (unfrozen) W/(m·K) used in Models 1 and 2. This results in an appreciable improvement of the fit to observations. Figure 7 illustrates the position of the current base of the IBP. The calculated present base of IBP is very close to the observed depth of 600 m and the GH layer base is at ~1.17 km (Fig. 3).

All the models indicate generally similar thickness variations of the IBP and GH layers during glacial-interglacial cycles. Both the IBP and GH layers increase in thickness during glacial intervals and decrease in thickness during interglacial intervals. For Model 3 these variations are about 190 m for the IBP and about 80–90 m for the GH layer.

Model 2 predicts that the base of both IBP and GH layers are 100 m higher than those predicted in Model 1, mainly due to a higher average temperature mainly due to assumed warmer glacial, -15°C instead of -17°C. Yet, the predicted current IBP and GH layer bases were still slightly deeper than observed values. Model 3 improves the fit between the observed and predicted current IBP and GH layer characteristics as a result of changes to the frozen-thawed conductivities resulting in an appreciably improved fit to observed values. Today, 13.5 ka after the end of the last glacial interval, Model 3 predictions are very close to the observed IBP base (600 m) while the predicted current base of the GH layer is just slightly deeper (1160–1170 m) than the observed depth (1100 m).

Models of IBP and GH layer characteristics that are based on historical surface temperature forcing are both robust and informative. The predicted heat flow-depth profiles for Model 1 (Fig. 4) illustrate the different phases of the glacial cycle (Fig. 3, Model 1). For example, at 10 ka after the onset of the glacial interval, the base of the IBP, at 700 m, is moving downward, with an attendant heat release, while simultaneously the base of the GH, at 1350 m, is moving upward and consuming heat. The thermal inertia impact on sub-permafrost GH layer thinning is delayed and responsive to surface forcing, rather than leading and causative, due to the buffering effect of the overlying permafrost layer.

Models indicate that heat flow at depths above 1.5 km is in a transient state. Heat flow below that depth is stable, within the measurement error. The simple glacial-interglacial model also indicates that the ratio of temperature gradients within and below the IBP has very little to do with the conductivity ratio of the permafrost and sub-permafrost layers, such that even current temperature profiles are transient. Models with an unfrozen-frozen conductivity ratio = 2.4/3.6 W/(m.K), and models with an unfrozen-frozen conductivity ratio = 2.1/3.4 W/(m.K) give very similar conductivity ratios 1:1.5 and 1:1.6, but are characterized by dramatically different thermal gradient ratios: 1:5.4 and 1:2.9 (Fig. 5).

Below the buffering effects of the IBP the estimated conductivity, K, in the GH zone (Wright et al. 2005; Henninges et al. 2005) is based on both temperature gradients from a precise temperature profile (Henninges et al. 2005) and the deep heat flow, Q = 60 mW/m² (Majorowicz & Smith 1999). The estimates employ the equation:

$$Q/GradT=K \tag{2}$$

This is a correct assumption for steady state situations only, such as non-ice bearing permafrost areas with constant surface *T*. The resulting conductivity estimates are correct below the IBP, within the heat flow measurement error of 10%–15%, (Fig. 4).

The impact of future warming

Surface temperature will change dramatically accompanying the projected doubling of atmospheric CO_2

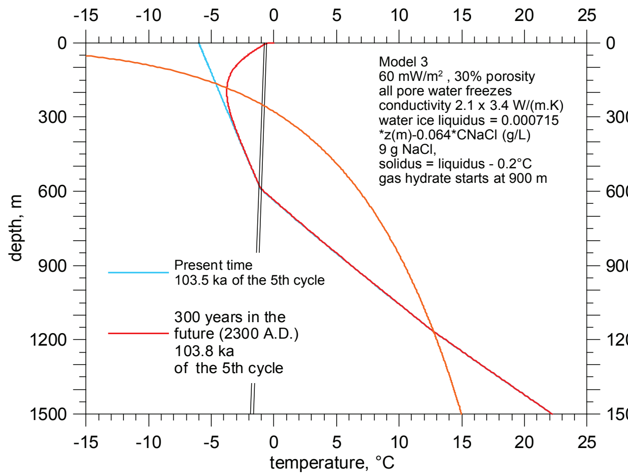

Figure 7. T-z profile corresponding to the expected future warming since present warming by a rate of 2°C/century from -6°C to 0°C.

resulting in future climate warming during the next 300 years. We predict the consequences of such a mean surface temperature change, from -6°C to 0°C, considering past history followed by gradual warming, at a rate of 2°C per century. The future predictions are shown in Figures 6 and 7. Hypothesizing a time corresponding to the "natural" end of this interglacial about 11.5 ka in the future, the model predicts that the IBP will have thawed by ~150 m from below and 70–80 m from the surface. The predicted accompanying GH layer thinning is very small and within the range of previous natural cycle variations (Fig. 3), in spite of the accelerated surface warming accompanying climate change.

Conclusions

Model results that consider latent heat effects of water/ice and GH formation and dissipation show that:

1. Historical and future surface temperature forcing implications for both IBP and GHs can be modeled successfully using available Pleistocene glacial-interglacial and Holocene surface temperature histories. Model GH layer thickness generally increases during colder intervals (i.e., glacial) and decreases during warmer intervals (i.e., interglacial). For Model 3, which most closely resembles observed values, these variations are ~190 m for the IBP and about 80–90 m for the GH layer. Where the IBP layer is thick it is unlikely that sub-permafrost GHs disappeared entirely during previous interglacial intervals, nor are they expected to disappear prior to the "natural" end of the current interglacial. In regions of thick terrestrial permafrost like the Mackenzie Delta, GH layers can act as a persistent sink for and barrier to the migration of methane.

2. Models that consider the consequences of current climate warming trends indicate that, when the current interglacial interval ends "naturally" ~11.5 ka from now, the study area IBP will have thawed ~150 m from below and 70–80 m from the top. The attending GH disassociation inferred is very small and comparable to that of model natural variations accompanying preceding glacial-interglacial cycles.

3. Temperature gradient ratios within the IBP are not strongly dependent on the conductivity ratio between permafrost and sub-permafrost layers, as the current temperature profile is a transient one. A model with an unfrozen-frozen conductivity of 2.4–3.6 W/(m.K) and a model with an unfrozen-frozen conductivity ratio 2.1–3.4 W/(m.K) result in very similar conductivity ratios, 1:1.5 and 1:1.6, but these two alternatives have dramatically different thermal gradient ratios of 1:5.4 and 1:2.9, respectively.

4. The hypothesis that links sudden glacial terminations to major methane emissions from large, rapid GH destabilization events (Nisbet 1990, 2002, Kennett et al. 2003) presumes that GHs destabilize rapidly in response to environmental change late in glacial intervals, and that they serve at other times as a sink for and barrier to the migration of methane into the atmosphere. This hypothesis applies mainly to marine GHs, which may be more easily destabilized than are the terrestrial sub-permafrost GHs we modeled.

Our study shows that terrestrial GHs below thick IBP vary in thickness in response to surface temperature history changes, but that terrestrial thermal inertia conserves both IBP and sub-permafrost GHs delaying and reducing methane release. Terrestrial thermal inertia also imposes a phase-delay between surface temperature warming and the subsequent onset of GH dissociation, making it unlikely that terrestrial GHs below thick permafrost could rapidly reinforce climate warming events, consistent with the hypothesis. The implications of latent heat effects and thermal inertia for submarine gas hydrates remain to be determined; however, our model results appear consistent with recent observations of methane isotopic compositions from ice cores (Sowers et al. 2006).

The Last Twenty-Five Years of Changes in Permafrost Temperature in the European Russian Arctic

G.V. Malkova
Earth Cryosphere Institute, Russian Academy of Sciences, Moscow, Russia

Abstract

The 24-year-long permafrost temperature records from the long-term permafrost monitoring station Bolvansky are presented in this paper and analyzed in relation to climatic changes. The results of this analysis show that changes in mean annual ground temperatures generally follow the mean annual air temperatures. The warming trend in the air temperatures for the entire period of measurement at this site is 0.04°C/yr. Observed trends in mean annual permafrost temperatures vary from 0.003°C/yr to 0.02°C/yr in different natural landscapes. The warming trend in permafrost temperature for the entire period of measurement in anthropogenic landscapes is 0.04°C/year. A weak negative trend is observed in thawed boreholes (-0.012°C/year). For the last 10 years, an increase in climatic variability and an interchange of extremely cold and extremely warm years were observed, that led at first to a considerable increase in permafrost temperature. In 2007, a weak decrease in temperature was observed in most of the monitored boreholes.

Keywords: air temperature; climate change; permafrost temperature; thermal monitoring; trend.

Introduction

The geocryological observations show a general increase in permafrost temperatures during the last several decades in Alaska (Clow & Urban 2003, Osterkamp & Romanovsky 1999, Osterkamp 2003, Romanovsky 2006, Romanovsky et al. 2002) and northwest Canada (Smith et al. 2005, Burgess & Smith 2003). At some locations near the southern boundary of permafrost in Alaska, this warming has already resulted in permafrost thawing from the top down (Jorgenson et al. 2001, Osterkamp et al. 2000).

The cryolithozone of the European part of Russia extends predominantly just north of the Arctic Circle. Permafrost in this region is well studied. During the 1970s and 1980s, due to oil and gas field exploration and development, many drilling and geophysical surveys were carried out in the European North. State engineering-geological mapping (1:200,000 scale) was also accomplished. These activities provided important information on permafrost extent, thickness, and temperature regime. In order to investigate in detail the geocryological conditions of this region, several long-term permafrost-monitoring stations were established, in both natural settings and in settings disturbed by human activities. During the 1980s, there were 14 geocryological long-term monitoring stations where the ground temperature was measured in several dozens of boreholes. During the last ten years, the development of oil and gas fields in the European North has progressed rapidly. The building of oil-shipping terminals was accomplished in the coastal zone of the Barents Sea and Pechora Bay (Varandey et al.). With all these developments, current data on changes in geocryological conditions have turned out to be insufficient. Today, regular temperature measurements in boreholes are carried out only at Vorkutinsky and Bolvansky long-term monitoring stations. In 2006 and 2007, after an 11-year time gap, permafrost temperature measurements were conducted successfully in several reference boreholes at two more former long-term monitoring stations, Rogovoy and Korotaikha. Results of these geocryological studies are cited in the scientific literature (Kakunov & Sulimova 2005, Kakunov et al. 2006, Oberman 1998, 2001, 2006, 2007, Malkova 2005, 2006, 2007, Mazhitova et al. 2004, Oberman & Mazhitova 2001). The locations of the active stations are shown in Figure 1.

According to the mentioned publications by Kakunov and Oberman, the considerable increase in mean annual permafrost temperatures during the last two to three decades is typical for southern regions of the permafrost in the Russian European North (Vorkutinsky, Rogovoy and Korotaikha stations). This increase resulted in partial permafrost thawing, from the top down, and in a reduction in size of permafrost islands in the sporadic permafrost zone. New closed taliks appeared in the areas of high-temperature permafrost; the thickness of the existing closed taliks has increased. In areas directly affected by the human activity, the increase of permafrost temperature at the depth of zero annual amplitude varied from 0.2°C to 1.6°C during the period of observation. Fewer changes in permafrost were observed at the Arctic coast of the Barents Sea where the Bolvansky long-term observation station is situated on undisturbed landscape. In this paper the changes in permafrost that have occurred at the Bolvansky monitoring station during the last 25 years and their relation to observed climatic changes will be examined.

Methods of Measurements

The long-term permafrost monitoring station, Bolvansky, was established in 1983 at the location of the Bolvansky Cape weather station which has existed since 1935 (Fig. 1). Within the region (total area of 10 km²) twenty-five 12–15 m deep and 65–87 mm diameter boreholes were drilled in various landscape conditions. Each borehole was equipped

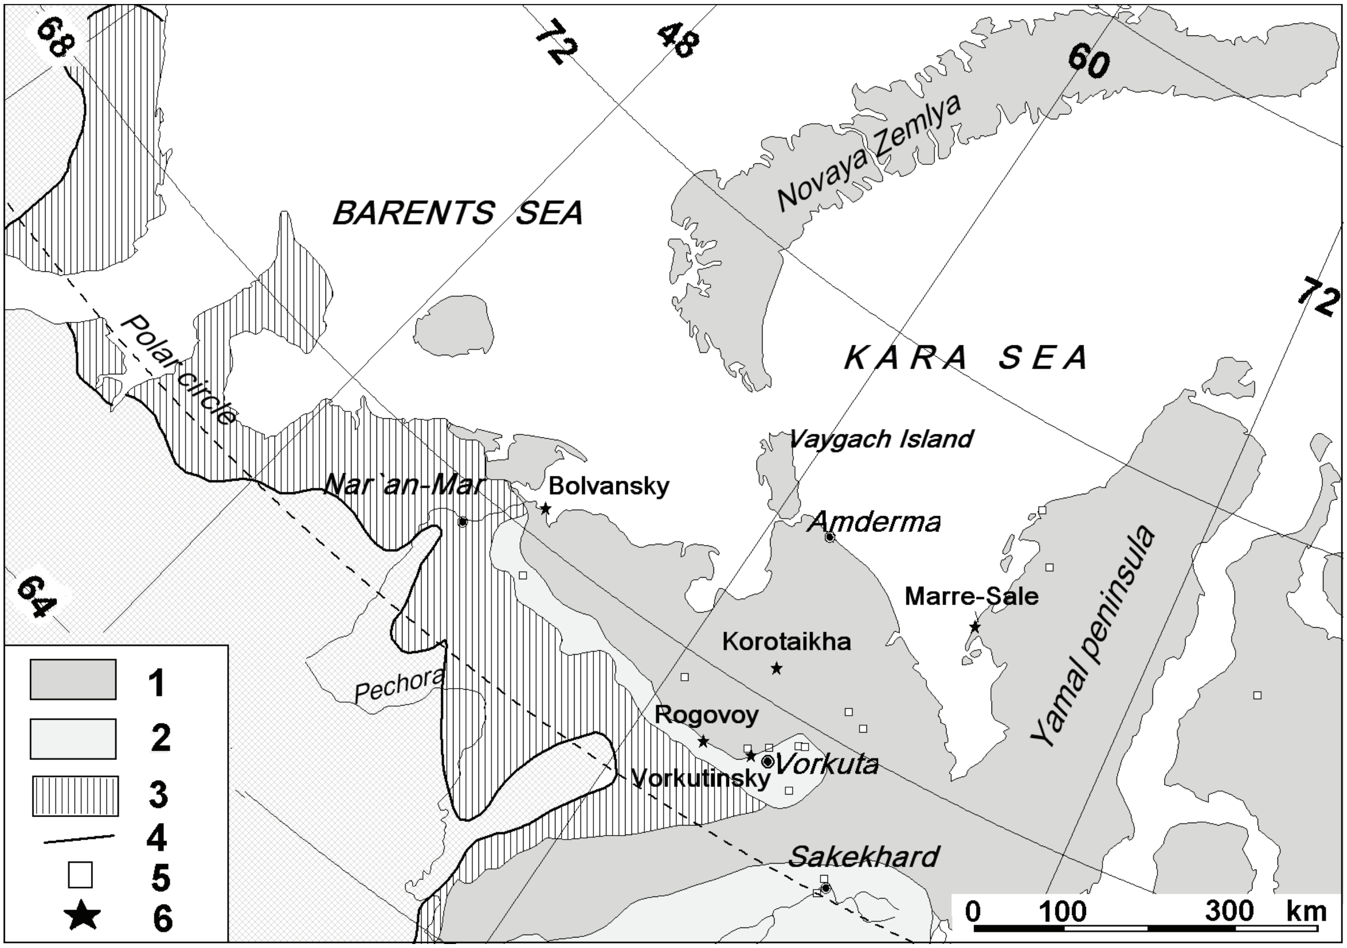

Figure 1. Location of long-term permafrost monitoring stations and permafrost spatial continuity in the European Russian Arctic: 1 – continuous permafrost, 2 – discontinuous permafrost, 3 – sporadic permafrost, 4 - southern boundary of permafrost distribution, 5 – closed permafrost monitoring stations, 6 – stations still in operation.

with steel casing to the depth of 3–5 meters, and was closed with a metal cap. A wooden box filled with sawdust was built around the aboveground portion of the casing to provide thermal insulation. Temperature measurements were taken three times a month using a string of mercury thermometers. The thermometers were located at depths of 1–6, 8, 10, 12, and 15 m. From 1983 until 1993, year-round studies were performed at this station. After 1993, observation sites and boreholes were abandoned for technical and organizational reasons. The results of the first ten years of geocryological study were archived as survey reports at the Russian Geological Data Center and have never been published in scientific literature.

In 1999, after a six-year break in measurements, 10 boreholes again were prepared for temperature measurements. Until 2005, ground temperature measurements were conducted there once a year at the end of the summer. LPC data loggers and strings of sensors in rubber cable were used in these measurements. The sensors were positioned at the same depths as in the previous period of measurements. Besides temperature measurements in boreholes, annual observations of temperature in the active layer have been carried out at the Circumpolar Active Layer Monitoring (CALM) project site. Soil temperatures are obtained with thermistor sensors inserted in the ground at various depths in the active layer and near-surface permafrost. The active layer depth at this site varies from 1–1.2 m. Therefore, the sensors in the active layer are installed at depths of 0.05, 0.25, 0.5, 0.75, 1, and 1.25 m. Readings are recorded at a regular time interval by battery-operated multi-channel data loggers (Brown et al. 2000).

In 2006, with technical support from the international project TSP, 4-channel automated HOBO U12 sets were installed in four key boreholes situated in various landscape conditions. Temperature is recorded automatically 4 times year-round. The first collection of data from the equipped boreholes was carried out at the end of summer 2007. At the same time four more HOBO U12 sets were installed in additional boreholes. Since 2007, all measurements are carried out every 6 hours; that is, four times a day. The sensors in the boreholes are installed at depths of 1 (or 3 m), 5, 7, and 10 m. This has permitted monitoring of permafrost temperature dynamics both in time and depth at each borehole. Through the entire time of measurements, we used three different types of thermometers. However, the error associated with the instrumentation was insignificant (<0.1°C) and corrections to the data were made accordingly.

The obtained information was processed in accordance with

Table 1. Mean annual permafrost temperature at the Bolvansky long-term monitoring station.

Borehole #	Landscape characteristics	Range of interannual fluctuations of the mean annual permafrost temperature, °C	Fluctuation amplitude, °C	Standard deviation	Long-term trend, °C /year (see Figure 2)
51	Edge of a drained lake, tundra	-1.0…-1.4	0.4	0.13	0.013
53	Gentle ridge, tundra	-1.7…-2.1	0.4	0.12	0.003
54	Gentle ridge, tundra	-1.8…-2.4	0.6	0.17	0.009
55	Edge of a ravine, tundra	-1.3…-1.9	0.6	0.21	0.015
56	Upper reaches of a ravine, peatland	-0.5…-0.8	0.3	0.10	0.011
59	Apex of a gentle ridge, tundra	-1.6…-2.3	0.7	0.21	0.023
60	Apex of a gentle ridge, disturbed tundra	-1.4…-2.4	1.0	0.36	0.040
61	Bottom of a drained lake, bog	+0.3…+0.8	0.5	0.17	-0.012
65	Gentle hillslope, tundra	-1.2…-1.7	0.5	0.15	0.011
83	Apex of a gentle ridge, tundra	-2.1…-2.5	0.4	0.17	0.007

prescribed protocol. Daily mean, monthly mean and mean annual ground temperatures were calculated. Calculation of trends and the regression equations were performed using the Microsoft Excel program. Climate data from the main weather stations (Nar'an-Mar, Vorkuta, Amderma, Fig. 1) of the European North were collected from the meteorological Internet site (http://meteo.infospace.ru/wcarch/html/r_index.sht) and processed similarly.

General Characteristics of the Research Region

The long-term permafrost monitoring station, Bolvansky, (68°17.3′N, 54°30.0′E) is located at the Pechora River Delta, on the northernmost extremity of Bolvansky Cape, which juts out into Pechora Bay (Barents Sea basin). The Bolvansky Cape weather station operated from 1935 to 1998. Long-term mean annual air temperature is -4.4°C, and precipitation is 404 mm. The area is represented by undulating marine plain with numerous lake depressions and large flat-bottomed valleys, some with permanent creeks. Elevations range from 20 to 35 m a.s.l. Quaternary deposit, a boulder sandy loam, is more than 100 m thick. Polygonal peatlands and fens with peat thickness ranging from 0.5–5 m occupy the inter-hill areas and depressions. The area is geocryologically unstable due to its location at the western extremity of the continuous permafrost zone in Europe and the near proximity of the discontinuous and sporadic permafrost zones. Permafrost exists just below the active layer under elevated and flat surfaces, whereas a deep position of the permafrost table is typical for valley bottoms, both dry and with flowing water. Open taliks occur under the Pechora valley, under Pechorskaya and Bolvanskaya Bays, and under many lakes (Mazhitova et al. 2004). The thickness of permafrost in this area is 100 to 200 m (Oberman & Mazhitova 2001).

The mean annual permafrost temperature at 10–12 m depth depends on landscape conditions and varies from -0.5°C to -2.5°C (according to measurements in 25 boreholes). In elevated areas and on hilltops the permafrost temperature varies between -2.0°C and -2.5°C. Within polygonal peatlands, on the slopes, and in the cols of hills with tundra vegetation the permafrost temperature varies from -1.5°C to -2.0°C. For the edges of lakes and terraces and also for the headstreams of small creeks, typical permafrost temperatures are in the range of -0.6°C to -1.4°C. On the bottoms of ravines and lakes, the permafrost surface is lowered in the depth from several meters to dozens of meters, and temperature of the thawed ground at the depth of 10 m is from +0.3°C to +1.0°C. The range of permafrost temperatures observed during the research period from 1983 to 2007 in presently operational boreholes are shown in Table 1 and Figure 2.

The mean annual air temperature in Bolvansky Cape according to the data from the weather station (until 1998) and from our data loggers (1999–2007) is shown in Figure 3. During the last decades, the two coldest periods, from 1985–1987 and from 1997–1999, are easily noticeable. Since the mid-1980s, two periods of warming were observed. The first one was from the mid-1980s to the mid-1990s and the second one in 2000–2005. According to the data from the Institute of Global Climate and Ecology (Rosgidromet and RAS), a general gradual increase of precipitation (5%–10% per 10 years) was observed. The years with maximum amount of precipitation (including snow) were 1990–1991, 1995–1996, and 2001–2002. The maximum snowfall occurred in 1981–1982 (snow accumulation was about 380 mm). The winters of 1985–1986, 1994–1995, and 2000–2001 had little snow accumulation (about 150 mm).

Results and Discussion

During the period between 1984 and 2007, a weak positive trend in the mean annual permafrost temperatures

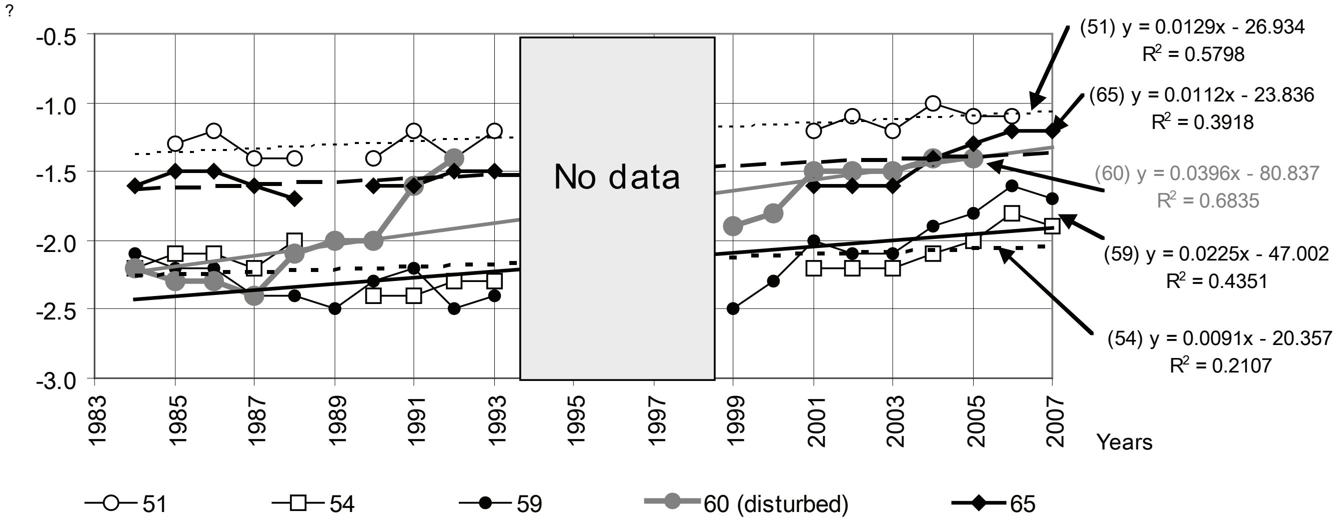

Figure 2. Mean annual permafrost temperatures and the long-term trends (from 1983 to 2007) in their variations measured in boreholes 51, 54, 59, 60, and 65 at the depth of 10 m.

(from 0.003°C/year to 0.02°C/year in the various landscape conditions) has been observed. During the same period, the trend of air temperature change of 0.04°C/year was much more pronounced (Fig. 3). An undoubted synchronism in soil and air temperature changes has been typical for all boreholes. During this period, the standard deviation of permafrost temperature interannual variability in the undisturbed landscapes has varied in rather narrow limits from 0.10 to 0.21. The standard deviation for disturbed conditions was 0.36.

During the last 8 years, the permafrost temperature has undergone especially considerable changes due to the greater interannual variations in the mean annual air temperature. Subsequent to anomalously severe 1998, we observed a noticeable decrease of the permafrost temperature in 1999. On the contrary, a warm 2000 as well as 2005 caused the increase in mean annual ground temperature in 2001 and its substantial increase in 2006. After relatively cold 2006 (the mean annual air temperature decreased by 2°C) some decrease (by 0.1°C to 0.2°C) of the permafrost temperature was observed in the boreholes at the end of the warm season.

Borehole #59 is the key for this long-term monitoring station. It is situated on the top of a gentle ridge in landscape conditions typical for this region. A CALM site where active layer monitoring is also performed is co-located with this borehole. The most complete set of observations of natural parameters is available for this borehole location. Besides the permafrost temperature measurements in the borehole (down to 10 m to 15 m in different years), the year-round active layer temperature data (with some gaps) and the maximum thawing depth are available for this location.

Figure 3 shows the mean annual air temperature variations at the Bolvansky station and the active layer and permafrost temperatures during the period of instrument measurements in the boreholes. During the last 10 years, the mean annual air temperature has undergone the greatest changes. The absolute minimum of the mean annual air temperature (-9.1°C) during the entire period of measurements started in 1935 was observed in 1998. Only 3 months in 1998 posted monthly mean temperatures above 0°C. At the same time, 2005 was the warmest on record with the mean annual temperature at -0.8°C. The duration of the period with positive monthly air temperatures was 6 months during that year.

The mean annual active layer temperature at a depth of 1.2 m ranged from -3.5°C to -0.5°C or 1°C to 2°C higher than the air temperature (due to the combination of a warming effect of snow and a negative thermal offset in the active layer). In general, the active layer temperature changes followed the changes in the air temperature, though within a smaller range. Especially significant decrease in the active layer temperatures was observed in the years with the low-snow winters. More frequently, the active layer temperatures ranged between -2°C and -3°C. As evident from Figure 3, the mean annual active layer temperature recently has a tendency towards increase. Since 2005, the active layer temperature has been increasing, staying in the range between -1°C and -2°C. In order to switch from seasonal thawing to seasonal freezing, the mean annual temperature at the bottom of the active layer is required to rise above 0°C. However, our data show that, up to the present day, the state of permafrost in the research region within each landscape type has been rather stable.

During the period of observations, the variations in the mean annual permafrost temperature in the Borehole 59 at the depth of zero amplitude have been relatively small. A decrease in ground temperature by 0.1°C or 0.2°C usually happens one or two years after a decrease in mean annual air temperature. The lowest permafrost temperature (-2.4°C) was observed in 1999 after a period of climatic cooling. Then, the permafrost temperature began to increase persistently following an increase in air temperature. However, the warming trend in the permafrost temperature was considerably smaller than the trend in the air temperature.

Borehole #60 was drilled on the same gentle ridge where the CALM site is situated, 100 m away from Borehole #59.

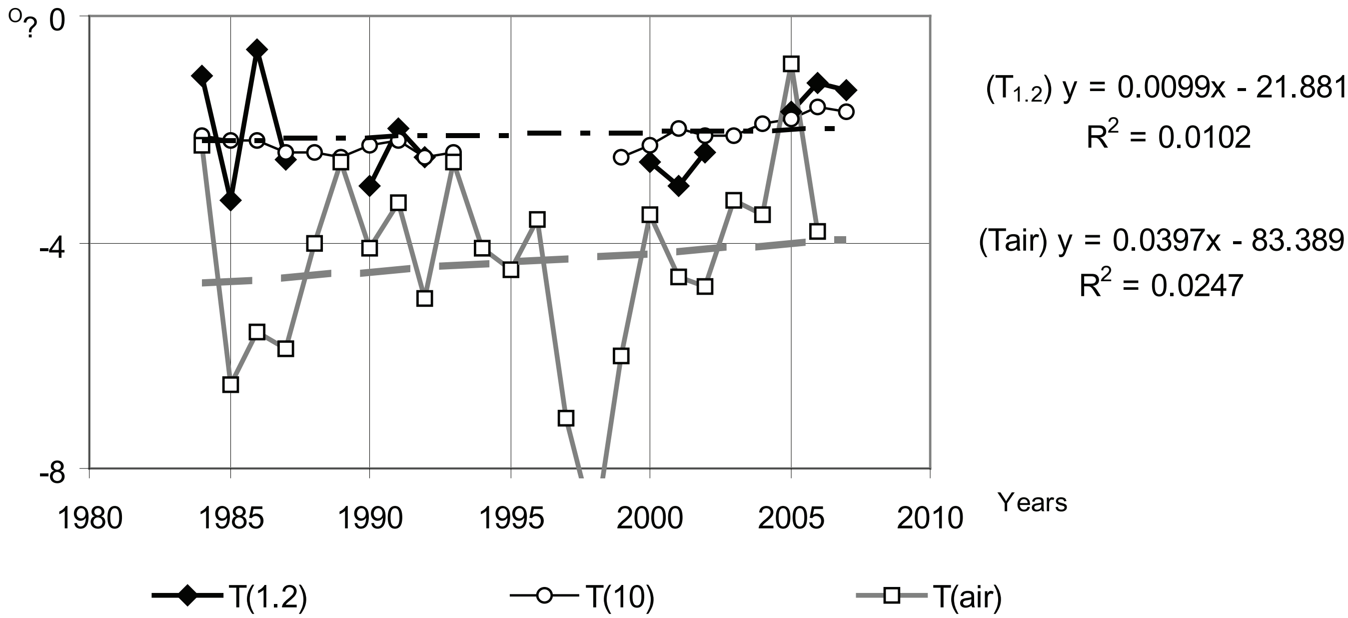

Figure 3. Mean annual temperatures of air, active layer (at the depth 1.2 m) and permafrost (at the depth 10 m) at the Bolvansky geocryological station, Borehole # 59. Grey dashed line is a linear trend of average annual air temperature.

This site was intentionally disturbed by removal of vegetation and organic soil layer. Figure 2 shows that during the first several years after the disturbance, after a small delay, a sharp increase in the mean annual ground temperature by 1°C occurred. During the first 15 years, a partial re-vegetation occurred at this site and, as a result, a decrease of permafrost temperature took place, by 1999–2000, but not to the initial values. The thickness of the snow cover did not change significantly at this disturbed site as compared with the undisturbed sites. In summer time, the amount of absorbed radiation was enlarged due to the stripping of the heat-insulating layers (vegetation and organic soil horizon). It resulted in the warming of the permafrost upper horizons. As the disturbed site gradually, naturally re-vegetated, a progressive decrease in mean annual permafrost temperature began (during 1992–1999 permafrost temperature at the depth of 10 m decreased from -1.4°C to -1.9°C) despite the observed increase in mean annual air temperature during this period (Pavlov & Malkova 2005, Malkova-Ananieva 2005). Further increase of the mean annual air temperature in 2000, 2003, and especially in 2005 again resulted in further ground warming by 0.3°C. According to our observations, the average long-term positive trend in permafrost temperature in the disturbed conditions was the largest for this long-term monitoring station and was equal to 0.04°C/year (Table 1).

Unfortunately, during the anomalously warm season of 2005, the thawing depth increased significantly within the limits of the disturbed site and Borehole #60 was filled with water and froze through the entire depth. Further temperature measurements are impossible.

Perennial observations of ground temperature in the thawed borehole situated in a drained lake basin (Borehole #61) have demonstrated a rather high long-term variability of ground temperature at the depth of 10–12 m (0.5°C) and a slightly negative temperature trend (-0.012°C/year). So, even under conditions of contemporary increase in mean annual air temperature, conditions for some decrease of ground temperature can be created at the bottom of drained lakes. Most likely, this is the result of changes in hydrological regime of the bog situated within the drying/drained lake bottoms. Namely, the lowering of the water level, due to the development of the erosion network, may explain these observations.

Conclusions

Conducted studies have demonstrated that the state of continuous permafrost of the coastal areas of the European North is still stable under the conditions of the recent increase in mean annual air temperature.

The permafrost temperature is a sensitive indicator of climatic changes, but the amplitudes of its variations were in a range between 0.3°C and 0.6°C, whereas the mean annual air temperature varied within 5°C during the same time period. Temperature changes at a depth of 10 m were observed in one or two years after the air temperature change.

The trends in the mean annual permafrost temperature increase are 2 to 10 times smaller than the trends of the increase in mean annual air temperature in various landscape conditions. For a significant change in the permafrost temperature regime, a combination of climate warming and surface disturbances is required.

The active layer temperature is determined both by the air temperature and by the snow cover thickness affecting the winter cooling rate under tundra conditions. The occurred climatic changes are not yet enough for the long-term thawing of the permafrost and for the transformation of the seasonally thawing layer into seasonally freezing layer in the studied area, which is located within the continuous permafrost zone.

Abstract

The Geophysical Institute Permafrost Laboratory model (GIPL) simulates soil temperature dynamics and the depth of seasonal freezing and thawing by solving 1D non-linear heat equations with phase change numerically. In this model the process of soil freezing/thawing is occurring in accordance with the unfrozen water content curve and soil thermal properties, which are specific for each soil layer and for each geographical location. At the present stage of development, the GIPL 2.0 model is combined with ArcGIS to facilitate preparation of input parameters and visualization of simulated results in the form of digital maps. The future climate scenario was derived from the Massachusetts Institute of Technology MIT-2D climate model output for the 21st century. This climate scenario was used as a driving force in the GIPL model. Initial results of calculations show that by the end of the current century widespread permafrost degradation could begin everywhere in Alaska southward from the Brooks Range.

Keywords: active layer thickness; ground temperature; numerical modeling; thawing permafrost.

Introduction

Many components of the cryosphere, particularly sea ice, glaciers, and permafrost, react sensitively to climate change. Climatic changes and changes in permafrost were reported recently from many regions of the Northern Hemisphere (Jin et al. 2000, Oberman & Mazhitova 2001, Harris & Haeberli 2003, Sharkhuu 2003, Romanovsky et al. 2002, Marchenko et al. 2007). Significant changes in permafrost temperatures were observed in Alaska. Ground temperature data from Alaska available for the last 30 years demonstrate an increase in permafrost temperatures by 0.5°C–3°C (Osterkamp & Romanovsky 1999, Osterkamp 2005). Recent observations show that the warming of permafrost has continued into the 21st century in Alaska (Clow & Urban 2002, Romanovsky et al. 2002, Romanovsky et al. 2003). While the increase in permafrost temperature may change many of its physical properties, the major threshold occurs when permafrost starts to thaw from its top down. The thawing and freezing of soils in arctic and sub-arctic regions is affected by many factors, with air temperature, vegetation, snow accumulation, and soil moisture among the most significant. To investigate how observed and projected changes in these factors influence permafrost dynamics in Alaska, we developed a numerical Geophysical Institute Permafrost Laboratory (GIPL) model. In this paper we will first describe this model. Then we will show how this model should be calibrated and validated before being used for projections of future changes in permafrost as a result of changes in climatic and other environmental conditions. After validation, the model was used to develop one possible scenario of the permafrost dynamics in Alaska during the current century.

Previous spatial modeling of permafrost

Recently, there have been a number of experiments to simulate soil temperature and permafrost dynamics on regional and global scales (Anisimov & Nelson 1997, Stendel & Christensen 2002, Sazonova & Romanovsky 2003, Oelke & Zhang 2004, Lawrence & Slater 2005, Zhang et al. 2006, Saito et al. 2007). There are two major approaches to spatial modeling of permafrost. One of them is to include a permafrost module directly into GCM. The second one employs the use of stand-alone equilibrium or transient permafrost models. These models are forced by the climatic outputs produced by GCMs. There were a few examples of simulations and forecasts of permafrost dynamics using coupled global climate models (Stendel & Christensen 2002, Lawrence & Slater 2005, Nicolsky et al. 2007, Saito et al. 2007), but some of the modeled results generated a significant controversy (Burn & Nelson 2006, Delisle 2007). The simplified treatment of subsurface thermal processes and problematic settings of the soil properties and lower boundary conditions precluded proper representation of the future permafrost dynamics in these GCMs (Burn & Nelson 2006).

In this research we used the GIPL-2.0 model, which is a numerical simulator of the temporal and spatial transient response of permafrost to projected changes in climate.

Methods

GIPL-2.0 model

A previous version of this model (GIPL-1.0) is an equilibrium, spatially distributed, analytical model for computation of the active layer thickness and mean annual ground temperatures (Sazonova & Romanovsky 2003). The GIPL-2.0 model simulates soil temperature dynamics and the depth of seasonal freezing and thawing by solving 1D non-linear heat equations with phase change numerically. In this model the process of soil freezing/thawing is occurring

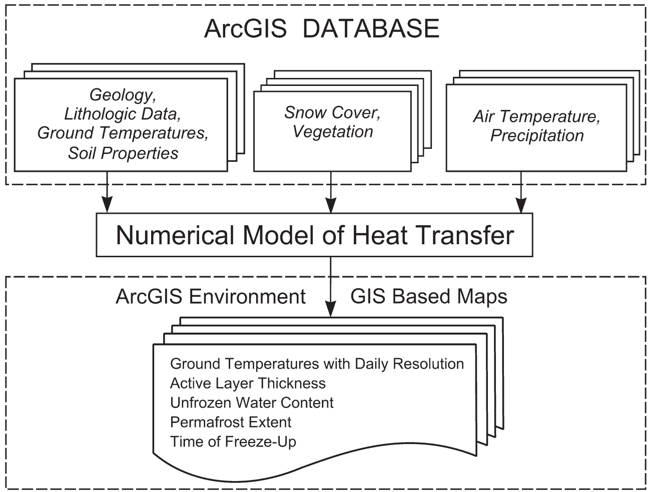

Figure 1. The GIPL-2.0 model schematic diagram.

in accordance with the unfrozen water content curve and soil thermal properties, which are specific for each soil layer and for each geographical location. The Special Enthalpy formulation of the energy conservation law makes it possible to use a coarse vertical resolution without loss of latent heat effects in the phase transition zone even in case of fast temporally and spatially varying temperature fields. At the present stage of development, the GIPL model is combined with ArcGIS to facilitate preparation of input parameters (climate forcing from observations or from Global or Regional Climate Models) and visualization of simulated results in the form of digital maps. The input data are incorporated into GIS and contain the information on geology, soils properties, vegetation, air temperature, and snow distribution (Fig. 1).

The soil characterization used in the GIPL-2.0 model is based on extensive empirical observations conducted in representative locations that are characteristic for the major physiographic units in Alaska.

The numerical solution of heat transfer is implemented in the extended program module, which can be called from the GIS environment. GIS allows visualization of input and output parameters and their representation in the form of digital maps. The new version of GIPL 2.0 simulates soil temperature and liquid water content fields for the entire spatial domain with daily, monthly, and yearly resolution. The merge of the new GIPL and the GIS technique provides a unique opportunity to analyze spatial features of permafrost dynamics with high temporal resolution.

Mathematical model

The basic mathematical model in our approach is the Enthalpy formulation of the one-dimensional Stefan problem (Alexiades & Solomon 1993, Verdi 1994). We used the quasi-linear heat conduction equation, which expresses the energy conservation law:

$$\frac{\partial H(y,t)}{\partial \tau} = div(\lambda(y,t)\nabla t(y,\tau)),\ y \in \Omega,\ \tau \in \Psi \tag{1}$$

where $H(y, t)$ is the enthalpy

$$H(y,t) = \int_0^t C(y,s)ds + L\Theta(y,t) \tag{2}$$

where $C(y, t)$ is the heat capacity, L is the latent heat, $\lambda(y, \tau)$ is thermal conductivity and $\Theta(y, t)$ is the volumetric unfrozen water content. The Equation (1) is complemented with boundary and initial conditions. The computational domain $0 \le \Omega \le 1000$ is extended to 1000 m in depth, and the time interval Ψ is 200 years with an initial temporal step of 24 hours.

Dirichlet's conditions $t(\tau)$ were set at the upper boundary. An empirical method of geothermal heat flux estimating (Pollack et al. 1993) in each grid point was applied for the lower boundary conditions.

$$\frac{\partial t}{\partial \tau}\Big|_{y=0} = t(\tau), \qquad \frac{\partial t(\tau)}{\partial y}\Big|_{y=1000} = g \tag{3}$$

where g is a geothermal gradient at the lower boundary.

A fractional step approach (Godunov splitting) was used to obtain a finite difference scheme (Marchuk 1975). The idea is to divide each time step into two steps. At each step, the spatial dimension (in the depth) is treated implicitly:

$$\frac{H(t_i^{n+1}) - H(t_i^{n+1/2})}{\Delta\tau_n} = \frac{2}{(\Delta h_{i+1} + \Delta h_i)} \times \left(\lambda_{i+1/2}^{n+1} \frac{\left(t_{i+1}^{n+1} - t_i^{n+1}\right)}{\Delta h_{i+1,y}} - \lambda_{i-1/2}^{n+1} \frac{\left(t_i^{n+1} - t_{i-1}^{n+1}\right)}{\Delta h_{i,y}} \right) \tag{4}$$

where $\Delta h_{i,y}$ is the spatial steps on the non-uniform grid.

The resulting system of finite difference equations is non-linear, and to solve it Newton's method was employed at each time step. On the first half step (4) in a case when a non-zero gradient of temperature exists, we use the difference derivative of enthalpy:

$$\frac{\partial H(t_i)}{\partial t} = 0.5\left[\frac{H(t_i) - H(t_{i-1})}{(t_i - t_{i-1})} + \frac{H(t_{i+1}) - H(t_i)}{(t_{i+1} - t_i)} \right] \tag{5}$$

The analytical derivative of representation (2) has to be used in the case of zero-gradient temperature fields. The second half step (4) is treated similarly. Thereby, we can employ any size spatial steps without any risk of losing any latent heat effects within the phase transition zone for fast temporally and spatially varying temperature fields.

Model validation and calibration

Ground temperature measurements of a very high quality (precision generally at 0.01°C) in shallow boreholes were used for initial model validation. More than 15 shallow boreholes (1–1.2 m in depth) across Alaska from north to south were available for validation (Romanovsky & Osterkamp 1997). The temperature measurements in the shallow holes were performed with vertical spacing of 0.08–0.15 m. At most of these sites, soil water content and snow depth also were recorded. In addition, more than 25 relatively deep boreholes from 29 m to 89 m in depth (Osterkamp & Romanovsky 1999, Osterkamp 2003) along the same transect were available for model validation in terms of permafrost temperature profiles and permafrost thickness.

Different earth's materials have varying thermal properties. The soil thermal conductivity and heat capacity vary within the different soil layers, as well as during the thawing/freezing cycles, and depend on the unfrozen water content that is a certain function of temperature. The method of obtaining these properties is based on the numerical solution for a coefficient inverse problem, and on minimization locally on the misfit between measured and modeled temperatures by changing thermal properties along the direction of the steepest descent. The method used and its limitations are described in more detail elsewhere (Nicolsky et al., in review).

There are two basic approaches to the calibration of modeled permafrost temperatures against the observed data, which can be distinguished by their use of temporal or spatial relationships. With the temporal approach, the quality of the modeling series is assessed by time series regression against measured data. The quantitative relationship between simulated and measured data is then determined for a ‘‘calibration'' period with some instrumental data withheld to assess the veracity of the relationship with independent data. Figure 2 illustrates the results of the model calibration for the specific site, West Dock (70°22'28.08"N, 148°33'7.8"W).

In the spatial approach, assemblages of the observed data from a number of different geographic locations with different landscape settings determine the quality of the modeling results. To achieve geographic correspondence between the scale of observation and modeling, we utilized a regional-scale permafrost characterization based on observations obtained from representative locations. Additional comparison of model-produced ground temperatures, active layer thickness, and spatial permafrost distribution with measured ground temperatures at the Alaskan sites shows a good agreement.

Input data set

In order to assess possible changes in the permafrost thermal state and the active layer depth, the GIPL-2.0 model was implemented for the entire Alaskan permafrost domain for the 1900–2100 time interval. For this study we used an input data set with grid boxes size 0.5° × 0.5°. Input parameters to the model are spatial datasets of mean monthly air temperature and snow water equivalent (SWE), prescribed soil thermal properties and water content, which are specific for each soil layer and for each geographical location. Initial distribution of temperature with depth was derived from the borehole temperature measurements obtained in Alaska by different researchers during the last several decades (Brewer 1958, Lachenbruch & Marshall ti

For climate forcing we used two data sets. For the period of

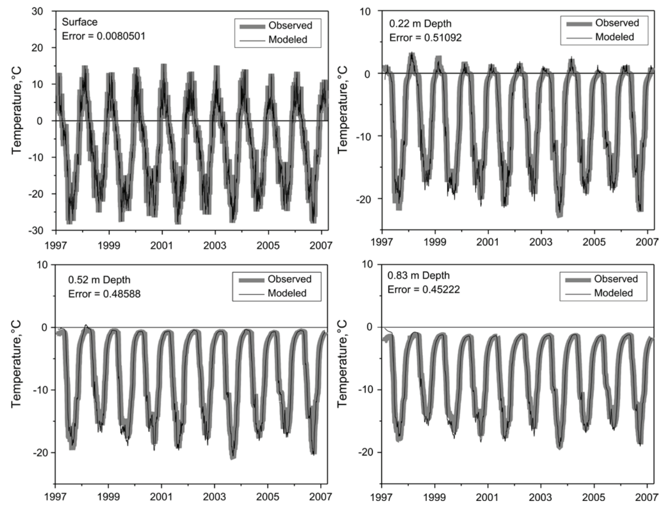

Figure 2. Example of the temporal model calibration for specific site.

1900–2000 climatic conditions, the CRU2 data set with 0.5° × 0.5° latitude/longitude resolution (Mitchell & Jones 2005) was used. The future climate scenario was derived from the MIT-2D integrated global system model (IGSM) developed at the Massachusetts Institute of Technology (MIT), which is a two dimensional (zonally averaged) atmospheric model coupled with a diffusive ocean model that simulates the surface climate over the land and ocean for 23 latitudinal bands globally (Sokolov & Stone, 1998). Snow data for the entire simulated period 1900–2100 were derived from the terrestrial ecosystem model (TEM) (Euskirchen et al. 2006). We used the MIT-2D output for the 21st century with a doubling, gradual increase of atmospheric CO_2 concentration by the end of the current century that corresponds to the IPCC SRES emission scenario A1B.

Results and Discussion

We compared ground temperatures at the depths of 2 m, 5 m, and 20 m for three snapshots of 2000, 2050, and 2100 (Fig. 3). If compared with present-day conditions, the greatest changes in temperatures for the 2050 and 2100 snapshots will occur at 2 m depth (Figs. 3 A, B, C). Results of calculation show that by the end of the current century, the mean annual ground temperatures (MAGT) at 2 m depth could be above 0°C everywhere southward of the sixty-sixth latitude, except for the small patches at the high altitudes of the Alaska Range and the Wrangell Mountains (Fig. 3C). The area of about 850,000 km^2 (about 57% of the total area of Alaska) will be involved in the widespread permafrost degradation and could contain both areas with completely disappeared permafrost and areas where thawing of permafrost is ongoing. It should be noted that by the term "thawing permafrost" we understand a situation when the permafrost table is lowered and a residual thawed layer (talik) between the seasonally frozen layer and the permafrost table continuously exists throughout the year.

According to calculations, the modern extent of the area with MAGT at 5 m depth above 0°C is about 125,000 km^2.

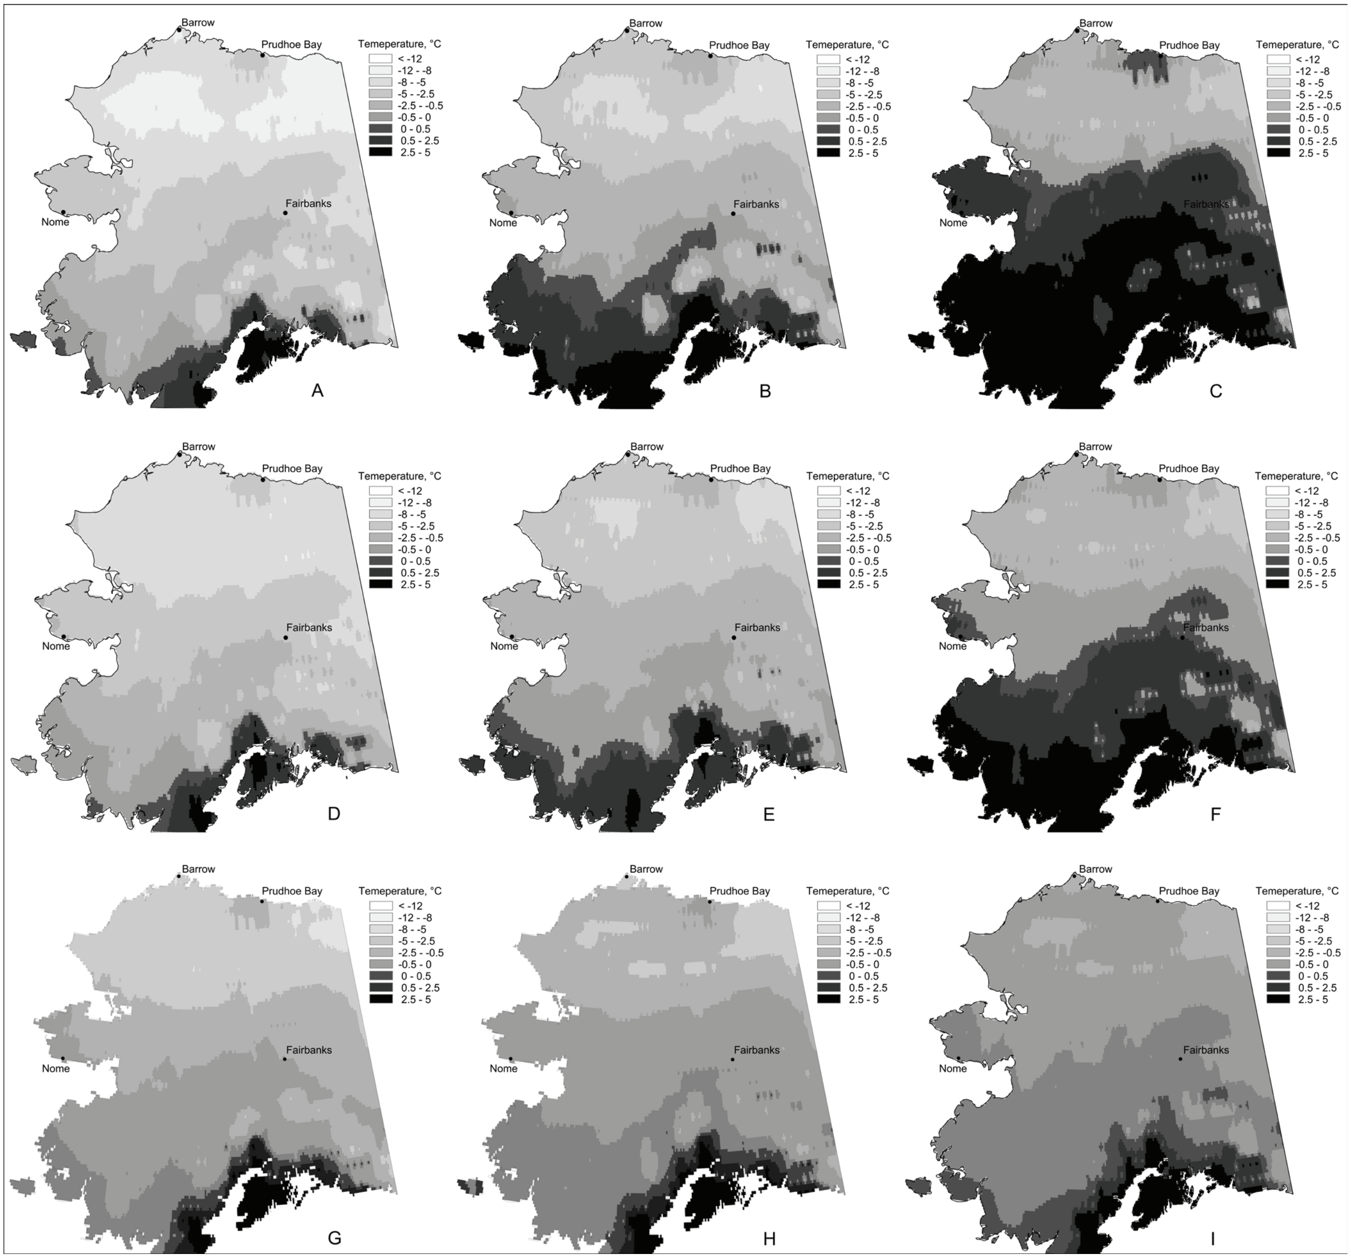

Figure 3. Projected mean annual ground temperatures at 2 m (A, B, C), 5 m (D, E, F), and 20 m (G, H, I) depths on 2000 (A, D, G), 2050 (B, E, H), and 2100 (C, F, I) using climate forcing from MIT-2D output for the 21st century.

The model-produced ground temperatures with positive MAGT at 5 m depth could occupy approximately 659,000 km^2 (about 45% of the total area of Alaska) by the end of the current century and could extend into the Interior of Alaska (Fig. 3F).

While the permafrost temperatures at 20 m depth could change significantly within a range of negative temperatures, the area with MAGT above 0°C at 20 m depth would not expand too much, even by 2100 (Figs. 3 G, H, I). The difference between these areas in 2000 and in 2100 does not exceed 100,000 km^2 (Figs. 3 G, I). Changes in permafrost temperatures will be much more pronounced within the areas with colder permafrost in comparison with areas where the permafrost temperature is presently close to 0°C. Also, it will not increase significantly in the areas of peat lands with a sufficiently deep organic layer. Projected changes in areas of MAGT above 0°C at the different depths and for the different times according to the MIT-2D climate change scenario are presented in Table 1.

Table 2 presents the statistics of modeled MAGT variables for the three snapshots obtained from 34,434 grid cells within the entire Alaskan domain. While the mean value and sums of MAGT at the depths of 2 m and 5 m turned to above 0°C by the end of the current century, the same characteristics for 20 m depth remain below 0°C (Table 2).

Statistics on active layer thickness (ALT) also have shown significant response to the scenario of climate change. The simulated mean values of ALT for the whole Alaskan permafrost domain are 0.78 m, 1.33 m, and 2.4 m for 2000, 2050, and 2100 respectively.

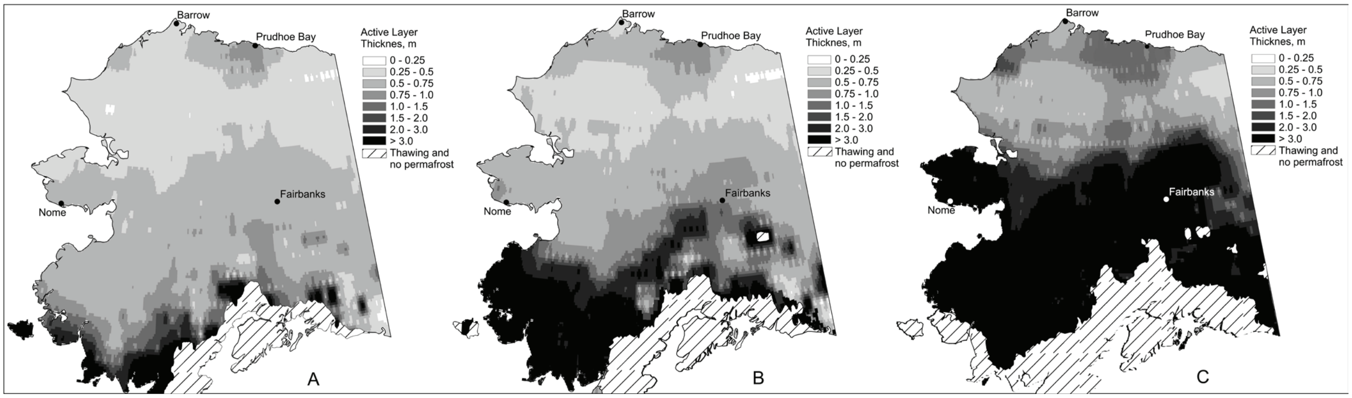

Figure 4. Projected active layer thickness and extent of thawing permafrost area in 2000 (A), 2050 (B), and 2100 (C) using climate forcing from MIT-2D output for the 21st century.

The area of thawing permafrost (permafrost table located deeper than 3 m) also increased according to our model from 65,000 km^2 in 2000, to 240,000 km^2 by 2050, and to 720,000 km^2 by 2100 (Fig. 4).

Conclusions

According to the future climate scenario derived from the MIT-2D climate model and the TEM output for the 21st century, widespread permafrost degradation could be observed everywhere in Alaska southward from the Brooks Range by the end of the current century. It means that the permafrost table in this region will be lowered down to 3–10 m in depth, and some small and thin patches of permafrost at the southernmost regions of Alaska could disappear completely. Nevertheless, permafrost thicker than 15–20 m in depth could still survive deeper than 10–15 m, even in the regions with widespread long-term thawing of permafrost. In the regions with ice-rich permafrost, the thawing processes will extended for a long time, especially in the regions with undisturbed surfaces. Modeling results show the Alaskan North Slope will not be experiencing a substantial widespread permafrost thawing and degradation during the present century.

Abstract

On the Tazovskiy Peninsula (north of West Siberia) patterned ground is spread on considerable territory. In July 2007 different aspects of the process in the central part of the peninsula were explored. Descriptions and measurements of contemporary and ancient polygonal structures and certain parts of them were done near the Yubileinoe gas field and the town of Yamburg. On this basis we retraced the development of polygonal relief from ice wedges of first generation to ice-wedge casts. In contemporary climate conditions in the central part of Tazovskiy Peninsula, the process of frost wedging and development of polygonal relief takes place on peat grounds. The most typical dimensions of blocks are 10–15 m, and very often they are poorly expressed in relief. Ancient ice wedging of the Pleistocene period had much greater scales and was spread on mineral grounds as well. The thickness of ice wedges evidently reached 1–2 m.

Keywords: frost cracking; ice wedges; polygonal relief.

Introduction

One of the distinctive features of the cryolithosphere is patterned ground. North of western Siberia the phenomena is well spread on considerable territories, where severe climate in combination with ground conditions leads to frost cracking and formation of polygons. In July 2007 different aspects of the process in the central part of Tazovskiy Peninsula were explored. The exploration took place near the Yubileinoe gas field and the town of Yamburg. On the basis of certain examples, we retraced development of polygonal relief: from ice wedges of the first generation to the ice wedge casts.

Study Area

Exploration was carried out in the eastern and southern parts of Tazovskiy Peninsula (West Siberia, Russia). The territory is tectonic plate with Palaeogenic basement covered with a thick layer of sediments (Popov 1989). In the upper part, the sediments have marine, alluvial, and lacustrine genesis of different epochs of Pleistocene and are made up with loam, clay sand, and sand. The territory in general has poor vertical disarticulation caused mainly by cryogenic and fluvial processes. The vegetation is mainly tundra and forest tundra: *carex*, shrubs and bushes *betula nano, salix, ledum, eriophorum*; moss and lichens are widely spread: *cetraria islandica, sphagnum balticum*; very often they form polygonal peatlands. The main climate features are big yearly and weekly amplitudes of temperature with very cold winters. Mean January temperatures are -28°C; mean July temperatures are -12°C. Descriptions and measurements were done in two spots: forest-tundra territories near the Yubileinoe Gas Facility (65°57′N, 75°42′E) and tundra territories near the town of Yamburgh (68°00′N, 74°50′E).

Methods

To study the processes of frost-cracking and polygonal-relief formation, we made descriptions and measurements on spots that were selected to provide grounds, vegetation, and landscape diversity. Ice wedges and ice wedge casts were described in an exposure and in pits. Measurements were done with tape, ruler, and compass. To estimate the climatic parameters from the point of frost cracking (and

Figure 2. A growing gully on the bank of Ngarka-Poilovo-Yakha River.

consequently polygonal system formation), we collected and analyzed meteorological data from Internet archives. We used meteorological data from the weather stations of Noviy Urengoi town and the village Noviy Port. The first town lies 40 km to the east of Yubileinoe and has nearly the same geographical conditions. Noviy Port and Yamburg are situated on the different banks of Obskaya Guba Bay, but have approximately the same latitude; the distance is 88 km. Thus a high correlation between meteorological conditions on the named weather stations and corresponding research sites is expected.

Site 1

The first place of exploration was situated in the valley of the Ngarka-Poilovo-Yakha River (67°53′40″N, 75°45′25″E). It is a wet territory with hummocks. During the Sartan time (22,000–18,000 years ago), strong cryogenesis led to formation of huge ice wedges in the lagoon sediments of Kargin time (40,000–22,000 years ago). During the Holocene the wedges partially degraded and formed ice wedge casts, overlain by

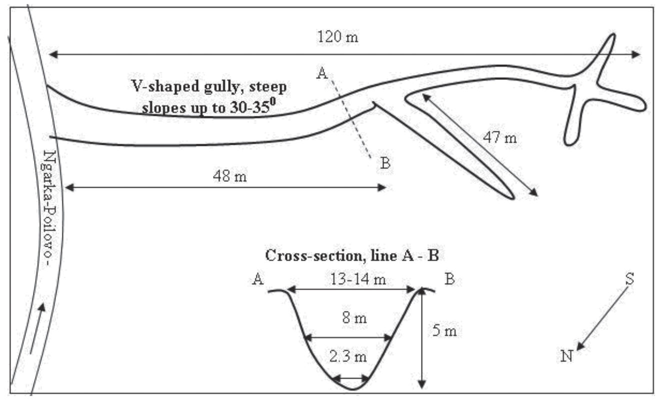

Figure 3. Gully scheme (67°53′40″N, 75°45′25″E).

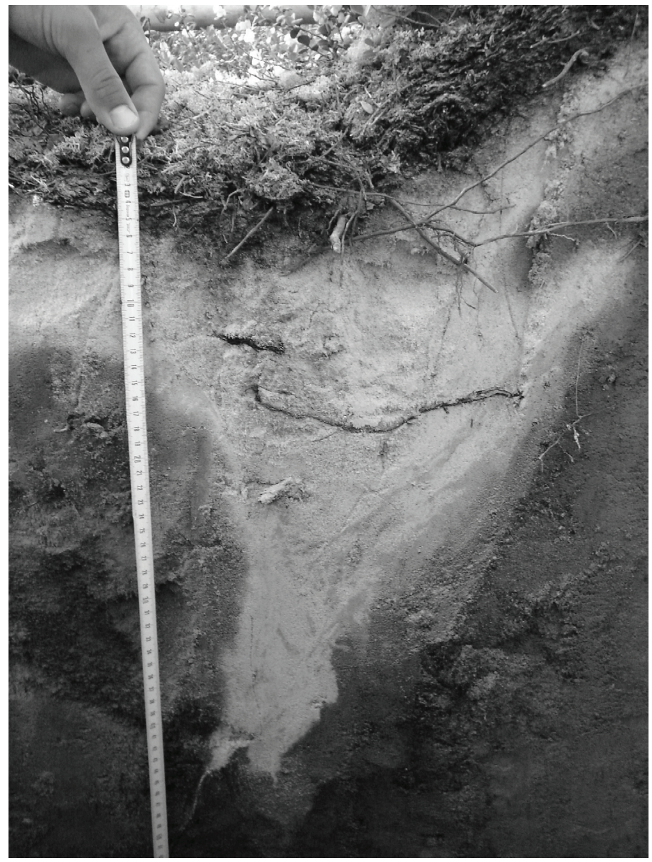

Figure 4. Sandy ice-wedge cast near the source of one of minor watercourses in the southern part of the Tazovskiy Peninsula.

peat up to 50 cm thick. On the surface of a small polygonal peat plateau, we sighted ice veins of the first generation. They are vein-like vertical ice inclusions up to 3 cm thick in the body of peat in different phases of decomposition. The peat plateau is a formed polygonal structure; typical dimensions of the blocks are 8–10 m in diameter. Judging by the considerable spreading of values, the polygons seem to be old enough as they reveal several generations of frost-cracking. In places where tensions in winter due to some reasons were higher, the peat is divided into polygons of smaller dimensions. Polygons are divided by depressions up to 0.4 m deep, in the depressions V-shaped ice wedges are detected. We have measured a group of polygons; the

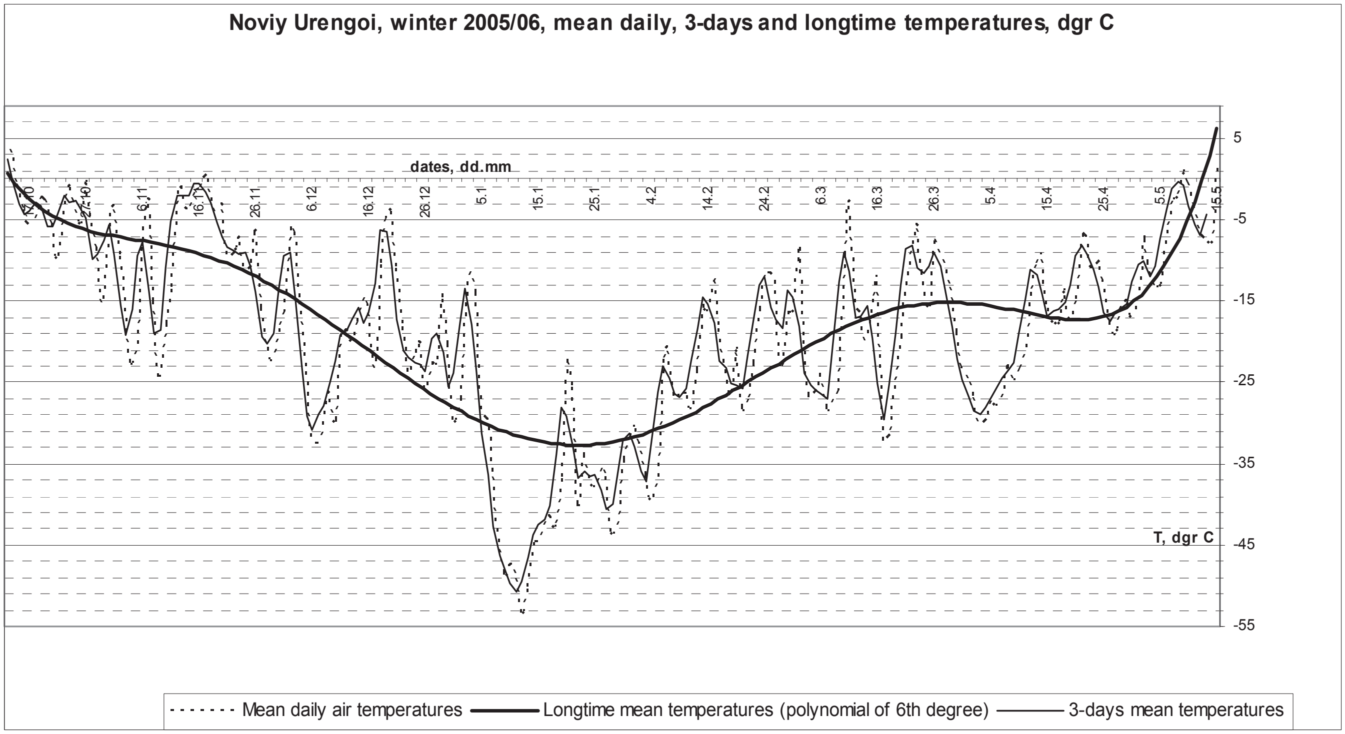

Figure 5.

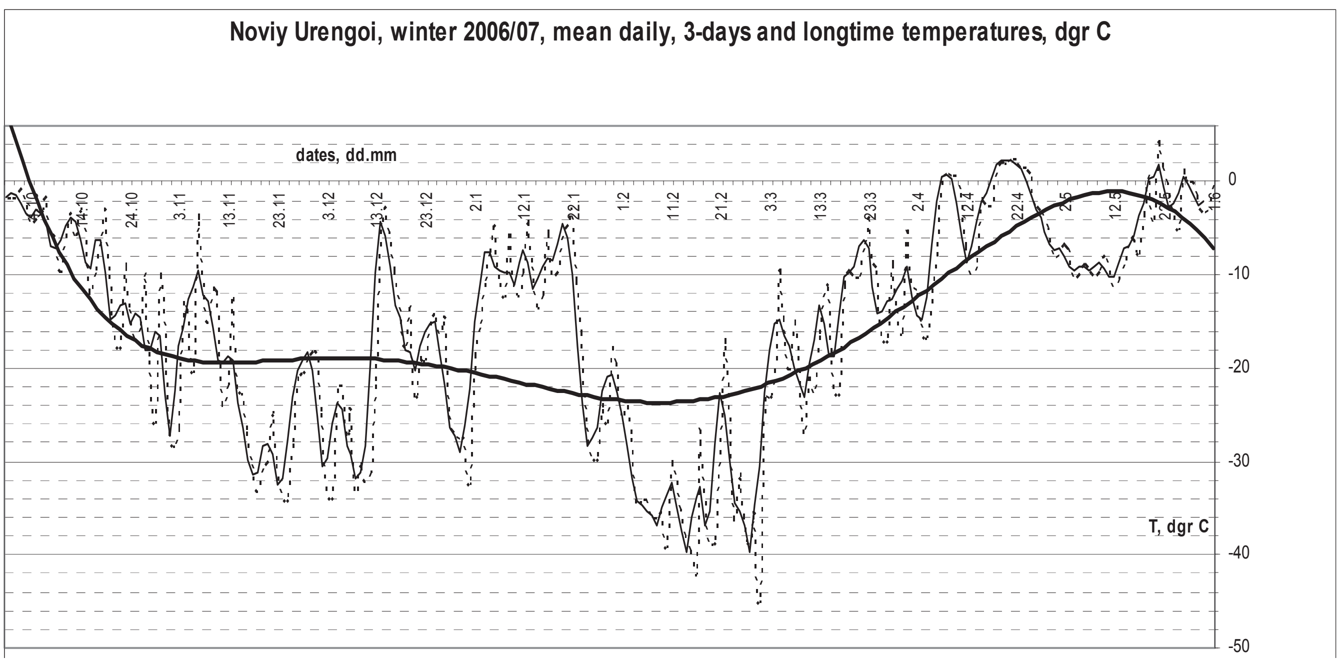

Figure 6.

results are shown on the Figure 1. The wedges separating the blocks open in the exposure on precipitous bank of the river Ngarka-Poilovo-Yakha; they can be retraced up to the depth of 2–2.5 m. Their complicated genesis is seen in the form: the bottom of a wedge is usually in the mineral sandy sediments where it developed as an epigenetic ice wedge, the part of wedge is almost strictly V-shaped; but in peat horizon which overcovers the mineral sediments from the depth of 1.5 it loses the strictness of form and is a syngenetic ice wedge. It is obvious that with the development of the peat plateau the conditions of heat exchange process changed, resulting in frost cracking and development of polygonal structures.

What is important about the ice wedges when they are revealed on banks of rivers, seas, and even minor

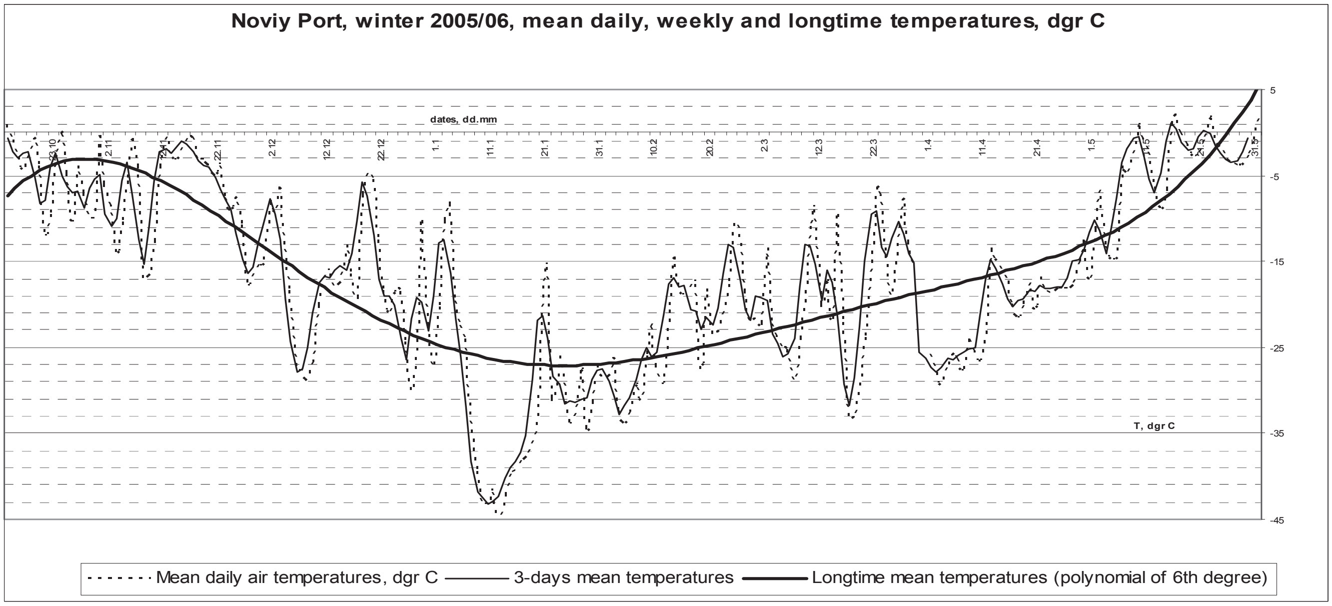

Figure 7.

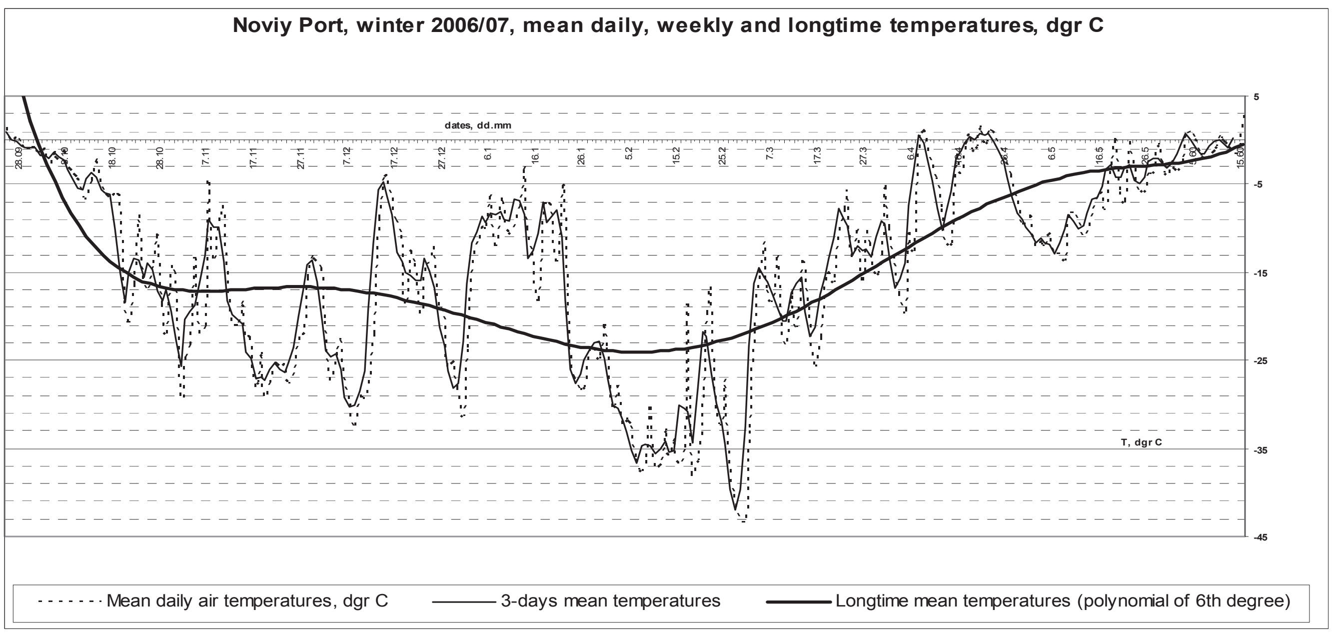

Figure 8.

watercourses is that while degrading they can advantage development of thermal erosion. Very often the forming gullies endanger different buildings, roads, plants, etc. And near the river Ngarka-Poilovo-Yakha vivid examples of the process can be detected (Figs. 2, 3).

The gullies form thermo-erosional outlets up to 8 m deep. One of them cuts through the right steep slope of the river and grows every year in the southwestern direction with speeds up to 4 m/year, thus endangering a gas cleaning and piping facility. The gully has a sophisticated formation with a number of tributaries; the tributaries inherit the polygonal form of wedges. Degrading, the wedges form linear depressions and during the spring seasons melting waters form watercourses in the depressions which hastens the gully growth. There was an attempt to stop the process - a unique construction of concrete and steel designed to help the melting waters in spring to flow faster and to prevent the banks from thermo-erosion was erected. But unfortunately the process of gully growing was not stopped completely. Another gully situated in 100 m to the south was detected (Fig. 3). Equal processes takes place on the bold shore of the Obskaya Guba Bay (Kara sea).

Site 2

On the bank of a thermokarst lake near the Yubileinoe gas field, northward of the previous spot, another small polygonal peat plateau is detected (67°57′01″N 75°52′13.3″E). It is

on the next stage of development, the polygons are uneven blocks usually pentahedral. The ice-wedges are on the stage of degradation – they do not reveal clearly in the upper 40 cm, while the wedges in the previous spot could easily be opened in the upper 30 cm. The depressions in between polygons are also poorly expressed. Measurements of a group of polygons were done. It was found out that apart from rather old polygons formed in the Sartan time, there were also new ones of smaller dimensions. The wedges and depressions dividing the old polygons are much more vividly expressed in the relief. Typical values for the first are 16–20 m in diameter. The latter are 8–12 m. and seem to have appeared after a fire that took place on the spot in 2005. The fire was quenched soon after it started, thus it did not spread on the nearby territories. Nevertheless it annihilated all the vegetation on the territory of about 30 by 30 m and now its spread is marked by poor vegetation and rests of ash. In winter 2005/06, that turned out to be extremely cold, frost polygons of a new generation developed on the territory limited by the edges of the fire spread.

Site 3

On the watershed near the source of one of the minor watercourses on the south of Tazovskiy Peninsula (66°0′35.6″N, 75°46′33.6″E), ancient polygonal structures were detected. They form characterful "avenues" up to 3–4 m wide, crossing with almost regular angles of 90 degrees. The "avenues" are also marked by vegetation: it varies from larch shaws on top of the polygons to lichens in the depressions. Typical dimensions of polygons are 17–20 in diameter. In about 500 m to the west the remains of a polygonal plateau were found. Ancient blocks are marked by relief features and vegetation. Differences are similar to those on the previous spot. In a dug prospect hole a sandy ice-wedge cast reveals itself in the loamy bearing strata (Fig. 4) Under the whitish sandy horizons there is a fine brownish horizon width, where the contents of organic material is increased. Below there are clear spots of ferritization on the contact with containing ground. The cast has the width of 30 cm in its upper part and 17 cm in the middle, while the depth is 50 cm.

Site 4

Near the valley of Halmer-Yakha River (65°58′45.8″N, 75°46′11.6″E) ancient polygonal structures on mineral grounds are detected, the surface is covered with larch shaws. Measurement of typical dimensions of polygons were made: the values for a typical group of polygons is 12.5 m by 12.5 m; 18.5 m by 11.5 m; 6.5 m by 9 m; 11 m by 9.5 m. The blocks are separated by depressions of considerable size: typical values of width are: 6.6 m; 5 m; 4.5 m; 5.7 m; they are up to 1 m deep.

Analysis of Meteorological Data

Frost cracking strongly depends on climatic conditions. Cracks appear when thermal tensions in the ground exceed the ground's tenacity. The tensions depend on thermal gradients and in general temperature increases with depth and temperature amplitudes decrease with depth. Thus thermal tensions that cause frost cracking depend on decreases of air temperature, especially when they reach considerable values in a short time. (Kudriavtsev 1978). According to the field research carried out by Mackay. (1974) north of Canada and by Podborniy (1976) in the lower reach of Yenisei River, frost cracking takes place when air temperatures lower below the average meaning for winter months. According to the research results near Ust'-Port (Yenisei delta, 69°39′45″N, 84°24′36″E) frost cracks can open both in the beginning and in the end of a rather long (1–2 months) cold period. The research also showed that even short (1–2 days) cold periods can lead to frost cracking. (Podborniy 1978). We tried to analyze meteorological data from the point of frost crack and consequently polygonal blocks formation. The results are given in the Figures 5, 6, 7, and 8 and in Tables 2 and 3.

Conclusions

According to the recent research done by Pavlov and Malkova (2005), the increase of annual air temperature relative to the norm in the region (calculated as mean in 1951–1990) of Tazovskiy Peninsula is 1.2°C, and in relation to the cold 1950s the value is about 1.6°C and the amplitude contraction owing to climate warming is 2°C. (Pavlov & Malkova 2005). On the basis of the data and of the descriptions and measurements done the following conclusions can be made. In contemporary climate conditions in the central part of Tazovskiy Peninsula, the process of frost wedging and development of patterned grounds takes place mainly on peat grounds with considerable humidification. In other cases degradation of frost-crack relief prevails. The factor of vegetation has a significant influence on the process, removing of destruction of vegetation can facilitate the development of polygonal structures. The most typical dimensions of blocks are 10–15 m, very often they are poorly expressed in relief. Development of polygons starts with formation of narrow ice wedges of the first generation, which slowly year after year grow and cross. While crossing they separate the polygonal blocks usually pentahedral or hexahedral. Ancient ice wedging of the Pleistocene period had much greater scales and spread on mineral grounds as well. The thickness of ice wedges evidently reached 1–2 m. Nowadays we can estimate the scale of cracking and development of polygons by investigating numerous ice wedge casts, forms of relief, vegetation, soils and other components of landscape.

Abstract

In this study, we produced maps of the uncertainty of predictions, provided by eight state-of-the-art modeling techniques for sorted (SP) and non-sorted (NSP) patterned ground, in subarctic Finland, at a 1.0 ha resolution. Five uncertainty classes (UC) represent the agreement between the different modeling techniques. The resulting uncertainty maps reflect the reliability of the estimates for the studied periglacial landforms in the modeled area. Our results showed a significant negative correlation between the uncertainty classes and the accuracy of the modeling techniques. On average, when all models agreed, the mean AUC values were 0.891 (NSP) and 0.886 (SP), and 0.494 (NSP) and 0.510 (SP) when only four models agreed. Mapping of the uncertainty of predictions in geomorphology can help scientists to improve the reliability of their data and modeling results.

Keywords: predictive accuracy; uncertainty classes; uncertainty mapping.

Introduction

Various modeling techniques are increasingly used in geomorphology in order to predict the spatial distribution of earth surface processes and landforms (Guzzetti et al. 1999). The development of spatial modeling in geomorphology is based on three trends: growth in the availability of remote sensed (RS) data and development of GIS techniques integrated with novel statistical methods (Walsh et al. 1998). Among several other applications, spatial modeling is used to assess the stability of terrain (Ermini et al. 2005) and to map glaciated landscapes (Brown et al. 1998) and periglacial processes (Hjort & Luoto 2006). In geomorphology, numerous areas have a lack of data, particularly in remote areas where field investigations are difficult to acquire. The predictions are used to fill these shortcomings in order to create more complete geomorphological maps (Vitek et al. 1996).

The used modeling techniques do not always provide robust predictions (Luoto & Hjort 2005). The reliability of the predictions can be improved by reducing the uncertainty of the models by using consensus methods (Thuiller 2004) or choosing a method which predicts most robustly a certain landform type (Luoto & Hjort 2005). However, these two approaches deal with the modeling uncertainty at a global scale (e.g., the whole modeled area). In this study, we propose a new approach, which does not aim to reduce the modeling uncertainty at a global scale, but to map it at a local scale.

Eight explanatory variables of 6998 grid squares were used as input into eight state-of-the-art modeling techniques to model the spatial distribution of sorted (SP) and non-sorted (NSP) patterned ground in subarctic Finland, at a 1.0 ha resolution. The eight modeling techniques are based on regression, machine learning, and classification algorithms. The accuracy of the models was evaluated using an independent test dataset (2999 grid squares) by the area under the curve (AUC) of a receiver operating characteristic (ROC) plot.

Material and Methods

Material

A dataset of 9997 grid squares at a 1.0 ha resolution was randomly divided into two subsets. The first subset (70%, 6998 grid squares) was used to calibrate the models, and the second subset (30%, 2999 grid squares) was used to evaluate the predictive performance of the models. In the whole study area, the prevalence of NSP and SP was 0.228 and 0.167, respectively. The prevalence was 0.227 (NSP) and 0.167 (SP) for the calibration dataset, 0.229 (NSP) and 0.167 (SP) for the evaluation dataset. Patterned ground was mapped *in situ* and it was located with a GPS-device in the whole study area of 100 km^2 during the field investigation in summer 2002. In total, eight explanatory variables were calculated for all of the grid squares to reflect the studied environmental conditions. The mean altitude (m), the mean slope angle (°), the wetness index, and the proportion of concave topography (%) were derived directly from a digital elevation model (DEM) at 20 m resolution. The proportions of four soil types, namely peat, glacigenic deposit, sand (and gravel), and rock terrain were derived from the digital soil map. More information about the record presences of the patterned grounds and the explanatory variables can be found in the study by Luoto & Hjort (2005).

Methods

The eight modeling techniques belong to three main categories of methods: three regression methods: Generalized Linear Model (GLM), Generalized Additive Model (GAM), and Multivariate Adaptive Regression Splines (MARS); two classification methods: Classification Tree Analysis (CTA) and Mixture Discriminant Analysis (MDA); and three machine learning methods: Artificial Neural Network (ANN), Random Forest (RF), and Generalized Boosting Methods (GBM).

GLMs are mathematical extensions of linear models (McCullagh & Nelder 1989) and have the ability to handle non-linear relationships and different types of statistical distributions characterizing spatial data. In this study, GLMs were built based on third order polynomial functions. GAMs are non-parametric extensions of GLM, using a smoothing spline with four degrees of freedom. GAM combines linear and additive response shapes within the same models (Hastie & Tibshirani 1990). MARS combines classical linear regression, mathematical construction of splines and binary recursive portioning producing linear or non linear models (Friedman 1991). These three regression methods are frequently used, and one example of utilization can be found in Luoto & Hjort (2005).

CTA is a binary based classification method and is an alternative to regression techniques (Breiman et al. 1984). At each node of the tree, a true/false decision is taken considering only one environmental parameter. Then the node separates a class into two different sub-classes whose purity level increases. CTA has been frequently used in geomorphology (Luoto & Hjort 2005). MDA is an extension of linear discriminant analysis (Venables & Ripley 2002). The environmental parameters form classes, for which density distribution is a mixture of Gaussian distributions. A set of environmental parameters is classified into the class with the maximum probability to belong to this class. MDA was used in geomorphology by Meritt & Wohl (2003).

ANNs, machine learning methods, are rule-based methods which have the ability to build accurate models when the functional form of the underlying equations is unknown (Lek & Guegan 1999). A network contains three different kinds of layers: the input layer, the intermediate layer, and the output layer. Each layer contains "neurons." The output of the previous layer of neurons is added, using weighted factors. This process is done until processing of the output layer. Examples of utilization of ANN can be found in Ermini et al. (2005). RF is based on multiple trees methods, generating several hundreds of random trees (Breiman 2001). Each tree is grown by selecting randomly a training dataset as many times as there are observations among the whole set of observation, with replacement from the original dataset. To be classified, vectors of environmental variables are input into each tree. Each tree gives a classification. The classification which appears the most often is attributed. GBM is the third implemented machine learning method and is also based on binary trees (Ridgeway 1999). To classify a vector, it is possible to use a CTA. A prior single tree classification can be improved as long as there is an estimate residual. This residual can be used as input into a second CTA, used to improve the prior classification. The sequence is repeated as long as necessary, decreasing step by step the estimate residual. To our knowledge, RF and GBM have not been used in geomorphological research.

All implemented modeling techniques except ANN were run in R environment (R Development Core Team 2004) under the BIOMOD framework (Thuiller 2003). ANN was run using the nnet library in S-plus.

The probability values of presence for SP and NSP provided by the modeling techniques were combined using a mean function as suggested by Johnson & Omland (2004). The outputs of the eight modeling techniques were then binarized using the prevalence of both landforms as a classification threshold (Liu et al. 2005). Each grid square of the modeled area was classified into five uncertainty classes (UC), reflecting the modeling agreement between the different modeling techniques (UC0 when all models agreed, UC4 when only four models agreed).

The predictive accuracy of the modeling techniques was assessed measuring the area under the curve (AUC) of a receiver operating characteristic (ROC) plot. This is a graphical method assessing the agreement between the observed presence/absence records and the model predictions, by representing the relationship between the false positive fraction and the true positive fraction of the related confusion matrix of the evaluated model (Fielding & Bell, 1997). The range of AUC is from 0.0 to 1.0, and a model providing excellent prediction has an AUC higher than 0.9; a fair model has an AUC in between 0.7 and 0.9, and a model is considered poor when the AUC is below 0.7 (Swets 1988).

Results

The performance of all eight modeling techniques is presented in Table 1. ANN was the most robust modeling technique, with mean AUC values of 0.861 and 0.859 for SP and NSP, respectively. On the contrary, MDA and RF had the lowest modeling performances with mean AUC values of 0.806 and 0.819, respectively. The AUC values of the mean projections were 0.898 for SP and 0.893 for NSP.

The mean AUC values were 0.891 and 0.886 for NSP and SP when all eight modeling techniques agreed, whilst 0.494 and 0.510 when only four models agreed. Furthermore, for all the models, there was a significant negative correlation between the uncertainty classes and the accuracy of the modeling technique (Table 1). The decrease of mean AUC values is the highest from the UC0 to the UC1, with a mean difference of 0.252 (NSP) and 0.219 (SP). ANN disagreed the most with the other modeling techniques, with 669 cases out of 1622 (amount of UC1 grid squares) for NSP and with 955 out of 1687 for SP (UC1).

Spatial distributions based on mean predictions of the eight modeling techniques and uncertainty maps of SP and NSP are presented in Figure 1. The majority of grid squares had a null

Table 1. AUC values based on of the eight different modelling techniques for non-sorted (NSP) and sorted (SP) patterned ground. Additionally, the correlation between uncertainty classes and AUC values are presented, as well as the false positive (FP; proportion of negative observations that were erroneously predicted as positive) and the false negative (FN: proportion of positive observations that were erroneously predicted as negative) fractions for each model and both landform types.

uncertainty for SP and NSP, representing 68.5% and 67.8% of the whole area, respectively. For the different uncertainty classes these indices were for SP and NSP 16.9% and 16.2% (UC1), 6.7% and 8.1% (UC2), 5.0% and 5.4% (UC3), and 3.0% and 2.6% (UC4). In addition, the prediction of NSP seemed to be underestimated by most of the models. On average, the false negative fraction (FN = 0.271; proportion of positive observations that were erroneously predicted as negative) is higher than the false positive faction (FP = 0.159; proportion of negative observations that were erroneously predicted as positive).

Discussion

Statistical modeling techniques are increasingly used to map earth surface processes and landforms (Gruber & Hoelzle 2001, Hjort 2006, Brenning et al. 2007). In general, geomorphological data are sparse, and the utilization of modeling techniques can help to gather new spatial information (Vitek et al. 1996). Nevertheless, predictive modeling is only relevant if the accuracy of the predictions is known. Several studies have focused on the predictive accuracy of the models (Gruber & Hoelzle 2001, Luoto & Hjort 2005, Hjort & Luoto 2006). The spatial uncertainty of the models has commonly been reduced by combining the output of several models (e.g., consensus methods) or by selecting the most robust modeling techniques for a given landform. However, both these strategies reduce the predictive uncertainty of the models in the modeled area as a whole, whereas the mapping of the spatial uncertainty at a local scale would improve our understanding of the behavior of the models in individual grid squares.

The strong negative correlation between the uncertainty classes and the predictive accuracy of the models underlines the relevance of the multi-model approach. Grid squares in which all models agreed had high modeling accuracy. However, when the predictions disagreed, the predictive accuracy of the models decreased significantly. These results are confirmed by Nilsson et al. (2000), who used a multi-model approach in cell biology.

In this study, the mean probability values of the predictions based on all eight modeling techniques were more robust than the probability values based on single modeling techniques (see Johnson & Omland 2004). This improvement of accuracy is global. The uncertainty maps presented in Figure 1 delineate that the uncertainty is the highest on the edges of the clumped presences. These areas are transitional zones between suitable and non-suitable environments for both SP

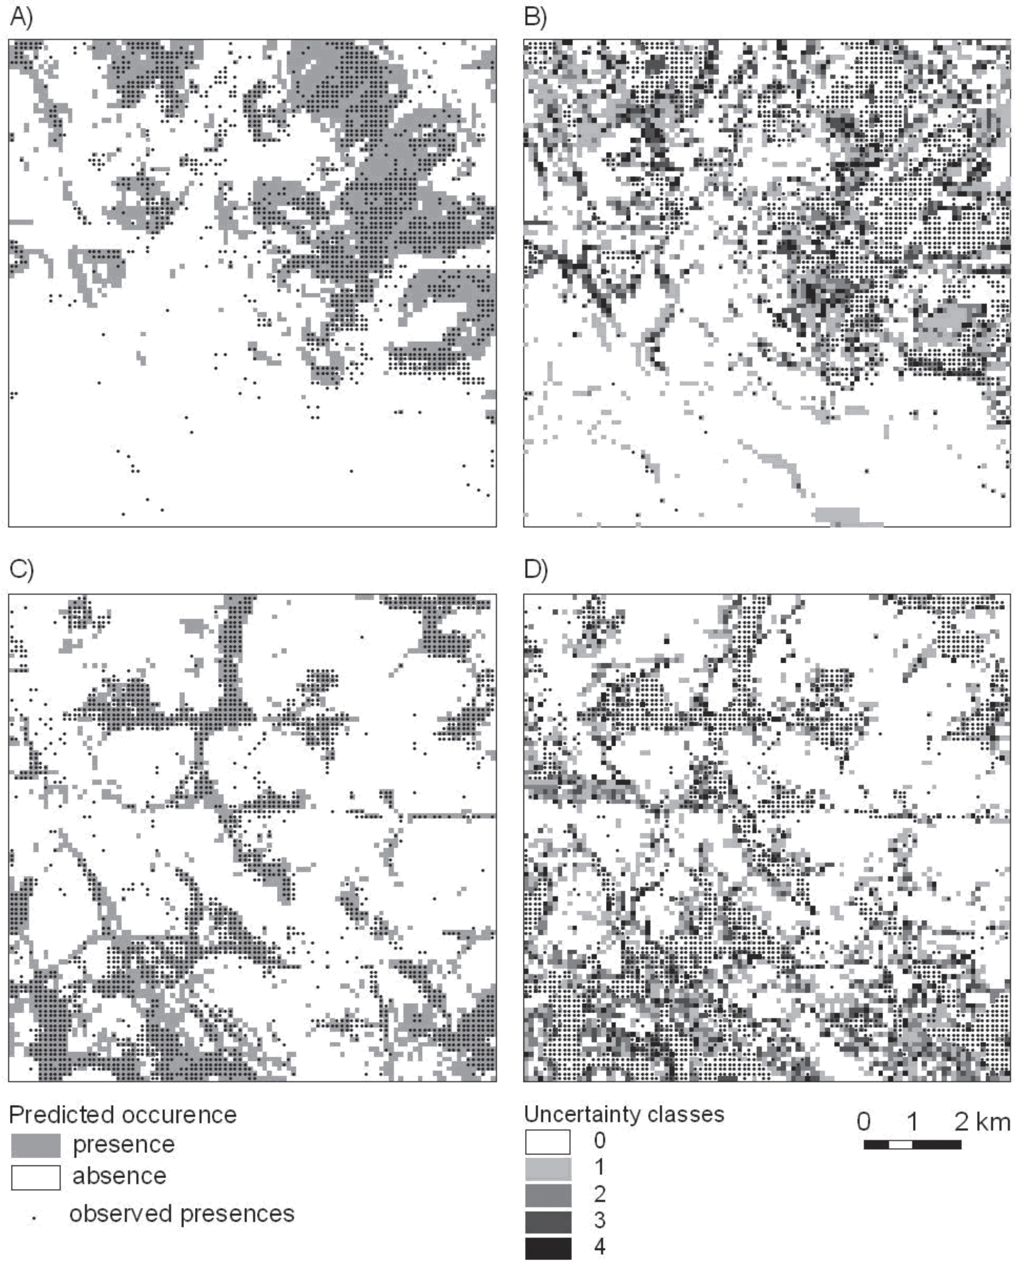

Figure 1. Spatial distribution based on mean predictions of the eight modeling techniques of sorted (A) and non-sorted (C) patterned ground and their uncertainty maps (B and D, respectively).

and NSP. As a consequence, the models have difficulty in differentiating the occurrence of the studied landform types in those areas. The fact that only few spots are predicted with a low accuracy is an asset for scientists who desire to improve the reliability of their data. In this case, the uncertainty analysis indicated that ca. 70% of the study area was accurately modeled for both landforms, thus the field investigations should be focused on the remaining 30% of the study area. It also confirms the assumption that models based on different mathematical algorithms provide rather similar predictions for most of the study area. Moreover, the fact that the NSP are underestimated by the models is partly due to the prevalence used as threshold to convert the output of the models to presences/absences.

Conclusion

Mapping of the uncertainty of predictions is a novel approach to representing the spatial reliability of predictions. It does not improve predictive accuracy of the models, but it provides a consistency map of the predictions. As a consequence, predictive maps can be interpreted simultaneously with uncertainty information, improving the understanding of potential pitfalls of the modeling exercise. We conclude that uncertainty mapping should be taken into account to deepen the understanding of the modeling procedure and to optimize field investigations to gather new field data.

Abstract

A large number of thaw lakes in the Western Canadian Arctic are prone to rapid or catastrophic drainage, with 41 lakes draining over a 57-year period in the study area. These lakes range in size up to 560 ha in area and up to 5 m in depth. Evidence suggests that such lakes may drain in less than 24 hours and the resulting drainage from even small lakes may have a peak discharge that is much larger than that experienced during normal spring snowmelt from small headwater basins. As a result, these drainage events play an important role in landscape evolution and may pose a significant threat to proposed pipelines in the study area. This paper will present information on the size and volume of lakes that have drained in the past, and provide order-of-magnitude estimates of discharge during lake drainage.

Keywords: discharge; lakes; rapid drainage; permafrost.

Introduction

The Arctic Coastal plain of northwest Canada is extremely lake rich. At the scale of approximately 10 km x 10 km, lake coverage varies from 15% to 50% of the total surface area. These lakes developed in an ice-rich permafrost environment during a postglacial warm period between 13,000 BP and 8,000 BP (Mackay 1992). Many of these lakes formed due to thawing of ice-rich permafrost that resulted in the settlement of the ground surface (Mackay 1992). Since that time, lake drainage, and disappearance of lakes from this landscape, has occurred at a rate of 1 to 2/year for Richards Is. and the Tuktoyaktuk Peninsula (Mackay 1992, Marsh & Neumann 2001). Such drainage occurs due to the melting or erosion of drainage channels through the ice-rich permafrost (Marsh & Neumann 2001). Similar thaw lake formation and drainage processes occur in the Alaskan Coastal Plain (Brewer et al. 1993) and Banks Island (Harry & French 1983), as well as the Yukon Coastal Plain, the Hudson Bay Lowland, and Siberia.

Mackay (1988, 1992) suggested that lake drainage occurs as underground tunnel flow through interconnecting ice wedge cracks, or by sustained flow through ice wedge troughs. Although drainage is often initiated as tunnel flow, the roof of the tunnel typically collapses during drainage, resulting in an open channel. Observations after drainage (Mackay 1988, 1992, Brewer et al. 1993), and through modeling of outflow (Marsh & Neumann 2001) suggest that lake drainage is often rapid or catastrophic, with partial or complete lake drainage occurring in less than 24 hours.

Through the application of an ice-dammed lake model, Marsh & Neumann (2001) demonstrated that the rate of drainage of permafrost-dammed lakes was at least partially explained by rapid melting of ground ice due to warm water flowing through the channel. They also demonstrated that the maximum discharge during drainage from a small lake (8.1 ha) was similar in magnitude to the spring peak discharge from a drainage basin of 6000 ha in area.

The rapid drainage of lakes modifies the landscape by decreasing lake area and deepening of lake outlet channels. Such events, with drainage channels up to 5 to 10 m in width and 5 m in depth and hundreds of m in length, may pose a significant hazard to pipelines proposed in the area north of Inuvik, NWT. In addition, the high discharge from these events may pose a danger to downsteam infrastructure related to pipeline development.

Marsh & Neumann (2001) estimated the discharge from two drained lakes north of Inuvik, NWT. However, there is no information on the size or volume of a wider range of drained lakes in the study area or of the possible discharge from these lakes. Since there are a large number of lakes in the area north of Inuvik where rapid lake drainage occurs, and since no approach has yet been described to predict which lakes are more prone to drainage, there are no observations of discharge from rapidly draining lakes. In addition, there is only a very small chance of obtaining such discharge measurements in the near future. As a result, the only method available to provide order-of-magnitude estimate of discharge for a lake drainage event is to apply a model such as tested by Marsh & Neumann (2001).

In order to provide order-of-magnitude estimates of discharge during lake drainage events, this paper will (1) evaluate the range of lake size and volume found in the study area and characterize the drainage channel dimensions for

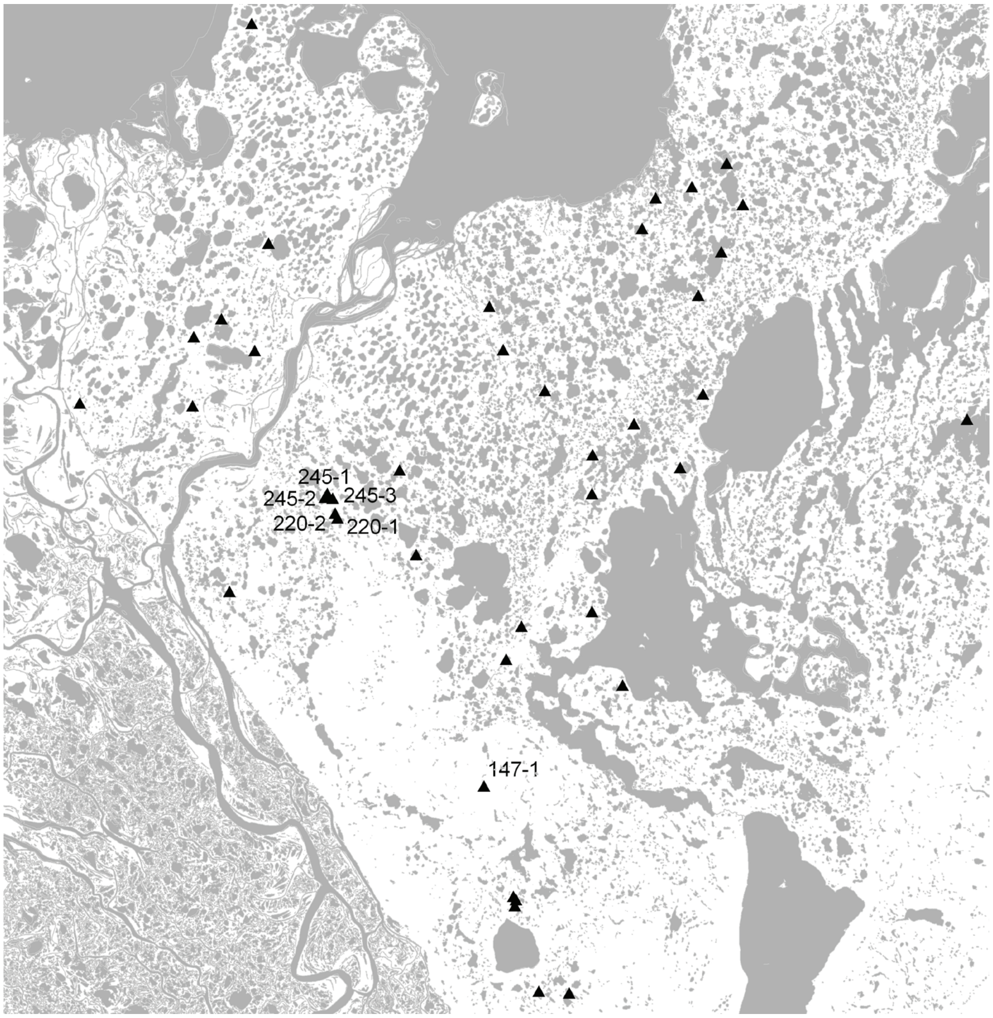

Figure 1. Study area north of Inuvik, NWT, and to the immediate west of the Mackenzie Delta. The 41 lakes that drained between 1950 and 2004 are shown by black triangles. Lakes studied in detail are numbered on the map. Lake number 147-1 is also called TVC Lake.

drained lakes in an area north of Inuvik, NWT, and (2) utilize a simple model to consider the range of possible discharge from these lakes.

Study Area and Methods

The study area includes the area north of Inuvik to the Beaufort Sea, and east from the Mackenzie Delta to near Tuktoyaktuk, NWT. There are 14,457 lakes, covering 19% of the 11,000 km^2 study area. Marsh et al. (2005) mapped drained lakes in this area (Fig. 1), using a combination of aerial photographs from 2000, topographic maps based on 1950 aerial photographs, and field observations. The present paper extends the size of the study area. For this expanded area, there are 41 lakes that drained between 1950 and 2000. The area of these lakes prior to lake drainage was determined from topographic maps and aerial photographs.

The area, volume, and average depth for 6 lakes (numbered in Fig. 1) in the study area was estimated from a high resolution digital elevation model (DEM) obtained from airborne LiDAR flown in August 2004. This DEM has 2 m pixels, with a vertical accuracy of 0.3 m and a horizontal accuracy of 0.6 m. Discharge from these 6 drained lakes was estimated using the methodology of Marsh & Neumann (2001), who applied an ice-dammed lake model from Clarke (1982).

Marsh & Neumann (2001), using discharge data estimated for Illisarvik Lake as derived from Mackay (1981), showed that modeled discharge for Illisarvik Lake was similar to observed for the first 3.5 hr of the modeled 5 hr discharge period. After this time, actual discharge was lower than modeled, with the observed peak being approximately 45% of observed. Marsh & Neumann (2001) suggested that this was due to the fact that channel enlargement by ice melt dominated the first portion of the melt period, while sediment erosion dominated the last portions of the lake drainage event. Following these results, modeled discharge estimates provided in this paper should be considered maximum possible discharge, with actual discharge likely being less.

Lake temperature, as required by the Marsh & Neumann (2001) model, was measured along a vertical profile from the lake surface to lake bed at a typical lake in the study area. Temperatures were measured from late June to early September, a period when many drainage events occur.

Results

Observations of a recent lake drainage channel

During the summer of 2006, a small lake in the study area drained. Although the lake was not observed during the drainage event, observations of the drainage channel soon after lake drainage, demonstrated two features typical of lake drainage as suggested by Mackay (1992) and Marsh & Neumann (2001). First, significant amounts of ground ice were observed along the walls of the drainage channel. Secondly, a surface vegetation mat extended across one portion of the channel, clearly suggesting that at least during the early portion of the event, drainage occurred by subsurface flow through a tunnel. At some point during the event, much of the tunnel collapsed, creating an open channel. Both of these observations further support the hypothesis that lake drainage occurs as tunnel flow through areas of high ground ice concentration, and provide further justification to use an ice-dammed lake model to estimate discharge from rapidly draining lakes (Marsh & Neumann, 2001).

Modeled discharge during lake drainage

Marsh & Neumann (2001) showed the sensitivity of lake discharge during rapid draining events to variations in lake water temperature, channel roughness, and ground ice content. However, due to a lack of data, they did not consider other factors affecting discharge, including lake volume, the length of the drainage channel, and the vertical drop along the drainage channel.

Lake area, volume, channel length, and vertical drop along the channel was obtained from LiDAR data for a series of 5 lakes within the study area and for TVC Lake discussed by Marsh & Neumann (2001). These data show a wide range of lake volumes, with average depth varying from 1.7 to 5.7 m. In addition, channel lengths varied from 8 m to over 500 m, and vertical drop varied between near zero and 14 m (Table 1).

In order to estimate discharge from these lakes during a period of rapid drainage, we used standard values for channel roughness and ground ice content from Marsh & Neumann (2001). Marsh & Neumann (2001) also showed that lake discharge is very sensitive to water temperature, with discharge increasing in magnitude with rising water temperature. The measured average water temperature for one year, from late June to early September, was 13°C at a typical lake in the study area. This temperature was used for all model runs. As noted by Marsh & Neumann (2001), modeled lake discharge increases with water temperature.

Figure 2. shows the discharge vs. time since start of discharge for each of the lakes in Table 1. Note the gradually rising discharge as the channel tunnel increases in cross-sectional area due to ice melting. Discharge continues to increase until the peak value is reached, after which the discharge rapidly drops to zero as the lake volume goes to zero, with maximum discharge ranging from 60 to 370 m^3/s.

As Marsh & Neumann (2001) suggested, however, it is likely that the peak value is less than shown in Figure 2, with the only example from Marsh & Neumann (2001) being 45% of modeled. In that example, discharge peaked,

Table 1. Lake area, volume, channel length, and vertical drop along the lake outlet channel for 6 study lakes as derived from LiDAR.

Lake #	Area ha	Volume m^3	Channel Length m	Vertical drop along lake outlet channel m
245-1	39.5	790,340	540	1
245-2	21.8	435,668	111	1
245-3	50.0	999,904	240	2
220-2	36.0	770,502	318	5
220-1	82.5	1,650,594	8	0.1
147-1 (TVC)	8.5	112,500	450	14
220-2 + 220-1	118.6	2,421,096	318	5

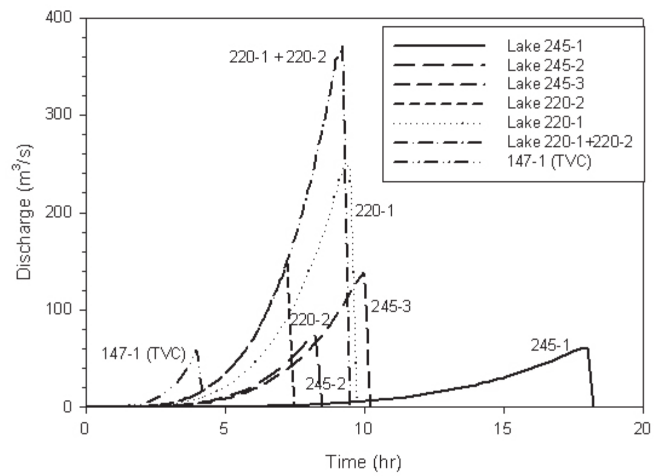

Figure 2. Modeled discharge during rapid lake drainage events. Time is in hours since the start of drainage. Note that Marsh & Neumann (2001) suggested that actual maximum discharge may be less than modeled as the regime changes from melt dominated to erosion dominated.

and then gradually decreased instead of rapidly dropping as shown in Figure 2. Even if discharge peaked at a value of 45% of that shown in Figure 2, it would be extremely high for such small headwater lake basins. For the larger lakes, it is likely that peak discharge would be orders of magnitude higher than the spring peak runoff.

Lake discharge compared to lake area

A total of 41 lakes drained in the study area during the period 1950 to 2007. These lakes varied in area from a minimum of 0.36 ha, to a maximum of 561 ha, with the majority of lakes less than 100 ha in area (Fig. 3). Since the 6 detailed study lakes described above, are within the size range typical of the study area, they allow us to consider the range of discharges that may occur from the majority of rapidly draining lakes.

Using measured lake volume, channel length, and vertical drop along the channel, the modeled discharge increases linearly with area (Fig. 4). The lack of scatter is surprising

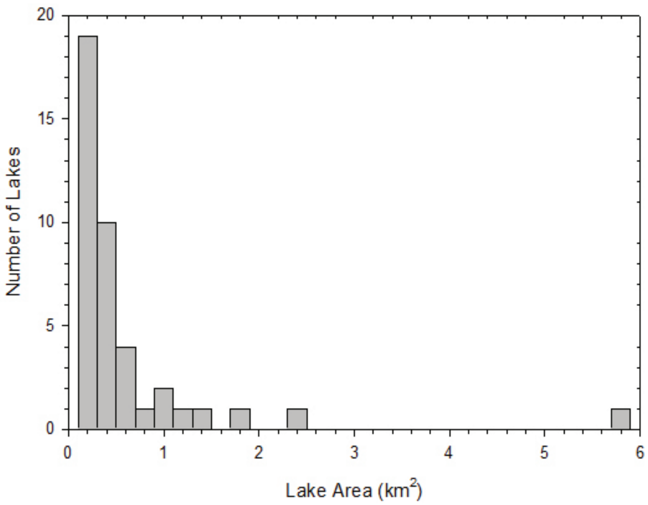

Figure 3. Histogram showing number of lakes within each area group. Note that of the 41 lakes in total, most lakes are in the range from 0 to 100 ha (0 to 1 km^2), a similar range to the 6 lakes in the detailed study area with LiDAR data.

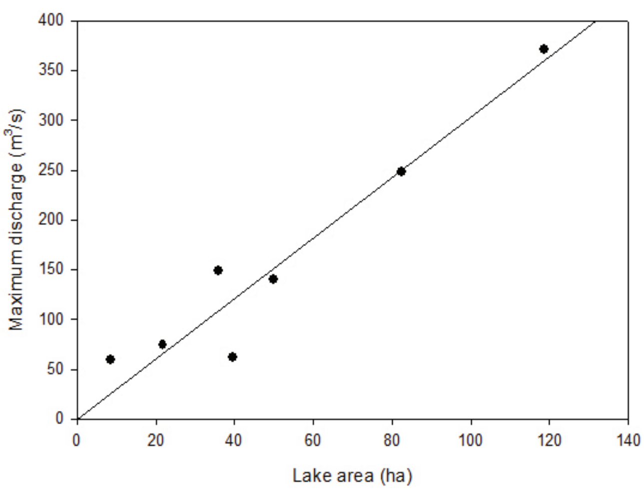

Figure 4. Relationship between lake area and modeled maximum discharge, showing a good linear relationship between the two. However, Marsh & Neumann (2001) suggested that actual maximum discharge is often less than modeled as the regime changes from melt dominated to erosion dominated.

given the range of lake depths (and therefore volume for lakes of any given size) and the variations in channel parameters (Table 1). However, it does suggest that lake size alone, may be used to provide order-of-magnitude estimates of lake discharge.

Although Figure 4 suggests a reasonable relationship between lake area and discharge for a small number of lakes, it would be expected that variations in average depth and channel length and vertical drop along the channel would result in a large variation in discharge for any lake of a given size. Given the data in Table 1, it is possible to estimate the range of possible discharges from rapidly draining lakes, of any given size.

Figure 5 shows possible discharge for increasing lake area, each with a range of lake conditions found in the study area (Table 1). As expected, there is a wide range of possible

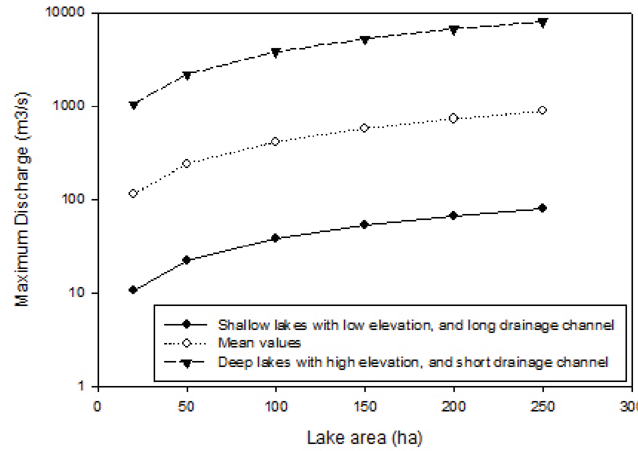

Figure 5. Discharge for lakes with average depth, channel length, and channel slope. Also shown, are maximum expected discharge for deep lakes, with short, steep drainage channels, and for shallow lakes with long, gentle drainage channels.

discharges, with higher discharge for deep lakes with short, steep drainage channels, and lower discharge for shallow lakes, with long, gradual drainage channels.

Grouping of drained lakes

Many drained lakes appear in groups, extending downstream along a drainage path. This is the case with lakes 245-1 to 220-1 shown in Figure 1. It is unknown if such groupings occur due to larger amounts of ground ice and ice wedge occurrence at these sites, or whether drainage occurred in an upstream lake with resulting higher downstream lake levels resulting in drainage of subsequent downstream lakes.

However, for the groupings of lakes 245-1 to 220-1, if drainage first occurred in the furthest upstream lake, we can estimate the maximum rise in water level for each downstream lake from our knowledge of lake areas and volumes.

In this case, drainage of the uppermost two lakes, followed by drainage of each subsequent lake would result in an increase in lake level by approximately 5 m, 14 m, and 34 m in the downstream 3 lakes. The increase in lake level is obviously an over-estimate, as it is assumed that all lake water would be added instantaneously to each downstream lake with no additional outflow from each lake. A complete and more accurate analysis of such a combined drainage event is not possible without additional information. However, it clearly indicates that if an upstream lake drained first, it would result in a very rapid rise in water levels in the downstream lakes. As Mackay (1991) noted, lake drainage can occur in ice-rich terrain under a number of conditions, including high water levels over topping ice wedges, with subsequent melting of ice wedges. Another possibility is that downstream drainage was initiated by mechanical erosion of the existing lake outlet channels and subsequent exposure of ground ice in the channel walls. Once ground ice was exposed, it would likely be prone to rapid melting of ice, channel enlargement, and increased discharge.

Conclusions

Previously drained lakes in the study area north of Inuvik, NWT, range in size up to 560 ha in area, with depths between 1.7 and 5.7 m. Previously published studies and observations in a recently drained lake suggest that lake drainage occurs over a short time, due to melting of ice-rich permafrost, and that flow often occurs within a subsurface tunnel. Detailed information on lake volume, channel length, and vertical drop along the drainage channel from LiDAR, are available for 6 lakes in the study area. Based on these data, as well as measured lake water temperature, and standard values for other parameters from Marsh & Neumann (2001), discharge from these 6 lakes would vary from 60 to 370 m^3/s. Using data for these lakes to estimate a range of possible lake discharge suggests that for shallow lakes with a long, low-slope outlet channel, discharge could range from 10 to 80 m^3/s, while for deep lakes with short, steep outlet channel, the discharge could vary from 1,000 to nearly 10,000 m^3/s. However, as noted by Marsh & Neumann (2001), it is likely that ice melting dominates only the initial rise to a peak, with actual peak discharge being roughly half of that suggested by the ice-dammed lake model. Even with this, model results suggest that discharge from a large, deep, rapidly draining lake could be orders of magnitude higher than that which would occur during spring snowmelt from such small headwater basins.

Acknowledgments

We would like to acknowledge funding from the Program for Energy R&D – Pipelines, from the Environment Canada Northern Energy Project, and from Environment Canada, National Water Research Institute. In addition, fieldwork in such northern locations would not be possible without support from the Aurora Research Institute and Polar Continental Shelf Project.

Ice Wedge Polygon Dynamics in Svalbard: High-Resolution Monitoring by Multiple Techniques

Norikazu Matsuoka
Geoenvironmental Sciences, University of Tsukuba, Tsukuba, Japan
Hanne H. Christiansen
The University Centre in Svalbard, UNIS, Longyearbyen, Norway

Abstract

Techniques were combined to detect the timing and magnitude of thermal contraction cracking and to associate cracking with seasonal soil deformation in low-centered polygonal ground. An ice wedge trough rimmed by ramparts was instrumented with extensometers, breaking cables, shock loggers, thermistors, moisture sensors and an automatic camera. Three years (2004–2007) of monitoring highlighted, in general, symmetrical horizontal movements between the trough and ramparts. The ramparts extended in winter and shrank in summer mainly associated with frost heave and thermal deformation within the active layer. The trough showed the opposite movements, with winter shrinkage and summer extension, except for extension during mid to late winter. The frozen active layer cracked significantly in a very cold period in the late winter of 2006. Following the generation of superficial cracking, the trough began extending when the surface temperature rapidly lowered below -20°C. A major cracking event occurred when the permafrost top temperature reached -10°C, although the crack did not reach the permafrost.

Keywords: field monitoring; ice wedge; periglacial; permafrost; Svalbard; thermal contraction cracking.

Introduction

Thermal contraction cracking and associated ice wedge formation in frozen ground have been studied by theoretical considerations (e.g., Lachenbruch 1962, Plug & Werner 2001) and by field observations (e.g., Mackay & Burn 2002, Fortier & Allard 2005, Kokelj et al. 2007). In particular, long-term monitoring in the Canadian Arctic has provided data on cracking frequency, spatiotemporal variability of cracking activity and seasonal deformation of ice wedge polygons (Mackay 1992, 2000; Mackay & Burn 2002). A notable result is that not only thermal contraction in winter, but also seasonal soil expansion and contraction contribute to the development of the surface morphology and subsurface structure around the polygons. However, the detailed processes of soil deformation and cracking, as well as thermal conditions at which the ground cracks, are still uncertain, because of the lack of continuous recording of soil movement, cracking and contributing parameters.

This paper proposes a synthetic automatic monitoring system allowing year-round, concurrent monitoring of soil dilatation and cracking across a polygon trough, soil temperature, moisture, and snow conditions. Data for the first three years (2004–2007) are combined with data from manual observations of new-crack distribution and soil movement to discuss the timing and detailed processes of soil deformation and cracking.

The Study Site

The monitoring site is located on a fluvial, loess-covered terrace in the Adventdalen valley, Svalbard, Norway (Fig.

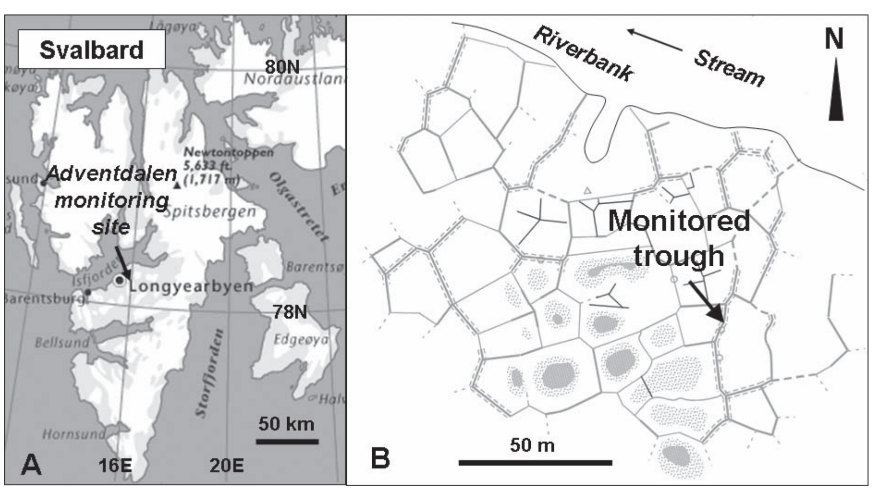

Figure 1. (A) Location map. (B) Polygonal patterns at the monitoring site. Thick solid line: major crack (trough). Thin solid line: secondary crack. Single broken line: tertiary crack. Solid line surrounded by broken lines: trough with well-defined ramparts. Dotted area: bog. Dark area: pond in July 2006.

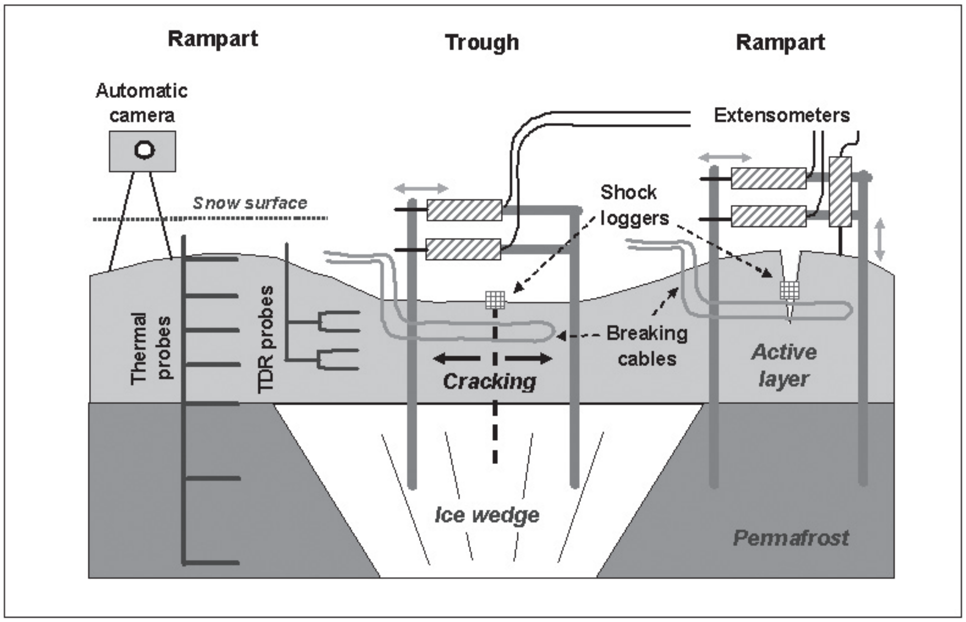

Figure 2. The schema of the automated monitoring system in a section (ca. 5 m wide and 2 m high) across an ice wedge trough with associated ramparts.

1A), where previous investigations report active ice wedge cracking (Christiansen 2005), and field measurements are carried out regularly throughout the year. Low-centered polygons (quadrangles to hexagons) 10–30 m in diameter dominate the ground (Fig. 1B). They are subdivided in places by secondary or tertiary cracks (troughs). The top 1.0 m of the soil consists of fine-grained loess, with the upper 0.5 m rich in organic material. The monitored ice wedge trough is 2.5 m wide and 0.3 m deep, with a rampart on each side. Open cracks develop at the top of the ramparts. Boreholes drilled across the trough showed that the maximum active layer depth (given by the top of the ice wedge) is about 0.95 m, and the ice wedge is about 2.5 m wide at the top.

The mean annual air temperature is -5.3°C and annual precipitation is 192 mm (1986–2006) at the Longyearbyen Airport meteorological station 10 km west of the monitoring site (www.met.no). Large fluctuations in air temperature between 0°C and -20°C to -30°C are common in winter due to the maritime setting with alternations in air masses between low-pressure system coming from the south and polar high-pressure conditions, contrasting with rather stable temperatures (5°C–8°C) in summer.

Instrumentation

Figure 2 illustrates the automatic monitoring system installed in the ice wedge trough and associated ramparts. Soil movements and cracking are monitored with three kinds of instruments. Kyowa extensometers attached to two vertical stakes anchored in permafrost measure horizontal movements across the trough and one of the ramparts at a resolution of 0.04 mm (cf. Matsuoka 1999). The base of the stakes is located at 20–40 cm below the permafrost table. Two extensometers at different heights (0.2 and 0.4 m above the ground) document tilting of the stakes. A vertical extensometer measures frost heave and thaw settlement on the rampart surface. The timing of cracking is monitored hourly by subsurface breaking cables made of very thin copper wires (cf. Mackay 1992) installed at 0.2 and 0.5 cm depth across the trough and in one rampart. Miniature 1-D accelerometers (Tinytag shock loggers, TGP-0605) placed in the top of thermal contraction cracks in the trough (3 loggers), and in the bottom of cracks in the ramparts (4 loggers), provide continuous hourly registration of impacts (e.g., cracking) given by the magnitude of acceleration up to 49 m/s2 at a resolution of 0.2 m/s2. Thermistors measure soil temperatures at 0.02, 0.2, 0.6, 1.0, 1.5 and 2.0 m depths below the top of a rampart every hour. The two deeper thermistors provide temperatures in permafrost and the one at 1.0 m nearly represents the TTOP (temperature at the top of permafrost). Campbell time domain reflectometry (TDR) probes measure the volumetric liquid moisture of the soil at 0.2 and 0.4 m depths below the rampart every six hours. An automatic camera photographs the monitoring site daily to display the snow depth, ground and snow surface conditions.

Following the monitoring of active layer temperatures and snow depth from 2002 (Christiansen 2005), the multi-technique monitoring started in the summer of 2004 (monitoring of the horizontal movement on the rampart started in the 2005 summer). Three years of data have been obtained by the summer of 2007. Most of the sensor-logger systems provided continuous data for the three years. However, problems with data loggers or sensors interrupted data acquisition of permafrost temperatures and vertical soil movement on the rampart in the first year (2004–05), cable breaking on the rampart in the second year (2005–06) and shock events from spring to summer of 2007. A year period is defined here as 365 days from 1 August.

Manual distance measurements have also been carried out since the 2003 summer. Distances between benchmark rods lined across the polygons were periodically measured. The occurrence of new cracks (or recurrence of old cracks) and snow depths are visually inspected all year round.

Results and Interpretations

Soil temperature and moisture

Ground surface temperatures showed significant fluctuations in winter, following air temperatures with minimum time lag (Fig. 3A, B). Such a correlation results from the shallow snow cover, the maximum depth being 5 cm over the ramparts and 30 cm in the troughs. The mean annual TTOP was coldest (-5.2°C) in the first year, followed by the third (-4.2°C) and second (-3.7°C) years.

The first year (2004–05) experienced cold periods in late November with a minimum surface temperature of -25°C and in early March with surface cooling to -33°C. TTOP fell below -10°C only during these two periods, which were separated by a long, relatively warm period.

Figure 3 summarizes results for the later two years (2005–2007), when nearly all datasets were available. The 2005-06 winter on the whole experienced mild climate. However, following a rise to nearly 0°C in mid-January 2006, the ground surface was cooled below -20°C (minimum -23°C) several times in February and March, during which TTOP fell below -10°C (Fig. 3B). The 2006–07 winter was also mild: the surface temperature fell below -20°C only briefly in late January (minimum -23°C) and in early April, and TTOP reached -10°C only in late February.

Water content in the active layer varied seasonally. The unfrozen soil in summer had high and variable contents, whereas the frozen soil in winter had low and stable values (Fig. 3C). The thawed soil at 0.2 m depth showed more varying water contents than at 0.4 m depth. In the 2006 summer, for example, the former experienced a period with relatively low volumetric water contents of 32%–35% from late July to early August, which was preceded and followed by periods with higher water contents of 38–45%, while the water content at 0.4 m depth was nearly stable at 33%–37%. The water content at 0.2 m depth temporarily rose to 62% in the early summer of 2007, reflecting rapid thawing of the soil (cf. Fig. 3B).

Soil deformation and cracking

In the first winter, the horizontal extensometers showed minor seasonal movement (<5 mm) with trough extension in early winter and shrinkage in early summer. Shock loggers located in the trough recorded frequent acceleration events from late February to middle March, when rapid ground cooling resulted in TTOP below -10°C. However, no breaking cables were cut, indicating the absence of cracking in the active layer below the monitored trough. Thus, the shock loggers probably sensed only superficial cracking.

The vertical extensometer recorded frost heave activity within the active layer for the later two years (Fig. 3D). The seasonal frost heave apparently amounted to about 20 mm, but this value probably underestimated the actual amount by about 40 mm, because the lowered level after the annual freeze-thaw cycle in 2005–06 implies upfreezing of the anchored stakes in winter. The lowering was possibly enhanced by deep thaw into the top of ice-rich permafrost during summer. Seasonal thawing was accompanied by two-step settlements in May and August, which presumably originated from thawing of ice-rich layers near the top and bottom of the active layer, respectively (cf. Matsuoka and Hirakawa 2000).

The horizontal extensometers showed, on the whole, opposite movement directions between the trough and rampart (Fig. 3E, F). The trough shrank in early winter and extended in early summer, while the rampart did the opposite at the same time. The symmetrical movements were also confirmed by the manual distance survey of the inter-benchmark distances across several parts of the ice wedge trough and ramparts. The repetition of seasonal movements resulted in interannual expansion of the rampart and contraction of the trough, and the former was about 50% greater than the latter (Fig. 3E, F).

A comparison between horizontal and vertical movements suggests that the crack in the rampart opened during frost heaving in winter and closed during thaw consolidation in summer (Fig. 3D, F). The correspondence was disturbed in early August 2006, during which the rampart crack extended by about 20 mm, while the ground gradually settled. Continuous records of cable breaking were missing, but a manual check of the cable continuity revealed that the two cables in the rampart were cut between 8 July and 16 August, probably due to the crack extension. The crack extension synchronized with the trough shrinkage by about 10 mm. The horizontal movements at both the rampart and trough were nearly stabilized in late August, while the ground significantly settled until seasonal frost heave began.

The horizontal extensometers also indicated temporary tilting of the stakes, as the upper extensometers (0.4 m in height) at both the rampart and trough showed wider annual ranges of horizontal movements than the lower ones (0.2 m) (Fig. 3E, F). The rampart experienced a maximum outward tilting of 1.8° during the third winter, and the trough had a maximum inward tilting of 0.2° during the second winter. Although the direction of tilting changed seasonally, the net outward tilting across the rampart and net inward tilting across the trough cumulated interannually. The former was greater than the latter, which corresponded to the difference in the net rampart extension and trough shrinkage.

The symmetrical movements between the trough and rampart were, however, disturbed in both late winters, during which only the trough extended in response to intensive cooling (Fig. 3E). This movement probably reflected thermal contraction in the frozen soil. The breaking cables in the trough detected cracking only in the second winter (Fig. 3I), although the shock loggers in the trough indicated increasing acceleration when the ground surface cooled rapidly below -15°C in all winters (Fig. 3G). The rampart shock loggers showed significant events which started when the ground

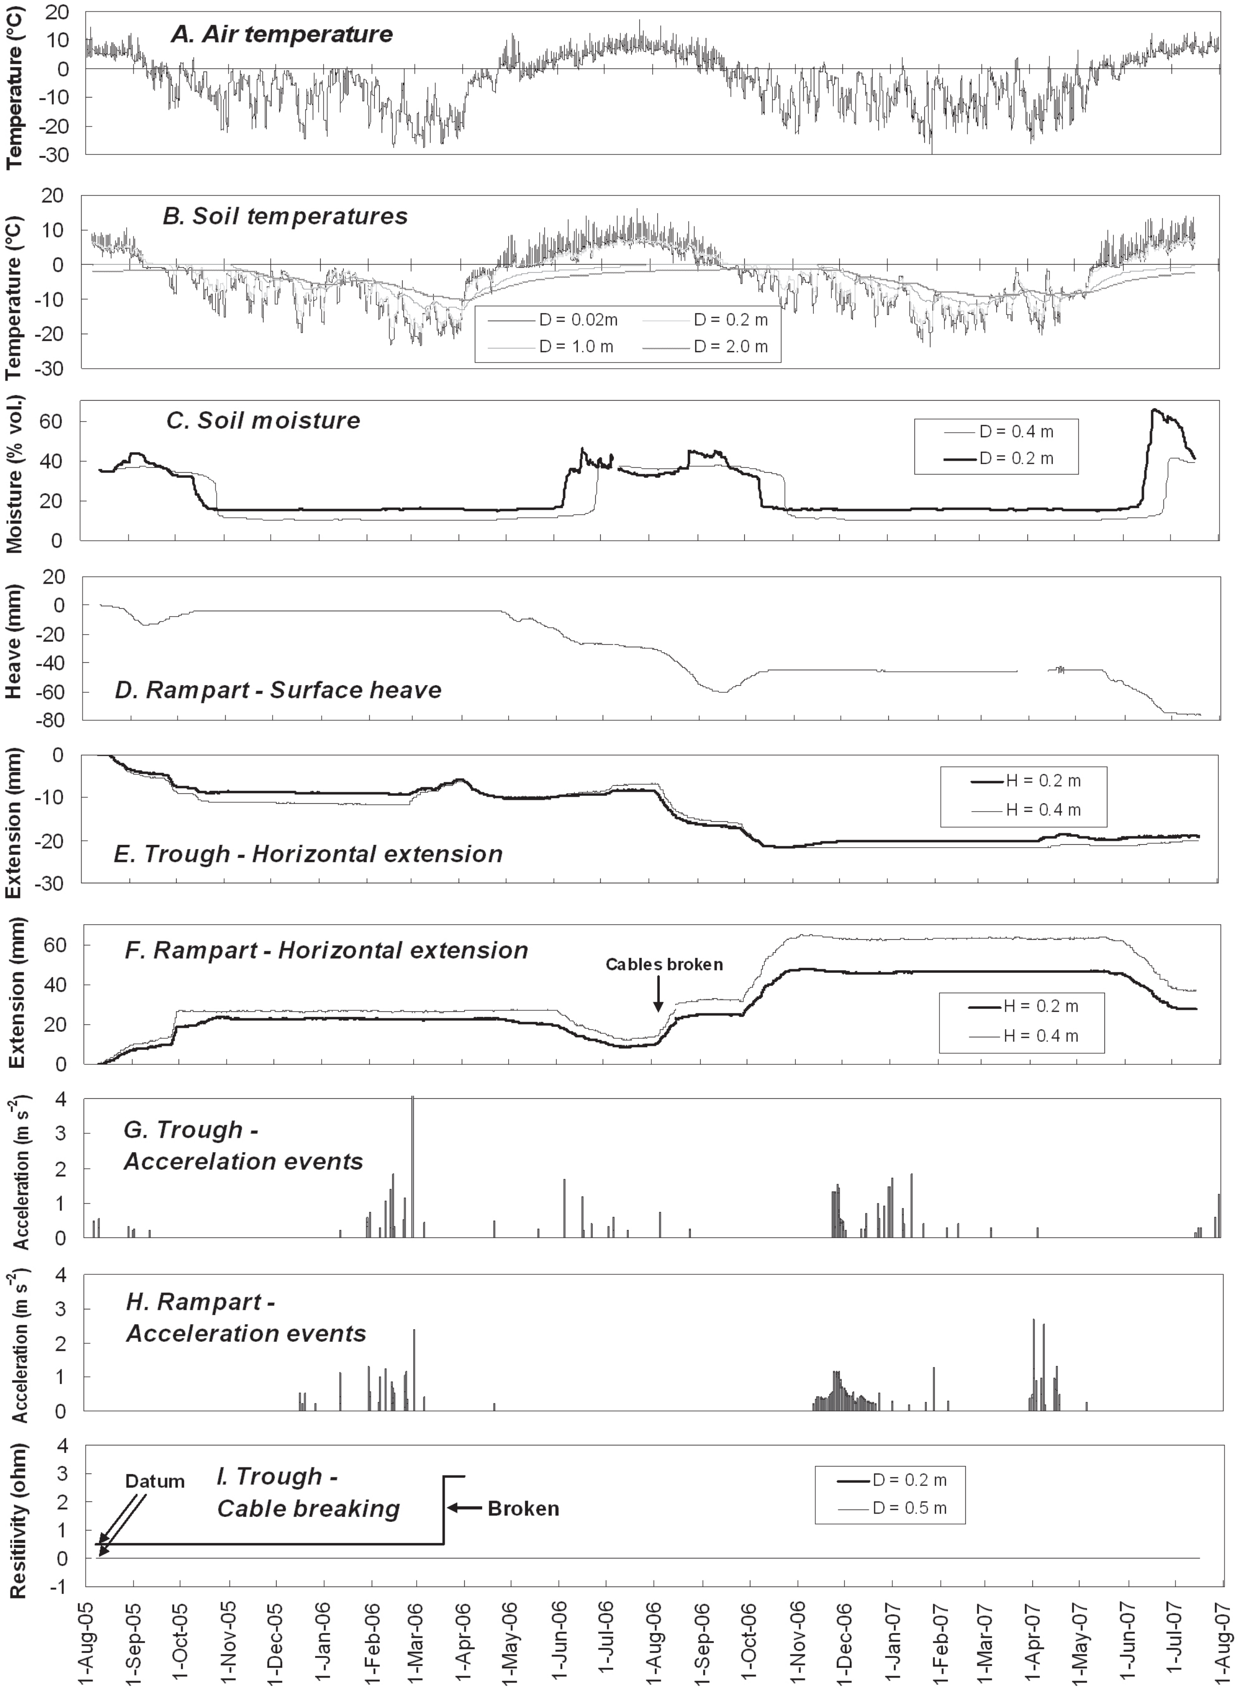

Figure 3. Summary of data from August 2005 to July 2007. The acceleration values in G represent averages of three loggers installed along the monitored trough and those in H averages of four loggers along the rampart. Acceleration values below 0.2 m s^{-2} are removed.

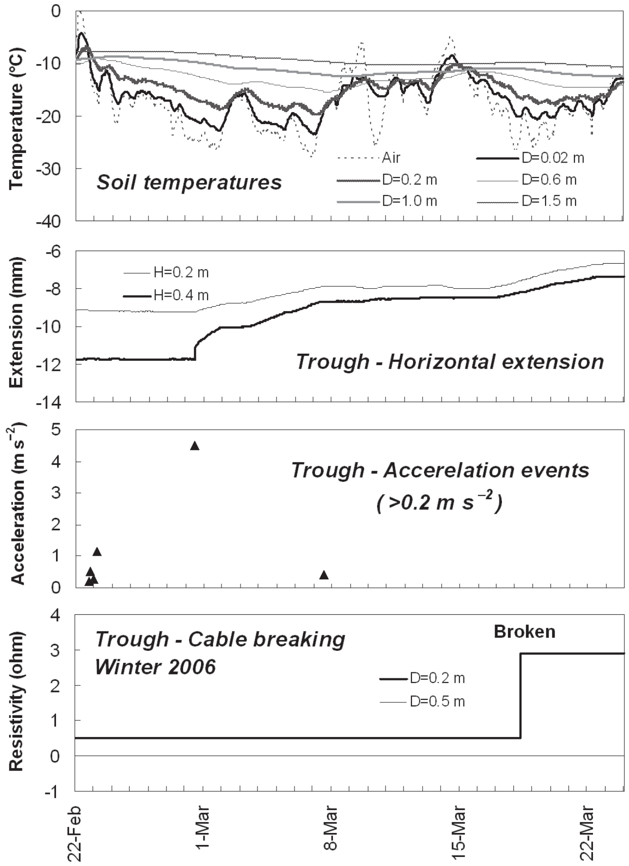

Figure 4. Close-up data in Winter 2006. The acceleration values represent averages of three loggers installed along the monitored trough.

cooled to around -10ºC in mid-December and terminated when the surface temperature became more stable cold around -20ºC in 2006 (Fig. 3H).

All sensors detected cracking in March 2006 (Fig. 4). First, the three shock loggers in the trough recorded frequent and intensifying acceleration events from mid February to early March, which probably indicated increasing superficial cracking starting when the ground had cooled below -10ºC. Next, the horizontal extensometers recorded gradual extension of the trough from 28 February to the end of March, with a relatively stable period in mid March. The copper cable at 0.2 m depth in the trough broke on 18 March, while the deeper cable at 0.5 m depth never broke during the winter. The shock loggers recorded maximum size events on 28 February, but did not record any events on 18 March. The shrinkage of the extensometers in early April (Fig. 3E) indicated the closure of the thermal contraction crack, when the ground started warming significantly (Fig. 3B).

The ground thermal data and visual observations of cracks on the snow surface suggest that a major crack was initiated most likely at the ground surface on 28 February, when the surface temperature fell below -20°C. The crack seems to have propagated gradually into the ground, and up through the snow pack, as the horizontal extension increased, quickest in the beginning (Fig. 4). Interrupted by a warmer and fairly isothermal period in the ground, the crack propagation recurred by rapid cooling and reached below 20 cm depth on 18 March. However, the subsequent termination of the cold period probably prevented further propagation of the crack into the permafrost.

The visual inspection also showed high spatial frequency of new cracks in the second winter. A new crack was actually found on the bottom of the snow-filled monitored trough on 9 April 2006, which supported the cable breaking. Thus, the thermal conditions in March 2006 were favourable for thermal contraction cracking.

In the third winter, similar horizontal movements were reproduced, but only minor late winter extension of the trough was recorded (Fig. 3E). The copper cables did not break. The shock loggers were not operating when the small horizontal extension in the trough occurred, but they did record activity, when ground temperatures first cooled below -10ºC in December. Visual inspection showed the generation of many fewer cracks than in 2006.

Discussion and Perspectives

Distance changes recorded with the vertical and horizontal extensometers and the benchmark poles are likely to reflect, primarily, seasonal thermal deformation and frost heave activity in the polygon and ice wedge trough system. In fact, the crack on the rampart opens during frost heaving in winter and closes during consolidation in summer (Fig. 3D, F). This relation is temporarily disturbed in mid summer, when opening of the rampart crack coincides with ground settlement. Corresponding to the highest near-surface temperatures, this movement appears to originate from thermal expansion in the rampart. The effect of soil moisture change is unclear but can not be ruled out, because the crack extension and subsequent stabilization in summer correspond, respectively, to relatively low water content and to raised water content at 0.2 m depth (Fig. 3C, E): the former possibly indicates crack opening by desiccation.

The symmetrical movements between the rampart and the trough indicate that the seasonal deformation within the active layer below a pair of ramparts basically constrains the deformation of the intervening trough. Before opening of thermal contraction cracks, superficial cracking is generated when the ground cools below around -10ºC, as recorded with the shock loggers. During mid to late winter, however, rapid ground cooling leads to intensive thermally-induced contraction in the frozen ground which has already cooled below -10ºC. The ground contraction induces extension of the trough when the surface temperature falls below -20°C, and crack activity is intensified when TTOP cools below -10°C. If the cold period is lasting for three weeks, a crack will propagate down below 0.2 m and possibly deeper into the ground. During the observed three years, however, the monitored trough did not experience intensive and long-lasting cooling enough to permit cracking into the permafrost. As a result, the ice wedge did not grow. Cracking reaching the ice wedge in the monitored trough most likely requires more rapid and/or intensive cooling, for instance, TTOP below -15°C (e.g., Allard & Kasper 1998, Matsuoka

1999, Fortier & Allard 2005). These results, however, do not exclude the possible occurrence of ice wedge cracking in other troughs at the study site. In fact, excavation of troughs with a number of new cracks in early summer displayed an ice veinlet on the frost table at 0.3–0.5 m depth.

The combination of various techniques presented here enables us to detect seasonal soil deformation and winter thermal contraction cracking activities, including superficial cracking, pre-cracking tensional soil deformation and major, deeper cracking. The observations show that, even in an overall warm winter, temporary intensive cooling can induce significant thermal contraction cracking of the active layer. However, the three years seem to have lacked large-magnitude cooling in combination with long-lasting cold periods which could cause ice wedge growth. This may be due to the recent relatively warm winters, in addition to the maritime Svalbard climate preventing long-lasting cold periods. Acquisition of the detailed critical thermal conditions for ice wedge growth probably requires widely distributed monitoring systems, as well as long-term, continuous monitoring over a decade or more.

The presented ice wedge monitoring system forms part of the project on "standardizing field techniques and constructing a global monitoring network for periglacial processes" that are involved in the activities of the International Permafrost Association Working Group "Periglacial Landforms, Processes and Climate." It will also form part of the periglacial process monitoring in the permafrost observatories that are being established in Svalbard during the International Polar Year in the "Permafrost Observatory Project: A Contribution to the Thermal State of Permafrost" IPY project.

Abstract

Nine-to-twelve-year-long records of thaw-depth monitoring from three 100x100-meter grids in the European Russian Arctic are discussed. The grids belong to the Circumpolar Active Layer Monitoring (CALM) network. In agreement with a warming trend in air temperatures, thaw depths increased almost continuously in the discontinuous permafrost zone and fluctuated with an increasing trend in the continuous permafrost zone. The increases in thaw depth were followed by changes in seasonal thaw patterns. Of climatic indices, the thawing index was best correlated with thaw depths. Differential ground subsidence, as measured at one of the grids, constituted 43% of the thawed permafrost layer and visibly changed the site topography. Statistical analyses highlighted moss and the soil organic layer as limiters of thaw depth with their effect weakening as the thaw increases.

Keywords: active layer; climate warming; ground subsidence; permafrost; thawing index.

Introduction

Numerous publications show climate warming in the Arctic including its Russian sector (e.g., Pavlov & Ananjeva 2004). Circumpolar Active Layer Monitoring (CALM) was organized to trace changes in the active layer (thaw) depth induced by the warming and to study climatic controls over the thaw depth. Over 100 CALM grids employ a common measurement protocol ensuring statistical reliability of results. Ground subsidence, as a hazardous consequence of the active layer thickening, is monitored at many grids.

Three 100x100-m grids operate in the European Russian Arctic with the record length from 9 to 12 years. Intermediate monitoring results were published elsewhere (Mazhitova et al. 2004). In this paper, we discuss longer-term trends based on the CALM measurements.

Materials and Methods

Site descriptions

The Bolvansky grid (68°17.3′N, 54°30.0′E) is located in the continuous permafrost zone, whereas Ayach-Yakha (67°35.4′N, 64°09.0′E) and Talnik (67°19.8′N, 63°44.0′E) are in the discontinuous permafrost zone (Fig. 1). By fall 2007, records were 9-, 12-, and 10-years long, respectively. Soils are upland loamy with 5- to 21-cm thick organic horizons. Altitudes range within 5 m at each grid. Permafrost temperatures at the depth of zero annual temperature amplitude range from -0.6 to -2.5°C. End-of-season thaw depths averaged for the period of observation were 110 cm at Bolvansky, 116 cm at Talnik, and 74 cm at Ayach-Yakha. At Bolvansky and Talnik, local closed taliks occur, occupying a few grid nodes and fluctuating in area from year to year.

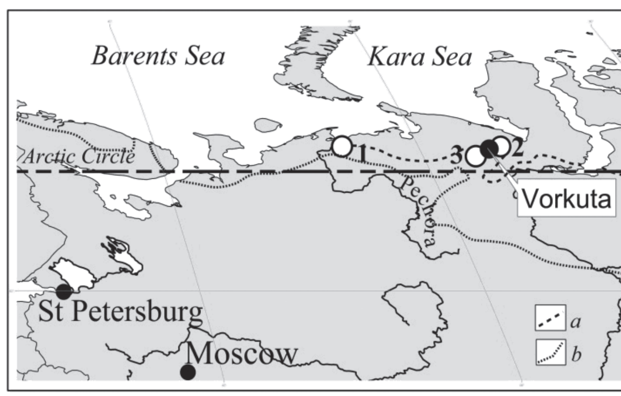

Figure 1. Location of Bolvansky (1), Ayach-Yakha (2), and Talnik (3) CALM grids in the European Russian Arctic. Southern borders of the continuous (a) and the discontinuous (b) permafrost zones are shown.

Field procedures

The European Russian CALM sites employ the standard systematic sampling design recommended under the CALM program (Brown et al. 2000). Permanent grids have been established with 10-m intervals between grid nodes. Grid dimensions are 100 x 100 m at Talnik and Bolvansky and 100 x 90 m at Ayach-Yakha. The nodes are marked with permanent stakes. Thaw depths are determined through 4 replicated measurements at each grid node. Measurements are conducted annually at the end of the warm season with the use of a graduated steel rod. Permafrost at all sites is cemented by ice, and hard enough to avoid errors due to rod penetration into it.

Besides the standardized measurements, additional datasets have been obtained for each grid. These sets differ depending on accessibility and other site-specific characteristics. At Talnik and Ayach-Yakha, seasonal thaw-depth dynamics are monitored through several measurements during the warm season. The same operations are performed at Bolvansky with a lesser number of field sessions due to difficulty of access. At Ayach-Yakha, snow depths are measured at each grid node annually in April. Volumetric water content in the surface soil horizon is determined for each grid node annually at the end of the warm season. At Ayach-Yakha and Talnik, where the portable Vitel Hydra® probe is used for the purpose, water content is determined several more times during the season. Air temperatures at a height of 2 m, as well as soil and upper-permafrost temperatures are recorded at all sites with the use of miniature Onset® data loggers. Permafrost temperatures at the depth of zero annual amplitude are measured in 3 boreholes at Bolvansky. Ground subsidence and/or heave are determined at Ayach-Yakha for each grid node annually at the beginning and at the end of the warm season with the use of a 2H-10KL leveling instrument (Russia) providing for 4 mm accuracy. A benchmark of the national geodetic network located near the grid is used as a base. At the same grid, angular displacement of several permanent pegs is measured to trace downslope ground movements. Moss and soil organic layer thicknesses at each grid node, vegetation maps, and soil descriptions are available for each grid.

Analytical procedures

The thawing index DDT (°C days) was calculated by summing average daily air temperatures for the period, beginning with positive daily averages and ending either with negative daily averages or on the day of grid probing, depending on the purpose. The freezing index FDD (°C days) was calculated by summing negative daily averages. ANOVA was conducted using the General Linear Models module of STATISTICA, version 7.2, software (©StatSoft, Inc).

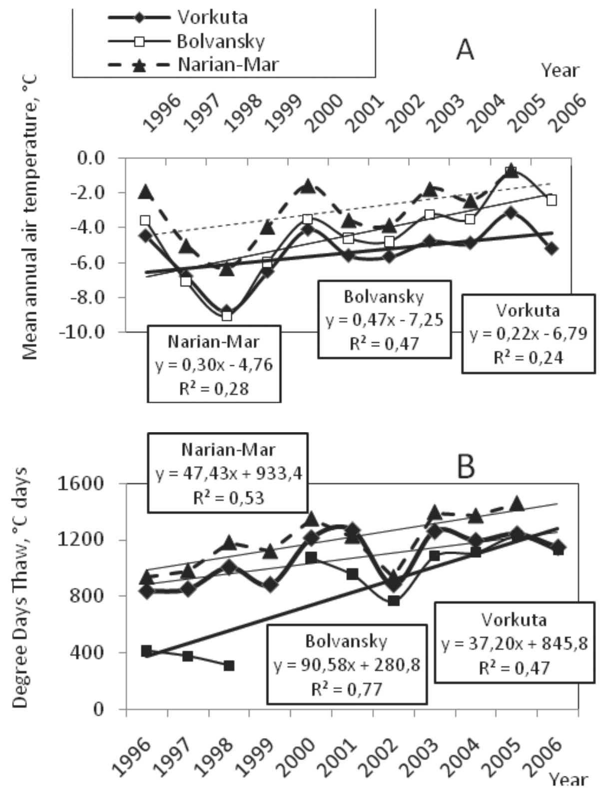

Figure 2. Mean annual air temperature (A) and Degree Days Thaw (B) dynamics during the period of CALM observations at the weather stations nearest to the grids. For Bolvansky, where the weather station was closed in 1999, the values measured at the CALM site are given for 1999–2007.

Results

Climate dynamics

Mean annual air temperature in the European Russian North rhythmically fluctuated during the 20th century, whereas in 1980–2006, showed an increasing trend with 0.02–0.05°C year^{-1} increments (Fig. 2, A). The increments were smaller than those registered in Siberia, where they amounted to 0.08°C year^{-1} (Pavlov & Ananjeva 2004). Mean annual air temperature dynamics during the period of CALM observations at the weather stations nearest to the grids is shown on Figure 2, A. During the same period, increasing trends in the thawing index were observed also (Fig. 2, B). Increases in permafrost temperature at the depth of zero annual temperature amplitude ranged from 0.003 to 0.06°C year^{-1} (Oberman & Mazhitova 2001, Pavlov et al. 2002).

Thaw-depth dynamics

At Ayach-Yakha and Talnik, grid-averaged end-of-season thaw depths showed almost continuous increase during the observation period with average annual increments of 2.3 and 5.5 cm, respectively. At Bolvansky, an increase in thaw depth was not continuous, yet had an increasing trend significant at p = 0.01 level with 1.7-cm annual increments (Fig. 3). Linear trend parameters were as follows: Ayach-Yakha y = 2.32x + 58.52, R^2 = 0.91; Talnik y = 5.51x + 74.38, R^2 = 0.94; Bolvansky y = 1.69x + 97.87, R^2 = 0.66.

Correlation between thaw depths and climatic indices

Thaw-depth dynamics duplicated dynamics of no one climate index; however, the increasing trends in thaw depths agreed with also-increasing, though less-significant, trends in mean annual air temperatures. Regressions of grid-averaged thaw depths by DDT$^{0.5}$ representing a form of Stefan solution (Boyd 1973) were widely used in the active layer modeling. The approximations are highly reliable for all 3 grids with R^2 equal to 0.87–0.92 when not only end-of-season thaw-depth values are used, but also those obtained earlier in the warm season (Fig. 4, A). With only end-of-season values considered (Fig. 4, B), the approximation reliability is obviously higher (significant at $p < 0.01$) for the Bolvansky grid located in the continuous permafrost zone than for the 2 grids located in the discontinuous permafrost zone ($p < 0.05$ for Ayach-Yakha and $p < 0.10$ for Talnik). No significant correlation was found with annual precipitation, liquid precipitation, snow depth, or freezing index. For example,

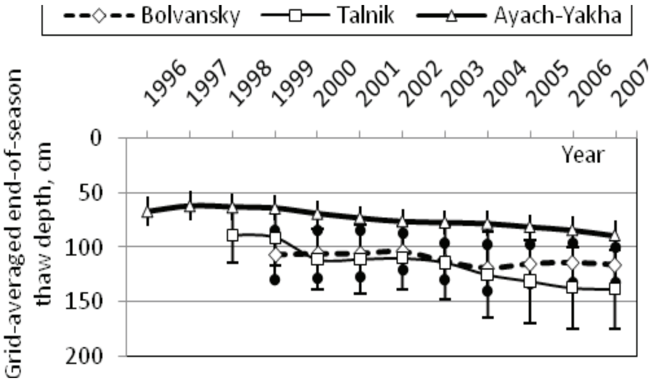

Figure 3. Statistical representation of the end-of-season thaw-depth dynamics at the CALM grids. Values are averages of 484 measurement points at Bolvansky and Talnik, and of 396 measurement points at Ayach-Yakha. One standard deviation extends in either direction.

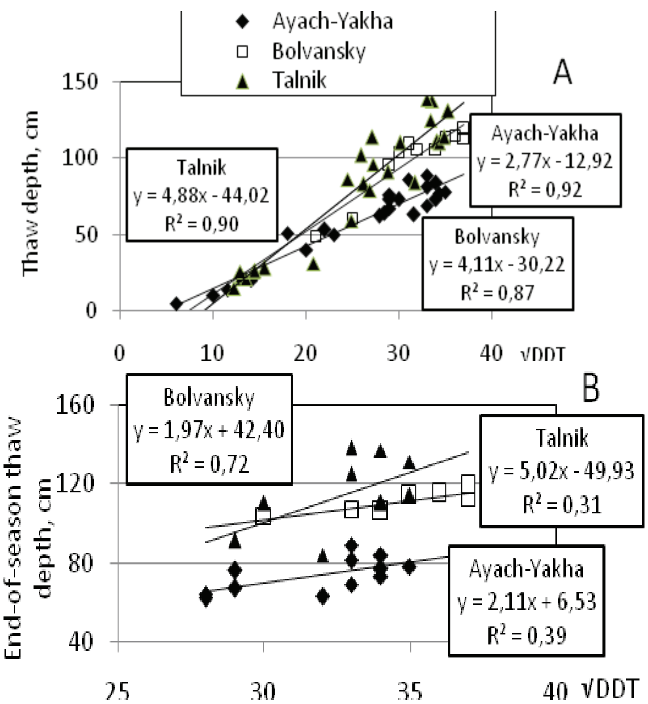

Figure 4. Thaw depth (A) and end-of-season thaw depth (B) plotted against the square root of the thawing index at the three European Russian CALM grids.

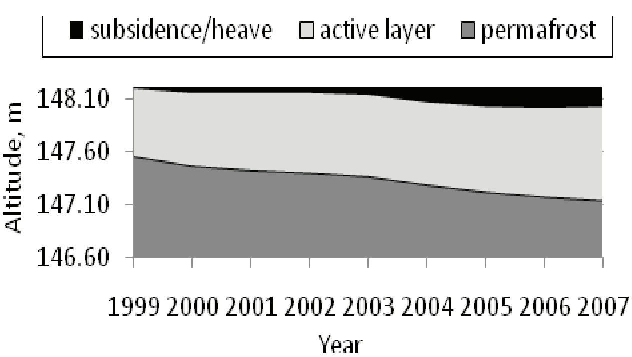

Figure 5. Inter-year dynamics of permafrost table, soil surface subsidence/heave, and active layer thickness at the Ayach-Yakha CALM grid. Grid-averaged altitudes are given for each year.

correlation between freezing index and thaw depth was insignificant ($p > 0.10$) for both Ayach-Yakha with its longer record (correlation coefficient R = 0.64) and Bolvansky with a shorter record (R = 0.01). Node-specific snow depths averaged for the period of observations at Ayach-Yakha showed no significant correlation with node-specific thaw depths averaged for the same period (R = -0.19, $p > 0.10$); similarly, annual site-averaged snow depths were not correlated with annual site-averaged thaw depths (R = 0.52, $p > 0.10$).

Ground heave/subsidence

Thawed or active layer thickness is a function of the permafrost table dynamics and ground heave/subsidence. Interrelations between the 3 indices were studied at the Ayach-Yakha grid. From 1999 to 2007, when these indices were monitored, the permafrost table sank annually at most grid nodes so that the decrease in its grid-averaged altitudes totaled 40 cm (StD 20 cm) by the end of the observation period (Fig. 5). The permafrost layer which had thawed seemed a transient-layer thawing and refreezing under long-term climatic fluctuations (Shur et al. 2005). It had volumetric ice content of 40–50%, higher pH values than those in the active layer, and relatively high organic matter content due to cryoturbations. Because of high ice content in the uppermost permafrost, the permafrost table sinking was followed by ground subsidence. In 1999–2006, the subsidence compensated for winter heave, and in most years its values were nearly proportional to the thickness of the newly thawed permafrost layer (Mazhitova et al. 2004). In 2007, however, though the permafrost table sank farther down, subsidence, for the first time, did not compensate for winter heave at most grid nodes and on grid-average. In that year, thaw at many grid nodes reached the contact between the superficial loess-like loam and the underlying till, and for the first time during the observation period, minor downslope movements of the ground were registered. Three of five reference pegs were found to move 2 cm downslope. In total, from 1999 to 2007, the grid subsided an average of 17 cm (StD 9 cm), with annual increments varying from 7-cm subsidence to 2-cm heave. Grid-averaged end-of-season thaw depth increased by 23 cm (StD 11 cm). Given 40 cm of permafrost table sinking, if we assess the latter based on the increase in thaw depth, only without considering subsidence, it would be 43% underestimated (23 cm instead of 40 cm).

Topographic changes

At Ayach-Yakha, changes in soil-surface and permafrost-table topography due to multi-year differential subsidence/heave were monitored in 1999–2007. Initial surface topography was represented by a 3° slope with a shoulder in the middle part of the grid. Smaller landforms were local rises, dips, and a hollow with several transverse partitions crossing the grid. Permafrost table topography mostly duplicated the soil surface topography; however, the range of altitudes was 30 to 40% wider. Only slightly heaved active frost boils occupying 3% of the grid area demonstrated the opposite pattern with the permafrost table mirroring soil-surface to-

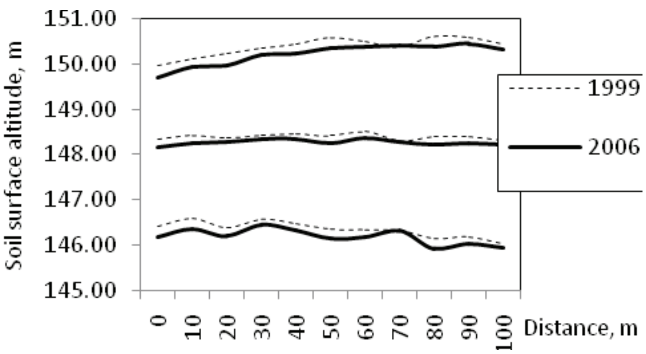

Figure 6. Changes in soil surface topography due to differential subsidence/heave as exemplified by three cross-sections through the Ayach-Yakha CALM grid.

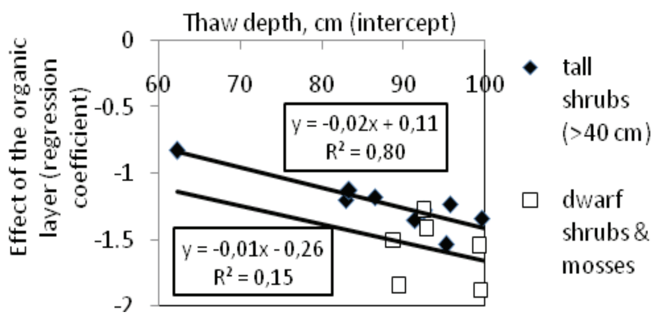

Figure 9. Moss/peat layer effect on thaw depth versus actual thaw depth expressed as the intercept and the coefficient of multiple linear regression, respectively. The independent variables included in the regression were the same as on Figure 8.

pography under them. In total, node-specific deviations of permafrost-table and soil-surface altitudes from the corresponding 2-dimentional linear surfaces modeled with the use of the least square regressions were correlated with R = 0.91. From 1999 to 2007, spatially-differential permafrost sinking changed the permafrost table topography. As the node-specific sinking values were well-correlated with subsidence values, soil surface topography changed accordingly (Fig. 6).

Changes in seasonal thawing pattern

Climate-induced intensification of the thawing process led to evident changes in seasonal patterns. As an example, seasonal thaw-depth dynamics in years with contrast weather conditions are presented for the Talnik grid (Fig. 7).

In 1999 (shallow thaw), thaw depth in late July was only 34% of the end-of-season value. The same value in 2007 (deepest thaw) was 87%. Late July thaw depth, averaged for the period of observations, was 75% of the end-of-season value. The displacement of maximal seasonal thawing rates to the earlier part of the warm season can be concluded.

Components of the thaw depth spatial variance

For the Ayach-Yakha grid, ANOVA under the General Linear Model approach was performed to reveal landscape predictors of thaw depth. Analyzed was the 1999–2005 period, since 1999 altitudes of all grid nodes were measured annually; the 2006–2007 data were not yet processed. Continuous independent variables were (1) surface "macro" topography (altitudes of grid nodes, range width 5 m); (2) surface "meso" topography (deviations of grid node altitudes from the 2-dimentional linear slope approximating the site surface, range width 1.2 m); (3) end-of-season volumetric water content in the upper soil layer, values from 10 to 82 %; and (4) organic (dense moss + peat) layer thickness, values from 4 to 21 cm. A categorical variable was (5) vegetation class (dwarf-shrub/moss versus tall shrubs). Sample size was 396 thaw depth; i.e., dependent variable, values (4 at each of 99 grid nodes) measured annually during 7 years; 99 annual measurements of dynamic independent variables 1–3, and 396 measurements of the organic layer thickness (4 at each of 99 grid nodes) conducted once.

In different years the examined factors explained in total from 18 to 33% of the end-of-season thaw-depth variability, with the organic-layer thickness explaining the largest portion of the latter compared to other variables (Fig. 8).

The effect of the organic layer was sensitive to thaw depth; it weakened as the latter increased, showing a linear trend significant at $p = 0.01$ for the vegetation class of tall (>40 cm) shrubs typical of the southern tundra (Fig. 9).

Discussion

Three European Russian CALM grids demonstrated increasing trends in the depth of thaw during the recent decade. In 2007 compared to 1999, the latter being the first year when all 3 grids were in operation in the discontinuous permafrost zone, thaw depths increased by 40% at Ayach-Yakha with its shallow thaw and by 51% at Talnik with deep thaw. The Bolvansky grid in the continuous permafrost zone, also with a deep thaw, showed only 9% increase, but still a high level of the trend significance: R^2 0.7 versus 0.9 at the 2 other grids. Given synchronous air temperature dynamics over the region as shown by weather stations, grid locations in dominant upland landscapes, and the maximum distance between the grids as large as 400 km, it is likely that the 3 records represent the main regional trend in thaw depth.

In the region under discussion, permafrost monitoring is conducted by the geological service. Thaw depths are mostly estimated indirectly based on ground temperature measurements at several depths. Only selected monitoring data were published. It was reported that from 1975–1995, thaw depths increased all over the region with exceptions registered at drained lake beds and technogenic sites (Oberman & Mazhitova 2001). For 1980–2003, data from 3 boreholes located at the Vorkuta field station 60 km south-west from the city of Vorkuta (see Fig. 1) were published (Pavlov et al. 2004). The authors, however, mentioned that more sites had been monitored during the same period and that, on average, a slightly increasing trend in thaw depths was observed. Still, the 3 selected records show different thaw-depth trends from 1999–2003: stability, increase, and decrease. Surprisingly, in the preceding 19 years the same sites demonstrated synchronous dynamics. On the whole, the bulk of our and other authors' data suggest that the increase in thaw depth was the dominant, though not universal, trend in the region during the recent 3 decades.

Correlation between thaw depth and climatic indices is widely discussed in the literature. As was shown above, at the 3 European Russian CALM grids end-of-season thaw depths were correlated with the thawing index at significance levels from $p = 0.01$ to $p = 0.10$. The R^2 values of corresponding linear regressions were 0.31–0.39 for the 2 sites located in the discontinuous permafrost zone. The value reported from the aforementioned Vorkuta field station located in the same zone is 0.44, based on the 1988–2003 period and a larger number of sites (Pavlov et al. 2004). During the period of our observations, the range of thawing index values composed 70% of its long-term range displayed by the 1947–2006 record of the Vorkuta weather station. Not represented were extremely cool summer seasons, whereas the extremely warm seasons responsible for thaw-depth jumping (Shur et al. 2005) were fully represented. The range of annual precipitation composed 80% and liquid precipitation 60% of the corresponding long-term ranges. These estimates show that the observation period covered most, though not all, of the long-term variability of climate indices. Still, thaw depths showed no statistically significant correlation with precipitation, snow depth, freezing index, or water content in the uppermost soil layer. Thawing index then seems to be the major control on thaw depth at present though under climatic warming. As other indices exceed the bounds of their natural variability, their effect on thaw depths can strengthen.

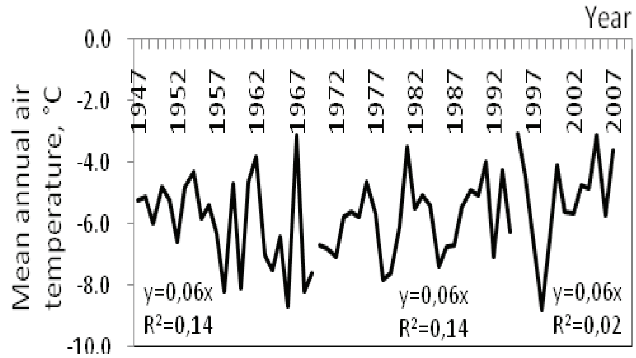

Figure 10. Trends in mean annual air temperature at the Vorkuta weather station. From left to right: a cooling branch of the assumed half-century climatic cycle, a warming branch of the same cycle, and the trend of recent 12 years.

Correlation between thaw depths and thawing index was confirmed by a large number of regressions based on long-term meteorological records from Siberia (Frauenfeld et al. 2004). Monitoring results from numerous CALM grids located in the Kolyma lowland in East Siberia (Fedorov-Davydov et al. 2004) showed that thaw depths were correlated with mean summer temperatures at upland landscapes and were not at intra-zonal landscapes. It is possible that the transitional position of most monitored sites explains the absence of the thawing index–thaw-depth correlation in Yakutia (Pavlov et al. 2004). North American data (Hinkel & Nelson 2003) suggest that thaw-depth response to air temperature forcing is best described by Markovian algorithm with a leading role of extremely warm or cool summer seasons in thaw-depth dynamics.

It is known that the lack of reliable climatic scenario impedes a climate change impacts assessment. Pronounced effects of natural climatic variability on permafrost conditions in the study region were reported. The monitoring conducted by the geological service showed effects of the warming branch of about a half-century climatic cycle (Oberman & Kakunov 2002, Oberman & Mazhitova 2003). A cooling branch, which onset was expected since the mid-1990s, did not show; however, instead, an insignificant ($p > 0.10$) warming trend was observed (Fig. 10).

A climatic scenario was developed for the study region by P. Kuhry using the HadCM2S750 model (Mazhitova et al. 2004). The modeling took into account a natural climatic variability signal and assumed gradual CO_2 increase in the atmosphere during the 21st century with stabilization at the 750 ppm level. The outcome was a lack of trend during the first quarter of the 21st century with further rapid warming by 3°C by 2085. Thaw depths, as modeled based on this scenario (V. Romanovsky in the same paper), were characterized by 30%-of-the-mean fluctuations during the first quarter of the 21st century, followed by an increase with talik formation in the mineral soil and peatland in 15 and in 70–75 years after the start of warming, respectively. During the recent decade, our observations and those of other authors agreed better with the modeled trend than with the trend expected under the superiority of natural climatic variability.

CALM design ensures high precision of major indices determination. At Ayach-Yakha, thaw depth was correlated with thawing index with the grid-averaged correlation coefficient (R) value of 0.36. However, R values were above the average (up to 0.6) at grid nodes located at even and convex micro-sites, whereas below the average and often negative (-0.6 to 0.2) at concave micro-sites. From the CALM grids in Yakutia, higher inertance of the thaw depth was reported for concave compared to convex micro-sites (Fedorov-Davydov et al. 2004). These examples highlight advantages of the CALM statistical approach and warn about possible errors of point measurements.

Conclusions

A climate warming signal in the European Russian Arctic, though weaker than that in Siberia, exerts itself on the sensitive high-temperature permafrost. Depths of seasonal ground thaw show increasing trends especially clear in the discontinuous permafrost zone. Potential increases in active layer thickness which could result from the sinking of permafrost table are partly consumed by ground subsidence. Thawing index correlates with seasonal and inter-annual thaw-depth dynamics in the greatest degree compared to other climatic indices. At present, permafrost is still protected from rapid thaw by a high-icy transient layer and the insulating effect of moss/peat layer. Regressions obtained, however, show that the latter effect weakens with the active layer thickening. Together with passing the threshold of the transient layer, this can lead to acceleration of thaw in the nearest future if the warming trend persists. Continuation of the monitoring with special regard to developing proper up-scaling methods is highly desirable.

Acknowledgments

The study was funded by the NSF through the grants OPP-9732051 and OPP-0352958. Help in the fieldwork and with data processing was provided by Drs. D. Drozdov, D. Karelin, D. Kaverin, and E. Vanchikova, and Mr. A. Kalmykov. Dr. J. Kimble upgraded the English.

The Degradation of Ice Wedges in the Colville River Delta and Their Role in Pond Drainage

Molly McGraw
Southeastern Louisiana University, Hammond, LA USA

Abstract

A 58-year record of aerial photographs was used to examine bank retreat, the thermoerosion of ice wedges, and subsequent tapping of the ponds in the Colville River delta, Alaska, USA. The photographic record consists of aerial photographs acquired during seven different years between 1948 and 2006. ArcGIS was used to determine the rate of bank erosion and melting of the interconnecting ice wedges. The riverbank has eroded approximately 38 meters during the 58-year study period. This erosion is equal to a rate of about 0.7 m/year. Most of the bank erosion (29 m) occurred since 1971. The rate of degradation of the ice wedges, as reflected in trough size, coincides with the rate of bank erosion. The tapping of the first lake—that is, the one closest to the river—occurred between 1992 and 2002, while the other lakes drained between 2002 and 2006.

Keywords: Colville; degradation; ice wedge; lake drainage.

Introduction

The Colville River is the largest river north of the Brooks Range, Alaska, USA. The 600-km-long river is located entirely within the zone of continuous permafrost. The river flows through three physiographic provinces: the Arctic Mountains, the Arctic Foothills, and the Arctic Coastal Plain (Wahrahaftig 1965), before discharging into the Arctic Ocean 75 km west of Prudhoe Bay (Fig. 1). The Colville River delta is 600 km^2 in size, and the head of the delta lies 40 km south of the Arctic Ocean.

Both high-centered and low-centered polygons are found in the delta. High-centered polygons are generally found on river bluffs, adjacent to large thermokarst lakes. Low-centered polygons are the most common type of polygon and are found throughout the delta. The low-centered polygons frequently convert to high-centered polygons due to thermal erosion (Walker 1983). When low-centered polygons are located adjacent to a riverbank that contains a high concentration of peat, the ice wedges undergo faster thermoerosion than the peat. This disproportionate thermoerosion of the riverbank results in an uneven or serrated form of the bank (Fig. 2).

Lakes and ponds occupy roughly 16% of the delta (Walker 1978). This concentration of lakes is similar to other areas of Alaska's Arctic Coastal Plain, where lakes occupy approximately 20% of the area (Black 1969, Sellman et al. 1975, Frohn et al. 2005). Oriented lakes occur near the mouth of the west or Nechelik channel; channel lakes are found in abandoned river channels; and seasonal point bar lakes, in the ridge-swale systems of point bars. However, the most common lakes in the Colville Delta are ice wedge polygon and thaw lakes (Walker 1983).

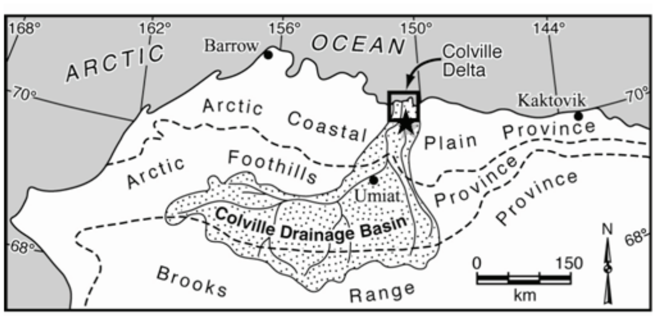

Figure 1. Location of the Colville River. The black star indicates the location of the study site.

The formation, degradation, and reformation, i.e., thaw cycle, of thermokarst lakes, has been the subject of much research (Britton 1958, Black 1969, Hopkins 1949, Lord et al. 1974, Billings & Peterson 1980, Everett 1980, Jorgensen & Osterkamp 2005, Jorgenson & Shur 2007). Thaw ponds form over ice wedge troughs and in the center of low-centered polygons. Low-centered polygons have shallow circular depressions that are completely enclosed by a low ridge or dyke. These depressions fill with meltwater and form ponds and lakes.

The ponds/lakes may expand laterally from mechanical erosion due to wave action and/or thermoerosion. During the summer months, the low albedo of lake water may absorb up to seven times the solar radiation of the surrounding soil (Harris 2002), contributing to the thawing of the surrounding

Figure 2. An example of a serrated riverbank along the Colville River. Photograph courtesy of H.J. Walker.

Figure 3. Peat overhanging the river. Photograph courtesy of H.J. Walker.

permafrost and ice wedge nets. In addition to albedo, lateral expansion rates also depend upon soil texture and ice content and the thickness of the overlaying organic mat (Jorgenson & Osterkamp 2005). Occasionally expansion taps into an adjacent lake. This is one of the main mechanisms for the coalescence of tundra lakes.

Catastrophic drainage of the ponds/lakes is common and may be triggered by tapping, bank overflow, stream piracy, and ice wedge degradation (Mackay 1988, Walker 1978). The Colville River is frozen for up to eight months of the year. During this period, snowdrifts protect the riverbanks from erosion. As temperatures rise in the spring, meltwater begins to accumulate on the surface of the river ice, and water begins to flow. The flowing water melts the snowdrifts and begins to undercut the riverbank producing a thermoerosional niche. The niche widens and deepens with increased water velocity and increasing water temperatures. If the niche deepens enough, the overlying peat will overhang the river and eventually slough into the river (Williams & Smith 1989, Jorgenson & Osterkamp 2005) (Fig. 3). During flood stage, the material that has sloughed off of the bank during the previous season is transported downriver exposing ice wedges. The ice wedges begin to progressively melt away from the riverbank (Fig. 4) and may lead to the eventual tapping and draining of adjacent thaw ponds (Walker 1983).

After drainage, organic matter begins to accumulate in the center of the drained lake basin. Eventually the ice wedges will regenerate and form low-centered polygons and the cycle will repeat its self.

Remote sensing has been extensively used to classify and study morphologic features on Alaska's Arctic Coastal Plain and the Colville River delta. Dawson (1975) used aerial photographs to analyze the distribution of landforms in the Colville River delta. During the 1980s, both Mossa (1983) and Roselle (1988) examined landforms within the delta using aerial photographs. Mossa (1983) compared the use of aerial photographs to satellite imagery to classify and determine the distribution of ice wedge polygons in the delta. Roselle (1988) examined lake tapping using aerial photographs.

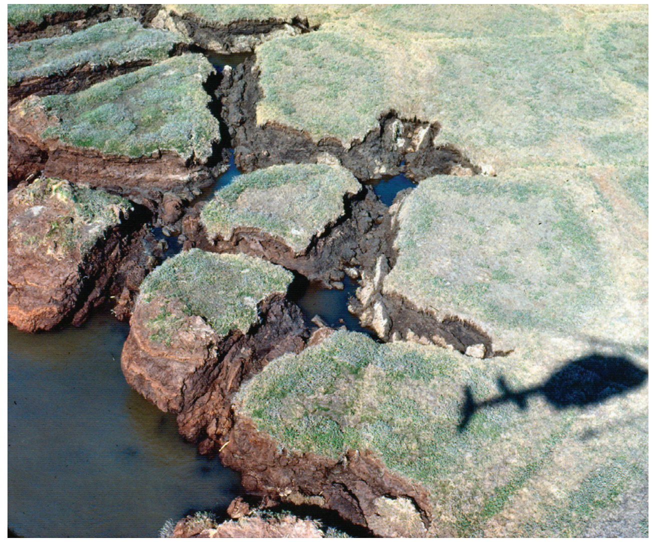

Figure 4. Progressive melting of polygons. Photograph courtesy of H.J. Walker.

Recent studies by Frohn et al. (2005), Hinkel et al. (2007), and Riordan et al. (2006), employed both aerial photographs and satellite imagery to examine the temporal change in several large thaw lakes near Barrow, Alaska. Jefferies et al. (2005) explored the use of various types of remotely sensed imagery, including aerial photographs, satellite imagery, synthetic aperture radar (SAR), and passive microwave, to study the behavior of ice on frozen tundra lakes. Aerial photographs have also been used to examine temporal change in ice wedge degradation in northern Alaska (Jorgenson et al. 2006).

This paper examines the interconnection between riverbank erosion, the degradation of an ice wedge net, and the draining of several small thaw lakes in the Colville River delta using a temporal series of aerial photographs. The photographic record spans a period of 58 years and provides excellent documentation of geomorphic change.

Study Site

The study site, consisting of three small thaw ponds, is located on the right bank at the head of the delta (70°10′20″N, 150°54′31″W). The shallow drained ponds are located on the apex of a cutbank and are aligned roughly perpendicular to the river (Fig. 5). The ponds are roughly 2+ m deep and range in size from 500 m^2 to 1500 m^2. Pond A, the largest of the three ponds, is situated approximately 108 m (as measured from the center of the pond) from the riverbank. The pond is oblong shaped and appears to be the result of the coalescence of 2 or more smaller ponds. Ponds B and C are small, 500 m^2, circular ponds located 30 m and 64 m, respectively, from the riverbank. A well-developed melted ice wedge trough system connects the 3 ponds and the river.

The tundra surface in the vicinity of the pond is flat to gently sloping and is occupied by non-orthogonal polygons and numerous small-to-medium thaw lakes. The soils are silty loam and overlain with a thick layer of peat. The peat

acts as a thermal regulator, moderating thermal erosion of the underlying soil. The serrated riverbank is an active cutbank and is approximately 4 m high at this location. Ice-shove ridges are present.

Methods

Aerial photography was used to examine bank retreat, the thermoerosion of the ice wedges, and subsequent tapping of the ponds. The photographic record consists of 7 sets of high-resolution aerial photographs made between 1948 and 2006 (Fig. 6). The pre-1992 imagery was scanned at a resolution of 600 dots per inch (dpi) and georectified to a 2002 Digital Orthophoto Quarter Quadrangle (DOQQ) of the Colville River delta, obtained from the United States Geological Survey (USGS) Alaska Science Center. Because the distinctive character of ice wedge polygons allows the precise identification of specific locations (Walker et al. 1987), the intersection of ice wedges were selected as ground control points (GCPs) for each scanned image. The rectification process of each image produced a Root Mean Square (RMS) of less than 1. Rectification and subsequent analysis was performed using ArcGIS 9.2. The 2006 photograph (Fig. 6g) is oblique and was not georectified; therefore, it was not used in the bank retreat calculations. Instead, the 2006 oblique image was used to ascertain spatial change in the ponds and ice wedge net.

In order to determine the rate of bank retreat, 3 sets of feature class shapefiles were produced for each image. First, a shapefile containing control points was created. The control points were established at roughly equal intervals parallel to the riverbank (Fig. 7). Next, a guideline shapefile was generated. The guideline file contained lines extending out from the control points to the riverbank; these lines intersected the riverbank at 90-degree angles. Finally, a reference point shapefile was created for each image. Reference points were placed at the intersection of the guidelines and the riverbank. The difference between the control points and the reference points was calculated for each image using Hawth's Analysis Tools. The cumulative change in the distance was graphed in Excel (Fig. 8).

The thermoerosion of the ice wedges and lake tapping was explored by comparing the photographs. The integrity of the 3 study ponds and the ice wedges adjacent to and connecting the ponds was examined and noted for each photographic dataset. The datasets were then compared to earlier and later datasets, and a chronology of morphologic change occurring at the site was developed.

In addition to the photographic record, a ground and aerial survey of the thaw ponds was conducted by the author. The ponds were visited during the summer of 2006.

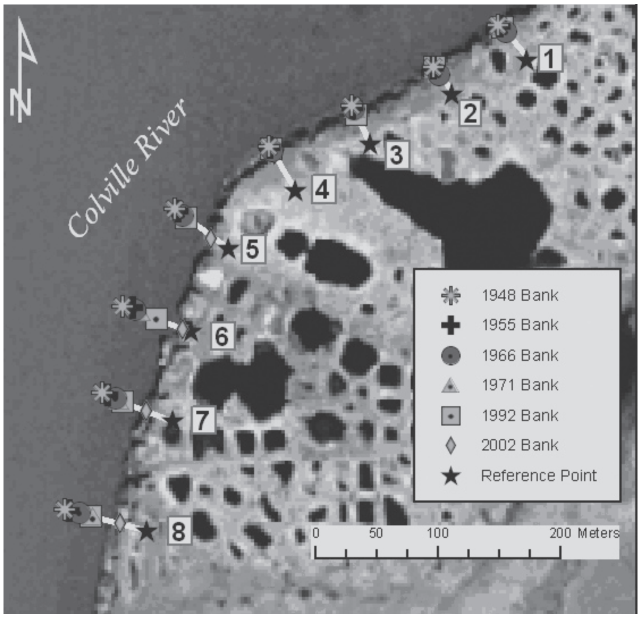

Figure 7. Bank retreat during the period 1948–2002.

Results

A comparison of the 1948 aerial photograph to subsequent aerial photographs traces the bank retreat, thermoerosion of adjacent ice wedges, and tapping of the 3 ponds. The cutbank, where the study site is located, has experienced differential retreat since 1948, with the southern or upstream bank experiencing the most retreat (Fig. 8). In 1948, Ponds A, B, and C are clearly visible, and the remnants of a fourth drained and partially eroded pond (Pond D) is evident adjacent to the riverbank (Figs. 6a, 9). Ponds A and B are joined by a well-defined 3-m long by 4-m wide trough created from the melting of an ice wedge. A longer 16 m by 2 m trough is present linking Pond C to the partially eroded pond.

By 1955 the entire bank has experienced a fairly steady retreat. The southern bank eroded about 5.7 m and the northern bank, approximately 3.7 m. The bank near Pond D had eroded ~3 m during this 7-year period (Fig. 6b).There appears to be no spatial change in the ice wedge net or in Ponds A, B, and C during this time.

Between 1955 and 1971, significant differential bank erosion occurred, with the southern bank experiencing almost 5 times more retreat than the northern bank. The southern bank retreated an average of 24 m compared to 5 m of retreat in the northern end (Fig. 8). Other than the almost-complete disappearance of Pond D by 1966 (Fig. 6c), there appears to be little spatial change in Ponds A, B, and C and in the adjacent ice wedge net during this time frame (Figs. 6b, c, d).

Similar to the previous time period, the 21-year period between 1971 and 1992 showed dramatic differential riverbank erosion, the southern bank retreating approximately 39 m compared to an average retreat of 4 m on the northern bank (Fig. 8). This steady, continuous bank erosion allowed thermoerosion of the ice wedge connecting the river to Pond C and the subsequent draining of Pond C by 1992 (Fig. 6e). This ice wedge, being perpendicular and adjacent to the river, was subjected to the annual thermoerosion of river floodwater and from thermoerosion and possible wave action of the surface water in Pond C. Additionally, Jorgenson et al (2006) suggests that the degradation of massive ice wedges has increased in northern Alaska since the early 1980s. He attributes this increase in degradation to the increase in regional summer temperatures. This multipronged erosion resulted in increased widening and deepening of the ice wedge trough as shown in subsequent photographs of this period.

The rapid bank retreat and thermoerosion of the ice wedge connecting Pond C to the riverbank continued during the next 10 years. A comparison of the 1992 and 2002 aerial photographs (Figs. 6e, f) shows uniform bank retreat along the entire riverbank. The southern bank retreated about 4 m during this time compared to 5 m for the northern bank. Additionally, an ice wedge trough between Ponds B and C has appeared by 2002, indicating degradation of the ice wedge linking Ponds C and B.

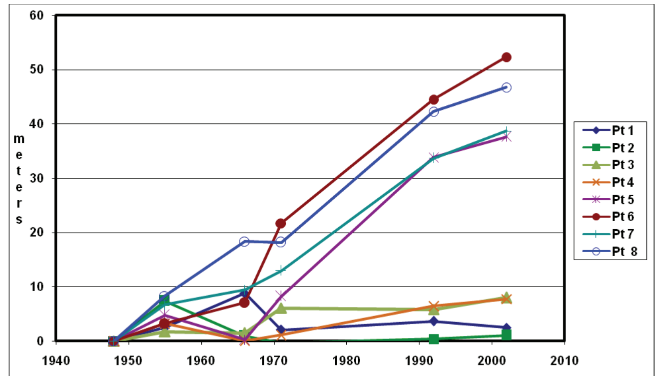

Figure 8. Calculated bank erosion rates from 1948–2002.

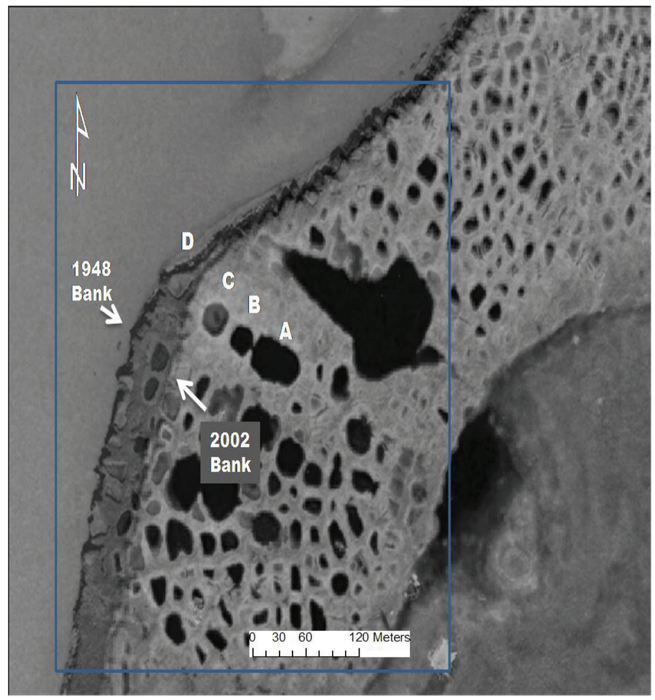

Figure 9. Figure showing the overall bank erosion from 1948 to 2002. Note the presence of a partially eroded polygon (D).

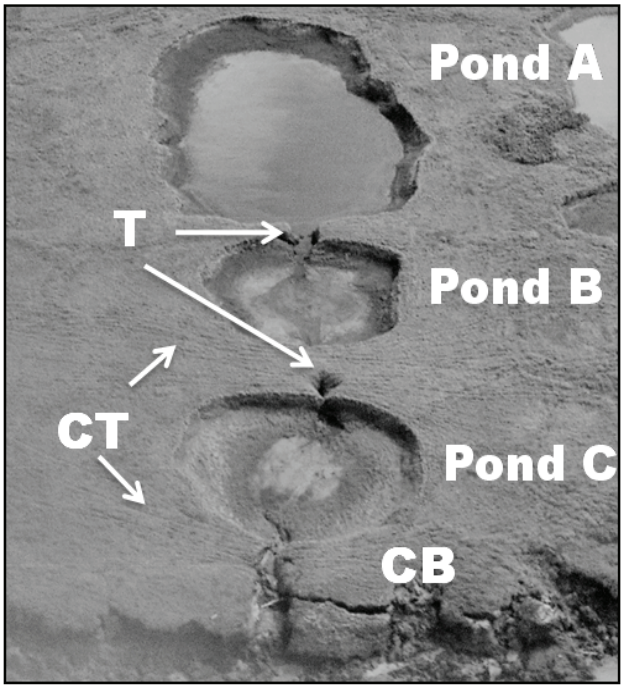

Figure 10. 2006 oblique aerial photograph of the thaw ponds. Note the melted ice wedge tunnels (T), caribou trails (CT), and collapse block (CB).

By 2006, vegetation is becoming established in Pond C, Pond B has drained and Pond A is partially drained (Figs. 6g, 10). The partial draining of Pond A suggests that the ponds were tapped during the 2006 flood. A partially collapsed melted ice wedge tunnel appears between Ponds B and C. Ice wedges which are oriented perpendicular to the river melt faster than ice in the surrounding peat, and may create a tunnel under the peat layer (Fig. 10). As evidenced by linear trails, the land bridges over the tunnels are used by caribou moving across the tundra.

Conclusion

In summary, the 58-year photographic record provides an excellent look into the sequential morphologic changes of an ice wedge net and associated thaw lakes. The photographic record clearly shows thermoerosion of an ice wedge net from both river floodwater and surface pond water. The riverbank adjacent to the study site has experience differential retreat for most of the study period. The greatest difference in the upstream or southern bank retreat and the downstream or northern bank retreat occurred from 1955 to 1992, when the southern bank was eroding as much as 10 times more than the northern bank.

The rate of ice wedge melt is tied to the local bank erosion. The degradation of interconnected ice wedges, all of which are perpendicular to the river, increased with the increasing riverbank erosion. The thermoerosion from river floodwater and surface water in the ponds, have degraded the ice wedges enough to allow the sequential drainage of each of the 3 ponds.

Managing Ice-Rich Permafrost Exposed During Construction

Robert L. McHattie

Abstract

In northern Alaska ice-rich permafrost is often encountered during the construction of roads and other projects. When ice-rich permafrost is exposed during late spring through early fall, the potential for thawing is great. Ice-rich permafrost, typically silts with segregated ice or massive ground ice, experiences a substantial reduction in strength owing to the exceedingly high water content and lack of drainage and consolidation during thaw. The result can be a quagmire that "bogs down" equipment or, if the exposure is a cutslope, slope failure. In addition to stability and trafficability problems, environmental oversight increasingly focuses on particulate-rich effluent and poor aesthetics which are common by-products of the thaw process. In future scenarios, even visually-clear effluent produced during thawing could be classified as biologically toxic and require treatment before release from the project site. This study presents several construction projects in northern Alaska where problems due to thawing permafrost became a significant environmental concern. Several techniques now used (or proposed) for mitigating the problems are briefly discussed.

Keywords: construction; environment; excavation; ice-rich permafrost; management; thawing.

Introduction

Thawing of ice-rich permafrost has produced a number of problems on Alaskan projects including substantially reduced equipment mobility, uncontrolled erosion and runoff, and slope failures. The consequences of thawed ice-rich permafrost are environmental distress, project delays, change orders, and claims. Well-defined procedures are lacking to handle ice-rich permafrost and manage a site with exposed ice-rich permafrost. In the context of this paper, the definition of "ice-rich" permafrost is *any* permafrost material with a water content sufficiently high to cause "problems" upon thawing. Given this context, and the recent advancement of environmental regulations, monitoring, and enforcement, the definitions of "ice-rich" and "problem" can be expected to change with time.

Unfortunately, various types of construction problems related to thawed ice-rich permafrost, documented more than one-half century ago, still occur. In many instances the mitigation strategies employed to reduce the consequences of thawing permafrost only met with partial success or were completely unsuccessful. Newer environmental laws have defined as unacceptable some of the techniques that were recognized as "best practice" for many years.

At present, the construction engineer charged with the successful completion of a project in a permafrost environment has few, if any, resources available to identify a suitable mitigation strategy, particularly in an era of increasingly stringent and challenging environmental regulations. Environmental pressures continue to increase the trend to make long-accepted Alaska Department of Transportation and Public Facilities (ADOT&PF) methods for dealing with ice-rich permafrost either undesirable or unacceptable.

This study examines several construction projects in northern Alaska where problems caused by thawed ice-rich permafrost were of major concern. Techniques employed or proposed to mitigate the problems are described. The purpose of the study is to promote awareness of changing environmental concerns with respect to construction in a permafrost environment and encourage practices that will satisfy the increasing oversight of resource/regulatory agencies.

Problem Background

In northern Alaska exposure of ice-rich permafrost during construction of roads and other projects is an all too common occurrence (Fig. 1). Ice-rich permafrost exposed during late spring through early fall has a very high potential to thaw. Permafrost excavated in winter will cause severe problems if it is not properly disposed of prior to spring thaw. When thawed, ice-rich permafrost, typically silts with segregated ice or massive ground ice, experiences a substantial reduction in strength owing to the exceedingly high water content and lack of drainage and consolidation during the thawing process. The result can be a quagmire in which construction equipment is "bogged down" or, if the exposure is on a cutslope, a slope failure will result (Fig. 2). Aside from stability and trafficability problems, serious environmental issues arise when thawed particulate-laden fluids (sometimes dense slurries) must be controlled. In future scenarios, even visually clear effluent collected from thawed permafrost may have to be treated prior to release from the project site.

Thawing of ice-rich soils has posed problems since the first construction projects in permafrost environments. During the summer of 1954, the Alaska Road Commission exposed

Figure 1. Road cut in ice-rich permafrost (ADOT&PF file photo).

Figure 2. Thaw degradation of cutslope in ice-rich permafrost inducing slope failure (ADOT&PF file photo).

ice-rich permafrost (lake silts) two miles north of Paxson (Fig. 3). Upon thawing, the material actually started to flow. Problems associated with thawing of ice-rich permafrost occurred on a number of North American road projects over the next half-century and have been reported for a number of international projects as well. Slumping of thawed material was noted on several cutslopes in ice-rich permafrost along the Qinghai-Tibet railroad. Chinese researchers report a close correlation relating thaw damage to the orientation of the cutslope (which has been noted by a number of other professionals). Specifically, failures on south-facing slopes were usually more common and dramatic than failures on north-facing slopes. The south-facing slope has a warmer mean annual ground temperature below the sliding mass due to more intense solar heating when compared to the north-facing slope.

A recent example (from 2005 to 2007) of thaw-related problems is provided by the Dalton Highway, just north of Milepost 35. Figure 4 shows a cut that extended about 300 m (1000 ft) in total length. During drilling exploration, the cut volume was judged to be bedrock and weathered bedrock. The cut was designed to have a stepped backslope and also incorporated an interceptor ditch for collecting water along the top of the slope (to prevent erosion of the slope face). The cut design was appropriate for the expected fairly competent weathered bedrock. However, much of the bedrock cut material was not only highly weathered but also ice-rich. There was no special containment berm used for the excavated material. It was simply stockpiled (see Fig. 4b). Fortunately, the stockpile of excavated material didn't "run" as it thawed as might have occurred. However, there were cutslope failures and maintenance issues that required attention as shown in Figure 5.

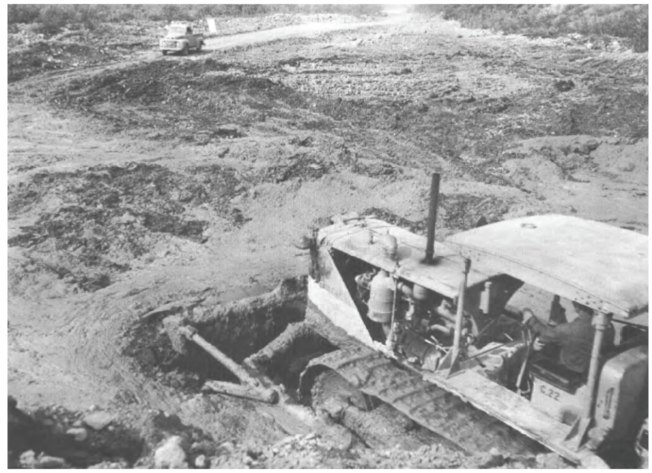

Figure 3. Thawed ice-rich permafrost flowing around a bulldozer blade. Ice-rich permafrost (lake silts) were exposed during the construction of the Richardson Highway (Photograph by Pewe 1954).

Disposal of excavated material is one of the most common problems associated with exposing ice-rich permafrost. It is no longer acceptable to simply waste the excavated permafrost at a convenient location without regard to the environmental consequences of failure or runoff from the eventually thawed material. One solution to the disposal of excavated permafrost is to construct retention berms and place the permafrost inside the berms as shown in Figures 6 and 7. When the ice-rich permafrost eventually thaws, it is restricted to the area inside the berms. The berm shown in Figure 6 allowed the thaw water to escape and cause other environmental concerns. Future retainment schemes may be complicated if excess water generated during thawing needs treatment prior to release from the containment area.

Finally, a problem in western Alaska, also related to permafrost degradation, is the use of excavated permafrost to construct road and airfield embankments. This unusual practice is necessary owing to the scarcity of suitable embankment fill at some locations. Permafrost is excavated in the winter and placed in the location of the required embankment (similar to the waste embankment shown in Fig. 7). Over a period of several years, the permafrost fill progressively thaws and becomes increasingly stable and viable as a runway embankment. If the thawed material is restrained from lateral spreading and flow, it eventually settles and drains and can be shaped and compacted to form the final load-supporting embankment. Snow berms can be placed adjacent to the embankment sideslopes to retain

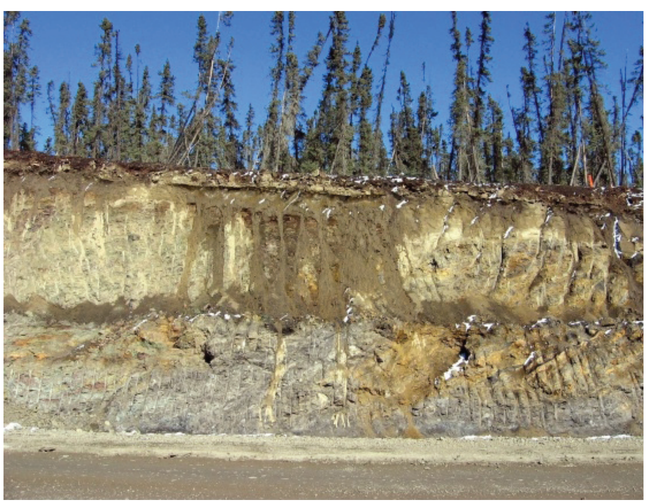
(4b) View across permafrost waste pile at newly cutslope face in ice-rich permafrost. The volume of waste exceeded the boundary limits of the permitted area.



(4c) Ice-rich permafrost cutslope just starting to thaw.

Figure 4. Dalton Highway cut in ice-rich permafrost–before thaw (all photographs from ADOT&PF file courtesy of S. Lamont & J. Russell).

the thawing permafrost. Thawed soil, initially retained by the snow berm, drains and forms its own soil berm that continues to contain the spread of additional thawed material after the snow disappears. In the future, with all containment schemes, excess water collected behind the berms may need to be processed before release.

Mitigation Strategies for Ice-Rich Cutslopes

Documented concern for the instability of cutslopes in ice-rich permafrost and massive ground ice was presented in the 1969 design guidelines for the 123-km (56-mile) Livengood to Yukon River initial segment of the Trans Alaska Pipeline System (TAPS) haul road (Rooney 2006). The original engineer's sketch of the procedure to be employed is shown in Figure 8.

Anecdotal and published sources of information suggest that several techniques have been employed, with varying degrees of success, to mitigate problems related to thawing ice-rich permafrost. A few examples are:

- Berg and Smith (1976), based on observations along the TAPS haul road, presented the procedure shown in Figure 9. At the time of construction, trees are cleared (by hand to minimize environmental damage) for a distance equal to 1½ H_{CUT}. The cut is nearly vertical (1/4H:1V). The road grade is undercut approximately 1.5 m (5 ft) before placement of the gravel embankment. Wide ditches that will accommodate slumpage, while facilitating drainage flow and "cleanout," are constructed at the toe of the slope. During the first summer, the slope degrades rapidly. Hydraulic seeding is applied late in the thaw season (for best results). The lateral ditch is cleaned as necessary. The rate of degradation of the backslope decreases over a number of years. After 5 or 6 years, the slope usually becomes relatively stable and covered with surface vegetation that restores thermal equilibrium.
- Cutslopes may be protected with insulation to ensure stability and prevent slump material from reaching the drainage system.
- Cover the cutslope with a vegetation mat (closed netting) to provide minor insulation plus shading.
- Reduce the slope inclination to 1½H or 2H:1V; place topsoil on the slope; seed at 2 to 3 times the "normal" application rate (best suited to non-ice-rich permafrost)
- Cut the ice-rich permafrost slope about 1½H:1V and place a gravel berm adjacent to the slope face (berm height = cutslope height). The horizontal width of the berm is approximately 8 ft to facilitate construction, and the berm sideslope is approximately 1½H:1V

(5a) Pockets of thaw failure along cut face. —A gravel drainage blanket (left side of photo) was installed to slow thawing, retard slumping of thawed material, and provide drainage during the thawing process.

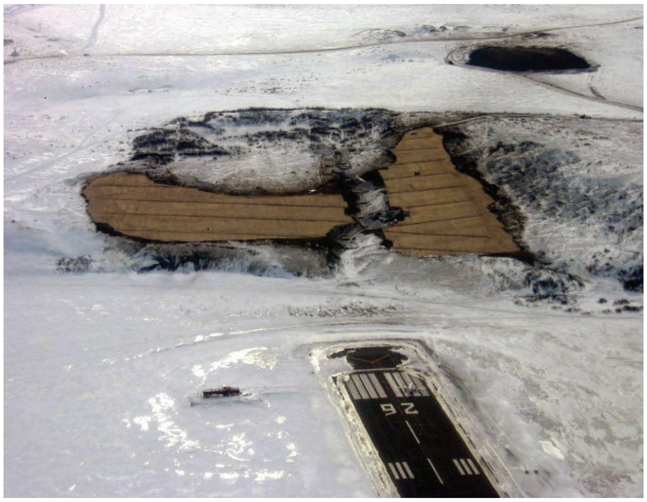
(5b) Advanced thaw condition along ice-rich permafrost cutslope shows ditch filling with saturated silt.

(5c) Advanced thaw degradation of cutslope shows block failures and runoff of highly fluid silt into ditch.

(5d) Advanced cutslope thaw with silty runoff flowing in ditch and general slumping of coarser material.

Figure 5. Dalton Highway cut in ice-rich permafrost—after thaw. (All photographs from ADOT&PF file courtesy of S. Lamont & J. Russell.). Each photograph shows damage that occurred as thawing progressed. The photos emphasize four major types of damage and associated environmental problems created during thawing: (1) damage above the cutslope, (2) damage on the cutslope, (3) ditch damage, and (4) high-particulate runoff. The damage creates and/or exacerbates the runoff problem. With much (and long-term) attention to ditch maintenance, such problems have "healed' themselves in the past when thawing progressed to a depth at which additional slumping and runoff finally ceased. Today, however, environmental-concerns/laws and close agency attention no longer permit creation of a problem that may continue for years. Methods must be devised to minimize, or hopefully eliminate, the types of damage shown in the photographs. Photograph 5a (left side) shows an example of a gravel drainage blanket used to slow thawing, retard slumping of thawed material, and provide drainage during the thawing process.

Figure 6. Containment structure for excavated permafrost on the North Slope of Alaska (photograph courtesy of G. Griffin).



(7a) The top of a hill that extended into aircraft glidepaths was excavated to improve the approach to the runway. Synthetic matting (center brown areas) was placed on exposed permafrost to retard thaw and erosion and promote stabilizing plant growth.

(7c) Close-up view of newly-placed snow berm and ice-rich permafrost waste material behind snow berm.

(7d) Organic material contained in snow berm that remains after berm thaw (spring).

(7e) Organic remnants from thawed snow berm (summer). Note vegetation growth on waste pile.

Figure 7. Kotzebue runway improvement, April through August 2006 (all photographs from ADOT&PF file courtesy of S. Lamont). The purpose of project was to excavate the top of a hill that extended into the glidepath of aircraft (7a). During wintertime excavation of ice-rich materials in western Alaska, nearby snow may be the only choice of material available that can be piled up to provide retainment for excavated permafrost. Photographs 7b and 7c show the newly-constructed snow berm. The "snow" berm is actually composed of snow plus miscellaneous vegetation, soil, and rock detritus unavoidably included as the snow is collected. Photographs 7d and 7e show the berm after it progressed through a spring and summer's thawing. The vegetative matter in the berm is exposed and remains as the snow thaws. During thaw, the increasingly exposed vegetation and other non-snow materials helps shade and insulate the underlying remaining frozen berm. The retained (thawing) permafrost tended to stay in place as it and the berm thawed, suggesting the berm may not have provided appreciable retainment as expected.

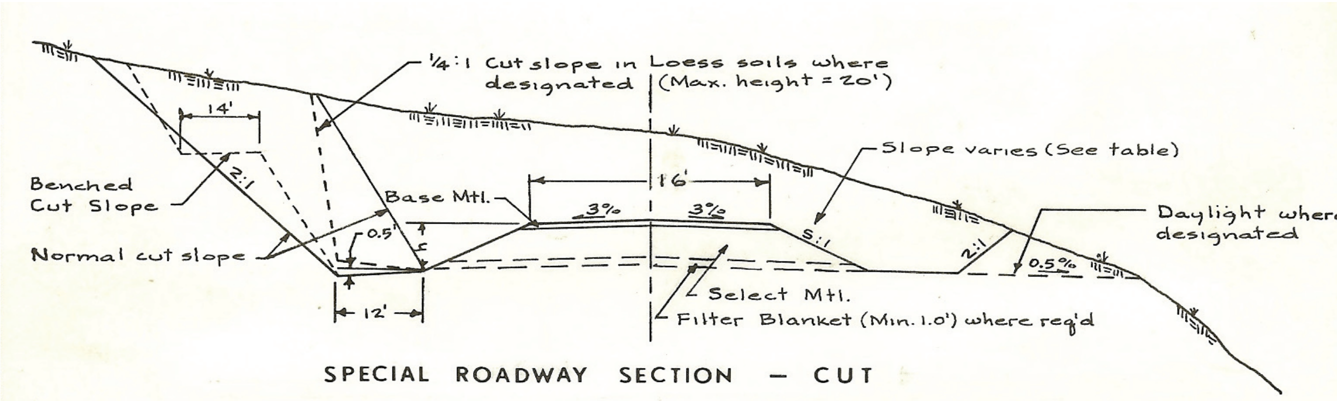

Figure 8. Original 1969 engineer's sketch of the procedure to be employed in a "special roadway section" defined as ice rich or massive ice cutslopes (after Rooney, pers. com.).

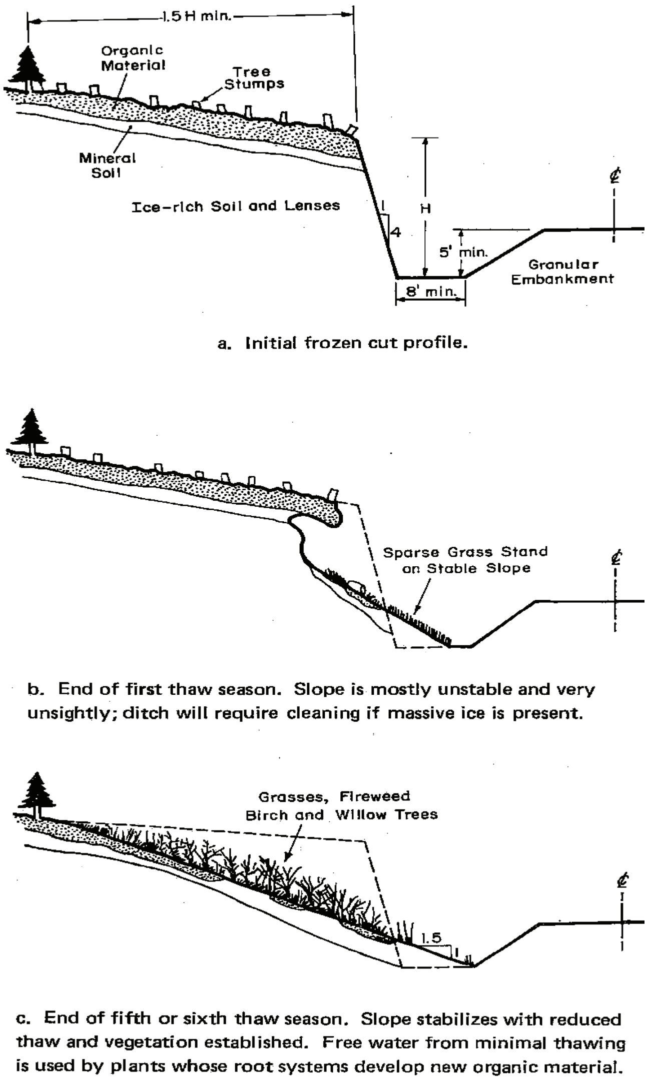

Figure 9. Idealized development of stability in ice rich cut (after Berg & Smith 1976).

Summary and Conclusions

At the present time engineers in Alaska do not possess a synthesis of design and construction methods to deal with the following:

- exposed and thawing ice-rich permafrost
- disposal of excavated ice-rich permafrost
- the use of permafrost to construct an embankment.

Increasing resource agency oversight requires evaluating all methods previously employed to address these problems, a number of which are reported herein, with respect to their environmental acceptability in addition to their engineering/constructability attributes. Best construction management practices will develop after a balance between reasonably attainable environmental goals and economical/practical engineering solutions is achieved.

Abstract

Methane and propane hydrate formation on 0.15–2.0 mm water droplets and dissociation of the hydrate droplets were studied optically at 243–275 K. The instrument setup and the experimental procedure have been described. For the first time, the formation of liquid (supercooled) water during the hydrate dissociation was reliably detected in the temperature range of 253–270 K. The induction time for recrystallization of the metastable liquid water into ice varied from tens of hours at 270 K to a few seconds at 253 K. The dissociation pressure of the hydrates was measured, and the molar enthalpy of hydrate dissociation was calculated. In the temperature range of 253–270 K the molar enthalpy of dissociation for hydrates formed on the water droplets agrees well with the molar enthalpy of the bulk hydrate dissociation into water (liquid) and gas at T>273 K.

Keywords: dissociation; gas hydrates; ice; self-preservation, supercooled water.

Introduction

Detection of anomalously low rates of gas hydrate dissociation below the ice point (Davidson et al. 1986, Stern et al. 2001, Yakushev & Istomin 1992) is one of the most significant results on the kinetics of hydrate dissociation obtained in recent years. First observed under specific laboratory conditions, the gas hydrate dissociation rate decreased in some cases to zero, so the phenomenon was named the gas hydrate self-preservation effect (Yakushev & Istomin 1992). The effect is interesting not only from the viewpoint of basic research on the thermodynamics and mechanism of this phenomenon, but also from a practical perspective. Because of the effect, it is possible to store and transport natural gas in the gas hydrate form at a pressure of 1 atm and temperatures of 253–268 K (Gudmundsson et al. 2000). At present, such technologies are being developed in some countries, primarily in the USA, Norway, Japan, and England (Rogers et al. 2005). It is suggested also that due to the self-preservation effect, gas hydrates can exist in the upper layers of permafrost (at depths of 150–200 m) outside their thermodynamic field of stability as metastable (relic) gas hydrates (Dallimore & Collett 1995, Ershov & Yakushev 1992). Gas hydrate accumulations in permafrost can also cause incidents associated with drilling and production operations in the northern hydrocarbon fields. Because of permafrost thawing in response to global warming, there is a possibility that shallow, self-preserved gas hydrates could liberate methane gas to the atmosphere when they are decomposed.

It is supposed by some authors (Davidson et al. 1986, Yakushev & Istomin 1992) that the anomalously low hydrate dissociation rate is caused by the formation of an impermeable ice coating on the surface of hydrate particles, which develops in the initial stage of hydrate dissociation. However, the mechanism of ice formation and development of an impermeable ice coating on the hydrate surface is still poorly understood. We previously reported (Melnikov et al. 2003a, b) that during propane hydrate dissociation at 1 atm and T>270 K, metastable (supercooled) liquid water was formed initially, and then the water transformed into ice. Formation of the supercooled liquid during propane hydrate dissociation and its crystallization was visually observed. An indirect conclusion about methane hydrate dissociation into liquid (supercooled) water and gaseous methane was made, based on calculated data on the activation energy of methyl radical decay during isothermal annealing of γ-irradiated methane hydrates at 235–260 K (Takeya et al. 2005). It should be noted that Makogon (1981) first proposed the scheme of gas hydrate dissociation at T< 273 K as hydrate $\rightarrow$ liquid water $\rightarrow$ ice + gas, but reliable evidence for the process was not presented.

The purpose of this study is to obtain direct evidence of the formation of metastable (supercooled) water during gas hydrate dissociation at temperatures below 273 K. To do this, a special procedure of optical observation of hydrate dissociation was developed.

Experimental Apparatus and Procedure

A schematic of the experimental apparatus is shown in Figure 1. Its main element is a high-pressure reactor, within

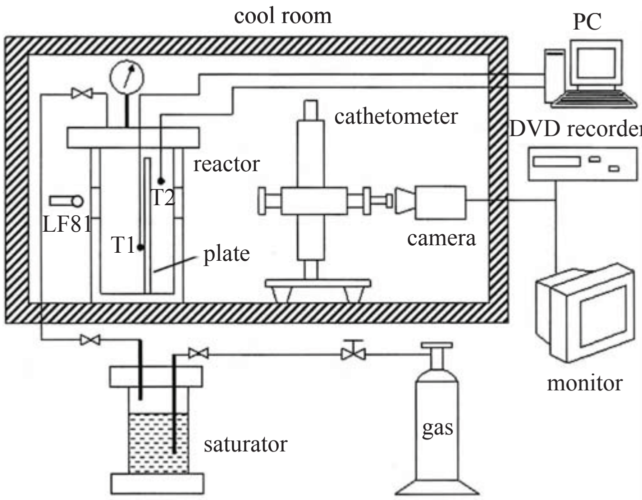

Figure 1. Experimental apparatus for study of hydrate formation/dissociation on water droplets. LF 81 – LED; T_1, T_2 – copper-constantan thermocouples.

which hydrates are formed and dissociate under controlled conditions. A reactor with a working volume of 100 cm^3 was made of stainless steel and equipped with quartz viewing windows on the side surface to facilitate visual observation of processes occurring within the reactor. The reactor was placed into the cool room (air thermostat) with a volume of 8 m^3 (2m x 2m x 2m). The temperature in the reactor was maintained to an accuracy of $\pm$0.1 K. A cathetometer was used for optical observation of hydrate formation/dissociation within the reactor. The ocular of the cathetometer telescope was joined with a Nikon Coolpix 995 digital camera. The image from the camera was displayed in parallel on the screen of a monitor and recorded by a DVD recorder. In this way we were able to make discrete pictures and a video film in a real time mode. Video capture and image analysis were performed using Pinnacle Studio Plus® v.10 and PhotoFinish® 4.0 software. Pure methane (99.9 mol.%) and propane (mol.%: C_2H_6 – 1.23, C_3H_8 – 94.27, C_4H_{10} – 4.13, $C_{5+higher}$ – 0.02, CO_2 – 0.35) were used as the hydrate forming gases.

The procedure to prepare the hydrate samples was as follows. Distilled water in the amount of 1.5–2.5 g was sprayed in the form of small droplets 0.15–1.5 mm in size on the surface of a transparent Plexiglas plate previously cooled to 253 K. It is well known that the hydrate formation induction time decreases when crushed ice or thawed ice is used for hydrate formation (Sloan 1998). Moreover, our numerous attempts to form propane hydrate directly from water droplets failed. Therefore, to obtain hydrates, we used the ice formed by freezing water droplets. All activities related to the assembly of the reactor, its evacuation and charging with hydrate-forming gas (about 3 atm for propane and 40 atm for methane) were carried out in the cool room at temperatures of 258–263 K. To increase the rate of hydrate formation, the reactor with pressurized gas and the frozen water droplets was heated above the ice melting point, because slow melting of the ice facilitates the hydrate forming reaction (Stern et al. 1996).

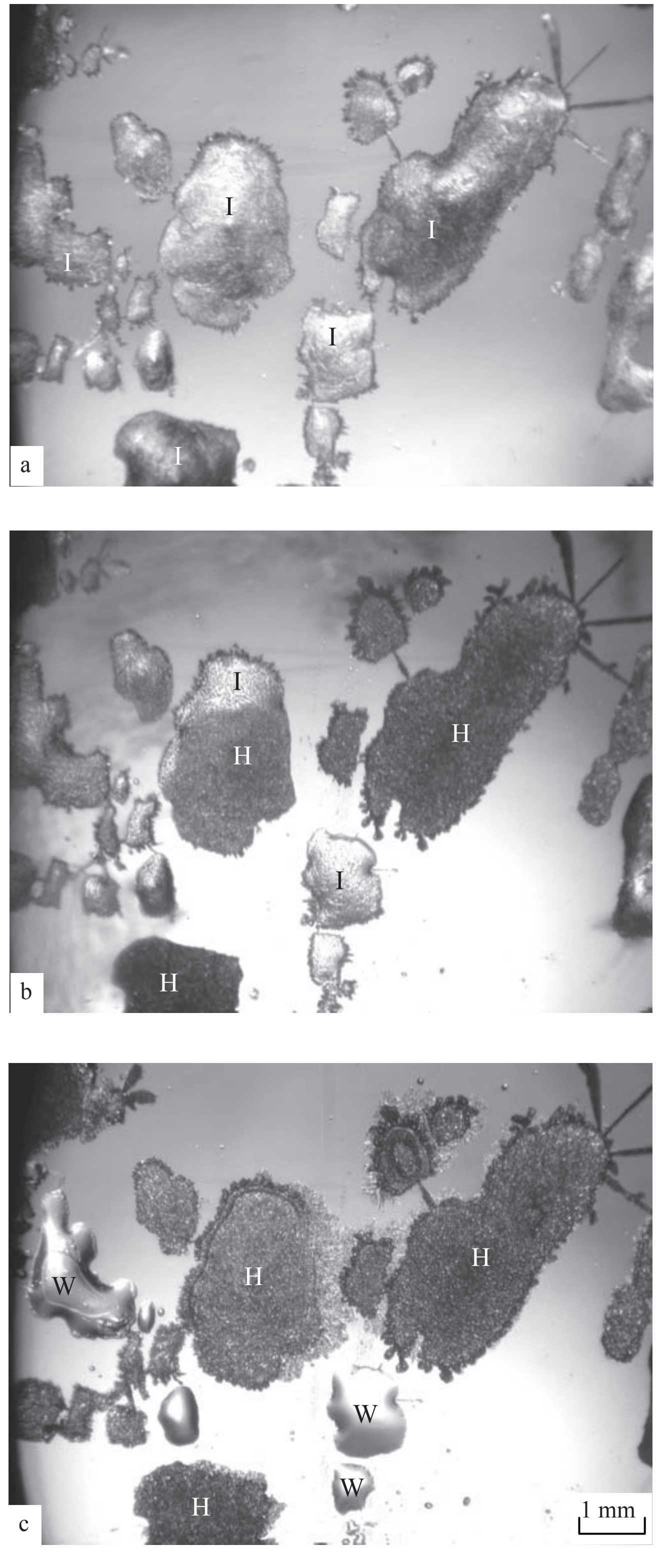

Figure 2. Propane hydrate growth on the ice surface (a-b) and appearance of water during melting of ice (c): a – 0 min(just before pressurization), *P*= 0 atm, *T*=258 K; b – 42 min, *P*=2.1 atm, *T*=270.0 K; c – 214 min, *P*=2.1 atm, *T* = 273.2 K. I-ice, H – hydrate, W –water.

Hydrate, ice, and water phases were distinguished by surface roughness and color (Fig. 2). The sample history and *P-T* conditions within the reactor were taken into account in addition to visual observation to identify the different phases observed in hydrate formation/ dissociation. Only the ice is presented in Figure 2a, where T=258 K, P=0 (just before the reactor was charged with propane). In Figure 2b (P=2.1 atm, T=270 K) the ice and propane hydrate, as well as the ice-hydrate boundary, are observed. On the monitor screen the hydrate surface looked rougher and darker. The ice-hydrate boundary corresponds to the propagation front of the gas hydrate film at the ice surface. Different mechanisms of ice surface coverage by a gas hydrate film were discussed by Genov et al. (2004). Monitoring movement of the ice-hydrate boundary at the ice surface, we were fortunate to measure the rate of the propane hydrate film propagation along the gas-ice interface. It was about 1 µm/s at P = 2.1 atm, T = 270 K, ΔT = 4 K. Here ΔT is supercooling, $\Delta T = T_{eq} - T$, where T_{eq} is the hydrate equilibrium temperature at the given pressure in the reactor. For comparison, the growth rate of the methane hydrate film along the methane-liquid water interface was about 40–100 µm/s at the same supercooling of ΔT = 4 K (Freer et al. 2001, Tailor et al. 2007). No data on the growth rate of a gas hydrate film at the ice surface have come to our notice.

Sometimes not all ice particles transformed into the hydrate, and when the temperature in the reactor increased above 273 K, the ice melt and water droplets appeared (Fig. 2c). At the same time an elevated pressure within the reactor provides the hydrate stability and additional hydrate formation. Because we used a small amount of water within the reactor, the pressure drop during the gas hydrate formation was insufficient to reliably estimate the amount of water converted into hydrate. Therefore the freezing/melting procedure (cooling of the reactor to 265 K and its heating to 273.5K) was repeated 4–5 times to provide a maximum of water conversion into gas hydrates.

To observe the dissociation of gas hydrates, a specified temperature was set in the cool room, and the reactor was kept at this temperature for another 2 h. Then, the pressure in the reactor was slowly reduced (0.05 atm/min for propane hydrate and 0.1 atm/min for methane hydrate). The dissociation of the hydrates was judged from the visually observed collapse of the rough surface of the hydrates, the appearance of smooth islands of the liquid phase on hydrate particles, and evolution of gas bubbles from the liquid. The pressure at which the first changes in hydrate particles were visually observed was taken as the hydrate dissociation pressure P_d at the given temperature. Once the hydrates begin to dissociate, the reactor valve was closed, and the pressure drop in the reactor was stopped.

Results and Discussion

Results describing the dissociation pressure for methane and propane hydrates formed on water droplets are shown in Figure 3. For comparison, the equilibrium pressure of

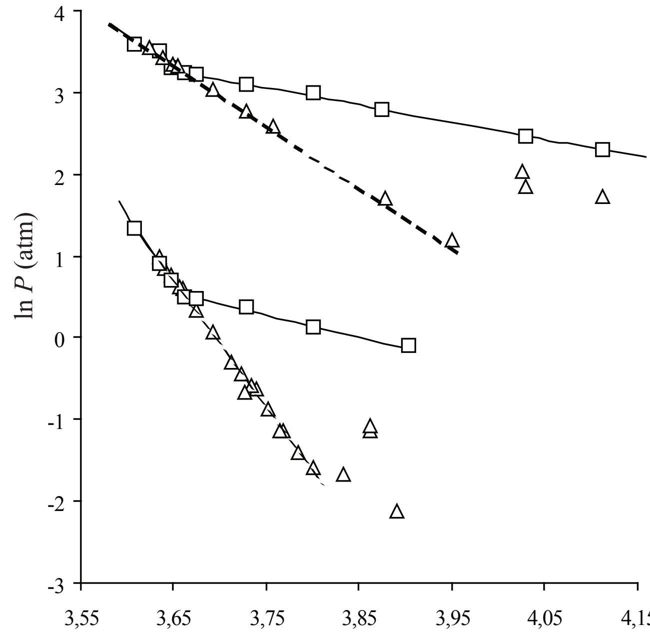

Figure 3. Dissociation pressure of gas hydrates, formed on water droplets (triangle), and equilibrium pressure of formation of bulk hydrates (square). The solid line is calculated data by the CSMHYD program. The dash line is the extension of the calculated water-hydrate-gas equilibrium curve into the metastable area.

hydrate formation for methane and propane bulk hydrates, P_{eq}, obtained in the control experiments and calculated by the CSMHYD program (Sloan 1998) are presented as well. In ln P – 1/T coordinates, the curve of the equilibrium pressure of gas hydrate formation $P_{eq} = P_{eq}(T)$ consists of two intersecting straight lines corresponding to water–hydrate–gas and ice–hydrate–gas equilibrium. The slope of these lines to the inverse temperature axis characterizes the molar enthalpy of hydrate dissociation into water and gas ΔH_{hwg} (hydrate (h) = water (w) + gas (g)) at T > 273 K and into ice and gas ΔH_{hig} (hydrate (h) = ice (i) + gas (g)) at T < 273 K (Sloan 1998)

$$\Delta H_{hwg(hig)} = - zR \frac{d(\ln P_{eq})}{d(1/T)} \tag{1}$$

where z is the compressibility factor for gas and R is the universal gas constant.

At temperatures above 273 K, the hydrate dissociation pressure P_d coincides with the equilibrium pressure of gas hydrate formation P_{eq} (Fig. 3). At 263 K<T<273 K for propane hydrate and 253 K<T<273 K for methane hydrate the values of ln P_d fall on a straight line (the regression coefficient is r^2=0.995) which coincides with the extension of the water–hydrate–gas equilibrium curve in the metastable area of supercooled water. This means that, at T <273 K the molar enthalpy of dissociation for hydrates formed on water droplets is equal to the molar enthalpy of hydrate dissociation into water(liquid) and gas for bulk hydrate. The experimental data on P_d and Equation 1 were used to calculate the molar enthalpy for the dissociation of methane

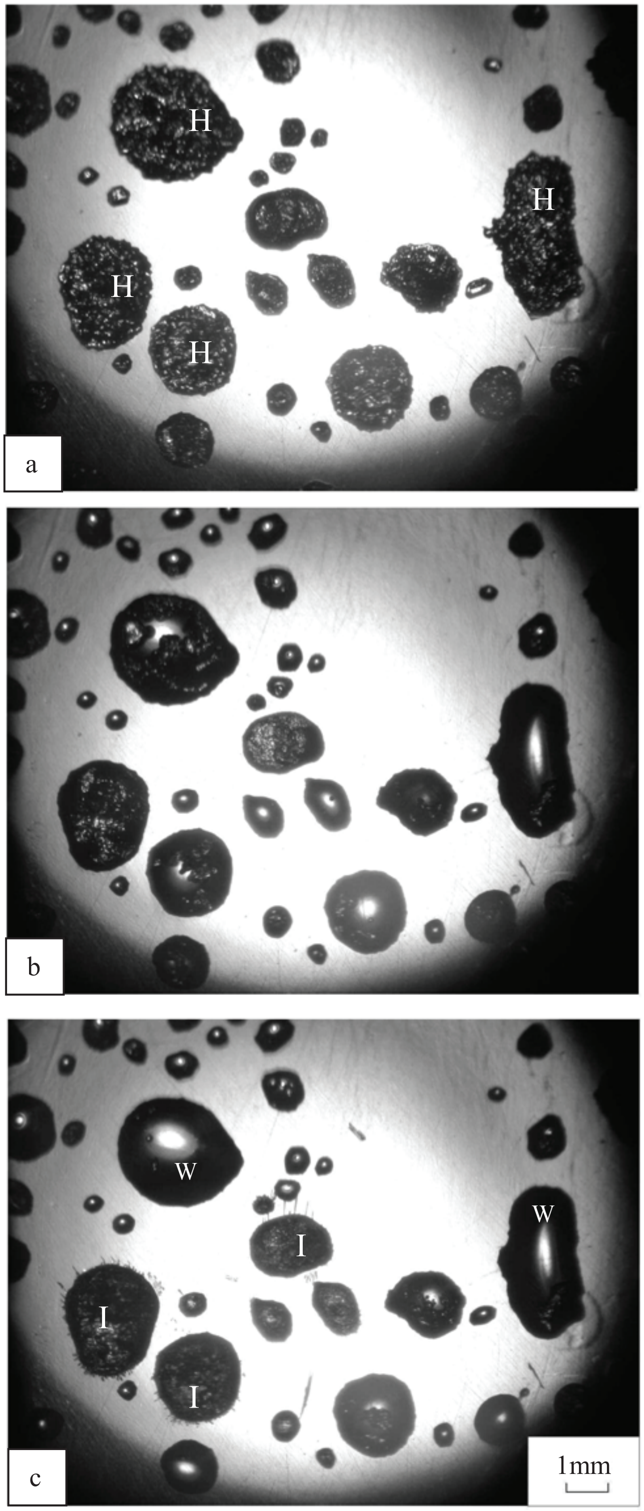

Figure 4. Dissociation of propane hydrates formed on water droplets. P_d = 0.54 atm, T = 267.9 K. a – 0 min (at the beginning of dissociation); b – 62 min; c – 89 min.

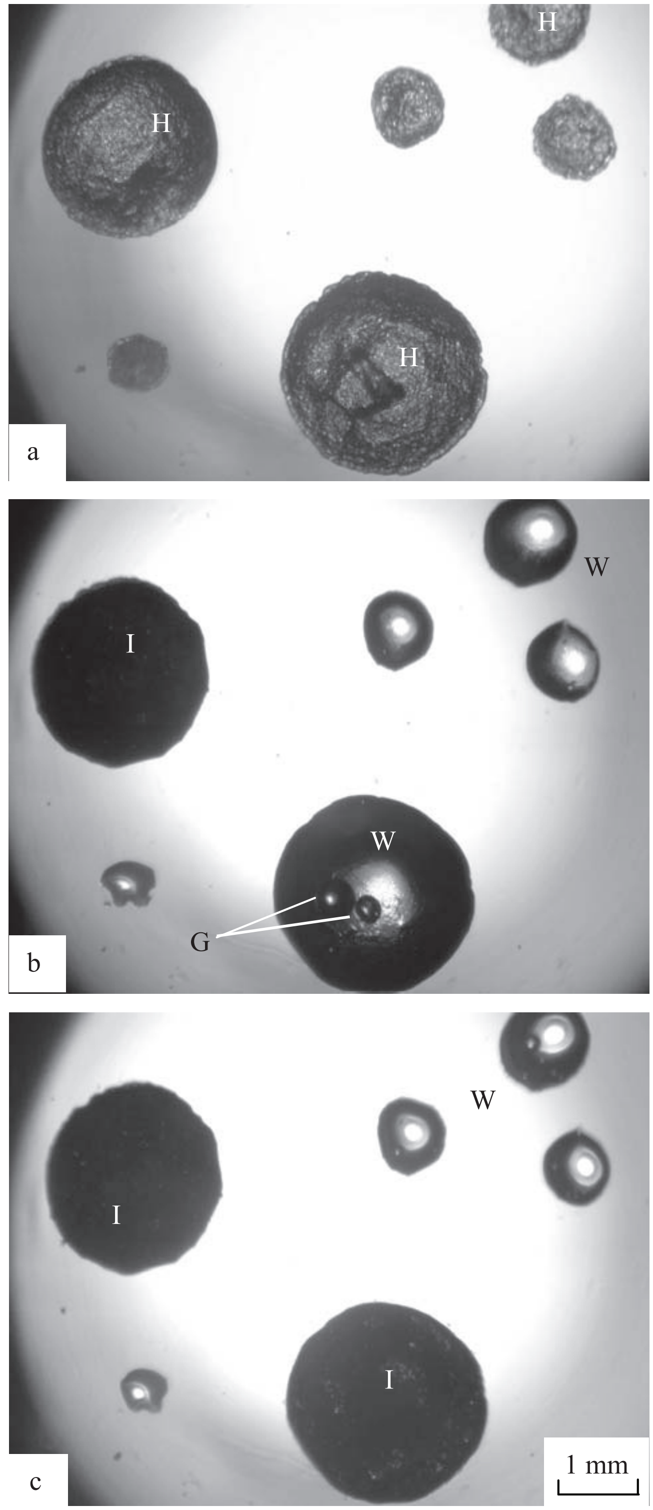

Figure 5. Dissociation of methane hydrates formed on water droplets. P_d = 9.9 atm, T = 263.15 K. a – 0 min (at the beginning of dissociation); b – 1 min; c – 115 min. G – gas bubble.

and propane hydrates formed on water droplets, into supecooled water and gas at T<273 K. The compressibility factor z was calculated with the Peng-Robinson equation of state (Peng & Robinson 1976). The calculated values are: ΔH_{hwg} = 54.6 kJ/mol for the methane hydrate dissociation into supercooled water and methane gas and ΔH_{hwg} = 128.9 kJ/mol for the propane hydrate dissociation into supercooled water and propane gas. The calculated values agree well with the molar enthalpy of hydrate dissociation into water and gas for bulk methane hydrate ΔH_{hwg} = 54.6 kJ/mol and bulk propane hydrate ΔH_{hwg} = 129.2 kJ/mol (Handa 1986). Hence the liquid phase detected visually in our experiments at $T < 273$ K during dissociation of hydrates formed on water droplets is nothing more nor less than supercooled water.

The consecutive series of visually detected changes occurring at 267.9 K during dissociation of propane hydrates formed on water droplets is shown on Figure 4. The zero time (Fig. 4a) immediately precedes the first changes of the image observed. By this time the pressure in the reactor had decreased to 0.54 atm and remained steady at that value. Only the hydrate phase is present in Figure 4a. After one hour of observation (Fig. 4b) small water droplets(size 0.2–0.3 mm) had formed on the hydrate as well as large droplets (1–2 mm) composed of both the liquid water phase and hydrates. It is interesting to note that the presence of the hydrate within the water droplets did not stimulate heterogeneous crystallization of the supercooled water. Only after 67 minutes from the onset of the hydrate dissociation, some (but not all) of the larger water droplets transformed into ice. In this case we observed that the droplets froze instantly in contradistinction to the terminal growth rate of hydrate on the ice surface (Fig. 2). However, the greater number of the small water droplets and some of the large water droplets did not freeze even 1.5 hours after the onset of the hydrate dissociation (Fig. 4c). When the reactor was heated above 273 K, the melting of the recrystallized water droplets was observed at 273.1$\pm$0.1 K.

The formation of metastable (supercooled) water during propane hydrate dissociation was reliably detected between 263 K and 273 K. In this temperature range, the transformations observed within the reactor were analogous to those presented in Figure 4, and values of the hydrate dissociation pressure P_d in all cases fell on the extension of the water–hydrate–gas equilibrium curve into the metastable area of the supercooled water at T<273.15 K, (Fig. 3).

Similar transitions were observed during methane hydrate dissociation at 253.15–273.15 K, (Fig. 5). Based on the P-T sample history (before cooling to 263.15 K, the reactor was heated to 274 K at 40 atm and no water droplets were observed, only the solid droplets) we can advocate that only the hydrates are presented in Figure 5a. The small liquid droplets along with the large droplet composed of the liquid phase, the solid and the gas bubbles, as well as the large dark solid droplet are observed in Figure 5b. In Figure 5c we can see the liquid droplets and two dark solid droplets. When we heated the reactor, we observed the melting of the dark solid droplets at the ice melting point. It follows that the dark solid droplets in Figures 5b and 5c were the ice.

A detailed study on the influence of the hydrate dissociation temperature on the induction time for the crystallization of supercooled water released during hydrate dissociation was not conducted in this work. Nevertheless, it follows from the data obtained that the induction time decreases with the decreasing temperature. For example, at temperatures close to the freezing point (269–270 K) none of the water droplets formed during hydrate dissociation had crystallized to ice within 24 hours of the observation.

Below 263 K for propane hydrates and 253 K for methane hydrates, the dissociation pressures P_d were higher than the P_d values corresponding to extension of the equilibrium

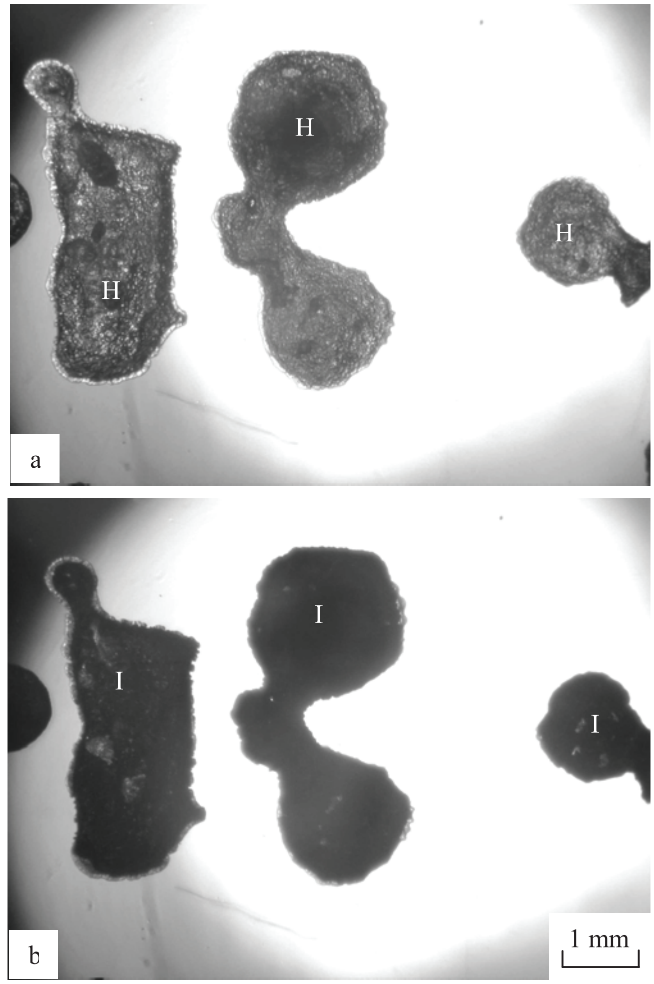

Figure 6. Dissociation of methane hydrates formed on water droplets. P_d = 5.64 atm, T = 243.15 K. a – 0 min (at the beginning of dissociation); b – 8 min.

curve for water–hydrate–gas in the metastable area of supercooled water (Fig. 3). The reasons for this deviation are still unclear. Appearance of the liquid phase was observed during propane hydrate dissociation below 263 K, however the induction time for its subsequent solidification did not exceed a few seconds. In the experiments with methane hydrates, only changes in the color of the hydrate samples were observed during the hydrate dissociation at T<253 K, whereas a distinct liquid phase was not observed (Fig. 6). Eight minutes from the beginning of the dissociation, no changes were observed within the reactor at 5.64 atm and 243.15 K. Because the dark solid droplets, formed during the methane hydrate dissociation (Fig. 6b) melted to liquid at 273.15 K, we have concluded that they were composed of water ice.

Conclusions

Visual observations of gas hydrate formation on water droplets and their dissociation at temperatures below 270 K were made. Direct optical evidence of the formation of metastable(supercooled) water during hydrate dissociation (between 257–270 K for propane hydrates and between

253–270 K for methane hydrates) were obtained for the first time. The induction time for recrystallization (freezing) of this supercooled water ranged from tens of hours at 270 K to a few seconds at 257 K. The dissociation pressures of gas hydrates formed on water droplets were measured. Molar enthalpies for the dissociation of these hydrates (into supercooled water and gas) were calculated based on the experimental pressure data. In the range of 263–273 K for propane hydrates and 253–273 K for methane hydrates, the calculated molar enthalpies are in good agreement with the enthalpies of dissociation of bulk propane hydrates and methane hydrates into water and gas at T>273.15 K. The data obtained supplement our knowledge about the mechanism of the gas hydrates self-preservation effect and the possibility of the existence of metastable (relict) gas hydrates within permafrost due to this effect.

Abstract

The research on frozen soil physical and mechanical characteristics has become a gradual focus in recent years. Traditionally, researchers take soil samples from the field and test their physical-mechanical characteristics in a laboratory using traditional universal testing apparatus. Although much useful data can be gained in this way, it is still time-intensive and uneconomical. The ultrasonic technique is an effective method to test physical-mechanical characteristics and is less expensive than traditional methods. According to the classical wave theory, there is a clear correlation between wave velocity and the medium characteristics. If we know the behavior of ultrasonic pulses in frozen soil, we will be able to obtain its physical-mechanical characteristic. In this article, the authors tested the ultrasonic pulses behavior in Lanzhou loess by RSM-SY5 ultrasonic apparatus. The results show clear correlation between frozen soil characteristics and ultrasonic behavior. From the results, the velocity of ultrasonic energy clearly increases with the decrease of temperature, and the change is especially prominent when the temperature exceeds -5°C. We also observed that the ultrasonic velocity increases with an increase in water content at the same temperature for the reason that ice content in frozen soil changes along with the water content. Based on the elasticity and laboratory test results, the dynamic properties of frozen soil can be determined. We conclude that the ultrasonic technique is a promising method that can substitute for traditional apparatus to test frozen soil characteristics.

Keywords: elastic modulus; frozen soil; physical characteristics; Poisson's ratio; shear modulus; ultrasonic velocity.

Introduction

The investigation on the physical-mechanical characteristics of frozen soil, along with the freezing consolidation in geotechnical engineering applications and the extensive development of the cold region, is currently a hot topic in the field of frozen soil. The present methodology, however, is labor-intensive because the researcher usually takes soil specimens from the field site and then tests them in the lab. According to classical wave theory, there is a close affinity between wave velocity and the physical-mechanical parameters of the propagating medium. Thus, if we can adopt ultrasonic detection, a simple and speedy method, to determine characteristics of frozen soil, it would be a significant work. In this article, in order to meet the need of rapid detection at the field site, the authors use the domestic RSM-SY5 ultrasonic apparatus to test the physical and mechanical properties of frozen soil. The results tend to summarize the relationship between wave velocity and the physical-mechanical properties of frozen soil.

Theory Basis of Ultrasonic Measurement

A certain point in the elastic medium is initially vibrated using an external or internal force. The vibration leads to wave formation and transmission in the medium. As an elastic wave, the process of a sonic wave transmission in the medium is a course of the transmission of the particle's elastic vibration. According to elastic mechanics, in an infinite medium, when the body force is neglected, we get the Lamei–Navier equation as follows:

$$Gu_{i,jj} + (\lambda + G)u_{j,ji} = \rho\ddot{u}_i \tag{1}$$

where ρ is the medium density, u represents the particle's displacement, and λ and G are Lamei coefficient.

When x_m is demanded to make partial derivative in Equation (1), we have:

$$Gu_{i,jjm} + (\lambda + G)u_{j,jim} = \rho\ddot{u}_{i,m} \tag{2}$$

In Equation (2), we contract the tensor's subscripts, i and m, and we note that volumetric strain θ is equal to $u_{i,i}$, so we have:

$$V_p{}^2\theta_{,jj} = \ddot{\theta} \tag{3}$$

where

$$V_p = \sqrt{\frac{\lambda + 2G}{\rho}} \tag{4}$$

Equation (3) is a wave equation, and it means that the velocity of volumetric strain in the medium is V_P; Equation (4) is the expression of transmission's velocity. If the coefficients λ and G are substituted by E and μ, we obtain:

$$V_p = \sqrt{\frac{E(1-\mu)}{\rho(1+\mu)(1-2\mu)}} \tag{5}$$

Exchanging the subscripts in Equation (2), we have:

$$Gu_{m,jji} + (\lambda + G)u_{j,jmi} = \rho\ddot{u}_{m,i} \tag{6}$$

According to strain analysis, the expression for the rotated tensor is:

$$\Omega_{im} = \frac{1}{2}(u_{m,i} + u_{i,m}) \tag{7}$$

Subtracting Equation (7) from (6), we obtain the expression of the rotated tensor that should meet the equation below:

$$V_s^2\Omega_{im,jj} = \ddot{\Omega}_{im} \tag{8}$$

$$V_s = \sqrt{\frac{G}{\rho}} \tag{9}$$

Equation (8) is the rotation part of the strain and means that, in the medium, strain transmission velocity is V_s. Equation (9) is the expression for the transverse waves. Employing E and μ to express Equation (9), we obtain:

$$V_s = \sqrt{\frac{E}{2\rho(1+\mu)}} \tag{10}$$

When the characteristic of the transmission of supersonic in the medium is obtained, we could measure the dynamical coefficients of the medium, such as E, G, μ and :

$$\left.\begin{aligned} E &= \frac{\rho V_s^2(3V_p^2 - 4V_s^2)}{V_p^2 - 2V_s^2} \\ G &= \rho V_s^2 \\ \mu &= \frac{V_p^2 - 2V_s^2}{2(V_p^2 - V_s^2)} \end{aligned}\right\} \tag{11}$$

where E is elastic modulus, G is shear modulus, and μ is Poisson's ratio.

From Equations (4) and (9), we know that the elastic wave velocity is determined by the characteristic of the medium and that, when the medium changes, the velocity is also changed. On the contrary, if the medium density and the characteristic of sonic transmission are known, we can derive the dynamic coefficients of the medium. Thus, we can employ the material's ultrasonic characteristics to analyze the medium's physical characteristics and to measure the material's dynamical coefficients such as the dynamic elastic modulus and the Poisson ratio. Although frozen soil cannot be considered as a completely elastic material, its elastic characteristic improves under comparative low temperature and, under the same stress level, the strain decreases with a reduction of the environmental temperature. The elastic strain is the most part one when the temperature is deceasing and therefore we can obtain the physical-mechanical characteristic of frozen soil by analyzing the transmission characteristics of supersonic in the frozen soil.

Experimental Methodology

Specimen preparation

The material used in the experiment was Lanzhou loess; its main physical parameters are as follows:

In order to ensure sample uniformity, which can ensure the comparability of the experimental results, we employ a remodeling artificial freezing method to produce the sample. First, undisturbed soil is dried, pulverized, and sifted. We then test the initial water content and subsequently beat up loess uniformly. After that, we load the soil sample into a columned mould with a diameter of 61.4 mm and height of 125 mm and then compact the sample. Second, we put the soil sample into a temperature-controlled refrigerator and remove the mould after 24 hours of freezing. The quantity, height, and diameter of each sample is precisely tested. Last, we place the sample in a temperature-controlled refrigerator and freeze it under required temperature. In addition, in the course of producing the sample, we reassure that at least three samples with the same water content are made.

The introduction of the ultrasonic system

The ultrasonic system used in this experiment consists of ultrasonic transducers and ultrasonic apparatus. The transducer, with a working frequency of from 20 kHz to 50 kHz, is a ceramic transducer. The ultrasonic apparatus, made in the Institute of Rock and Soil Mechanics, Chinese Academy of Science, is a RSM-SY5 digital unit. It has a visualized interface and is easy to operate. Meanwhile, the data can be accessed and refreshed, and the transmit time and amplitude can be identified.. A picture of the ultrasonic system is showed in Figure 1.

Figure 1. Ultrasonic system.

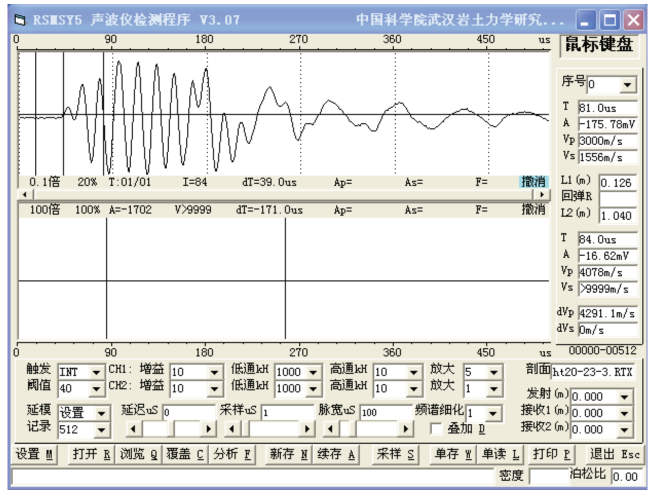

Figure 2. Screen shot of the ultrasonic software display.

Ultrasonic measurement procedure

At first, specimens were held for about 24 hours under a given testing temperature in the temperature-controlled refrigerator before it was tested. It was then placed into a thermostat tank, where the transmitting transducer and the receiving transducer were firmly pressed onto the end of the specimen. We should note here that good acoustical coupling between the soil sample surface and the face of the transducers is essential, as the ultrasonic waves cannot pass through air gaps between the transducer and the specimen. In this study, petroleum jelly was used as coupling media to improve the bonding between the transducers and the frozen soil specimen for compression wave and shear wave transmission. Finally, it sends an electric pulse (using a pulse generator) at a desired interval to both the transmitter on the end of the sample and the computer. This signal simultaneously triggers the computer to record and excites the transmitting transducer to vibrate at a frequency of 50 kHz. The vibration propagates through the frozen soil sample and arrives at the other end, where it is reconverted into an electrical signal by the receiving transducer. The operation is repeated many times. The wave travel time is determined by the time of the wave application and the time of wave arrival at the opposite end of the sample. The velocities of the waves were obtained as the quotient of the travel path to the wave travel time.

Experimental Results and Analysis

Both temperature and water content are important factors influencing the strength of frozen soils. In this research, the ultrasonic wave velocity in frozen soil at seven different temperatures and four different water contents was tested. From this experiment, we can infer the relationship between them.

Dilatational and shear wave velocity

The test results were shown in Figures 3 and.4 as follow. From the results, the velocity of ultrasonic wave was clearly increased with the decrease of temperature, and the change is especially prominent when the temperature exceeds -5°C. The reason is that the unfrozen water content became progressively smaller with the gradual reduction in temperature and the simultaneous increase of close-contact ice, intensified ice itself. From these figures we also can see that the ultrasonic velocity increased with the increase in water content at the same temperature; the reason is that the ice content in frozen soil changes along with the water content. If the water content is small, the ultrasonic velocity is largely determined by the contact condition of the soil grains; however, when the water content is large, the increased density of frozen soil will be helpful to the transmission of ultrasonic energy.

Dynamical parameters

If we take the frozen soil as an isotropic medium, dynamic modulus may be determined for frozen soil from a knowledge of the velocities of dilatational and shear waves. Hence, the dynamic elastic modulus E, dynamic shear modulus G and Poisson's ratio μ can be calculated as follows:

$$\begin{cases} E = \dfrac{\rho V_s^2 (3V_p^2 - 4V_s^2)}{V_p^2 - 2V_s^2} \\ G = \rho V_s^2 \\ \mu = \dfrac{V_p^2 - 2V_s^2}{2(V_p^2 - V_s^2)} \end{cases}$$

where V_p is velocity of the dilatational wave, V_s is velocity of the shear wave, ρ is density of the specimen.

Based on the formulas mentioned above and the laboratory test results, the dynamic properties of frozen soil can be determined. The results are presented in the following figures.

As seen in the figures, the dynamic elastic modulus and the dynamic shear modulus increase with a reduction in temperature. The variation trend of the dynamic modulus with the temperature reduction is in agreement with results

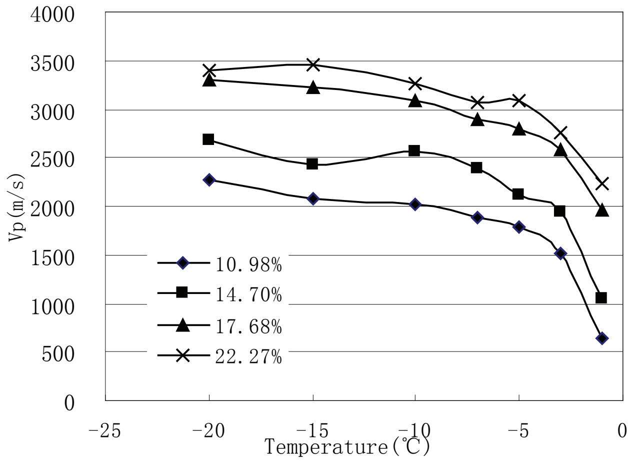

Figure 3. Relationship between temperature and compression wave velocity.

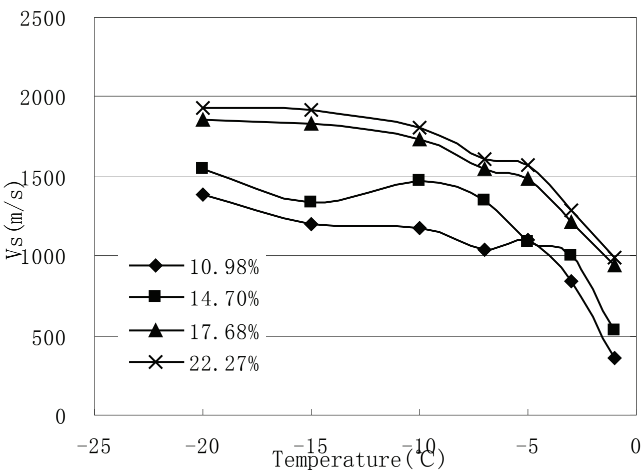

Figure 4. Relationship between temperature `and shear wave velocity.

obtained by a traditional universal test machine. The dynamic modulus has a close relation with water content such that the larger the water content, then the bigger the dynamic modulus. Compared with a universal material test machine, Poisson's ratio can be easily obtained by the ultrasonic apparatus. We can see from Figure 7 that, when the temperature increases, Poisson's ratio increases accordingly.

Conclusion

The wave velocity of ultrasonic energy in frozen soil decreases with temperature rising and increases with water content rising. Such velocity reflects the dynamical properties of frozen soil. Thus, using ultrasonic technology, we can instantly detect the dynamical coefficients of frozen soil. Furthermore, by this investigation method, we find that ultrasonic parameters can be used to estimate the mechanical properties of frozen soil. Therefore, in freezing consolidation and engineering construction in cold regions, in order to provide a powerful guarantee to such engineering, we can promptly test the mechanical properties of frozen soil at the site by ultrasonic techniques.

Abstract

Global warming is forecasted to cause significant thawing of the permafrost that surrounds lakes and rivers across the Arctic, with wide-scale effects on the water quality and biotic characteristics of these water bodies. The benthic environment is believed to be especially sensitive to permafrost-induced ecological change, and this has been the focus of recent field-intensive research. Five lakes affected and three lakes not affected by retrogressive thaw slumps were sampled during late summer of 2006 to assess the potential effects of slumping on benthos. Water quality parameters, submerged macrophytes, benthic invertebrates, and sediment were collected. GLM, Kruskal-Wallis, and ANOVA were used to test for differences between both groups, as well as for possible interaction effects from sample depth. A significant difference (p<0.05) between disturbed and undisturbed lakes was found for macrophyte, invertebrates, underwater light attenuation, and some sediment variables. The results suggest that thaw slumps can affect the freshwater food-web through an increase in benthic production.

Keywords: invertebrates; macrophytes; permafrost retrogressive thaw slumping; sediment chemistry; tundra lakes.

Introduction

The arctic region has been predicted to be especially sensitive to the impacts of global warming (ACIA 2005). It is forecasted that warming will cause significant thawing of the permafrost that surrounds the lakes and rivers that dominate much of the arctic landscape.

Permafrost terrains in non-bedrock areas commonly have an ice-rich zone at the top of the permafrost table that are formed from downward moisture movement from the active layer at the end of summers and upward moisture movement from permafrost at winter. The seasonal leaching from thawed soils and ionic movement resultant from thermal induced moisture migration contribute to the solute enrichment encountered at the near-surface permafrost (Kokelj & Burn 2003, 2005).

Deepening of the active layer in a warmer climate can lead to the release of these solutes at near-surface permafrost increasing nutrient input to freshwater bodies, which in conjunction with a raise in solute-rich runoff from the landscape will probably affect primary production (Wrona et al. 2005, Hobbie et al. 1999). It is further predicted these changes will consequentially be reflected in modification of food-web structures and biogeochemical cycles (Wrona et al. 2005).

Considering that benthic production can be an important part of the overall primary and secondary production in arctic lakes (Sierszen et al. 2003, Rautio & Vincent 2007) a more comprehensive understanding of the effects of permafrost slumping on the benthic compartment is warranted. Among the benthic biota, a special focus should be placed on macrophytes as they contribute significantly to primary production, increase habitat heterogeneity (being beneficial to benthic invertebrates and fishes), and are involved in other important in-lake processes (Vadebouncoeur et al. 2003, Kalff 2001).

Many variables have been considered important for macrophyte production, such as underwater light availability, water nutrient content, lake morphology, littoral slope, sediment composition, and organic matter content. Lake sediment, besides acting as a base for physical attachment, has been recognized as an important source of nutrient supply to submerged macrophytes (Barko et al. 1991).

Some studies have already documented differences in lake water chemistry related to permafrost retrogressive thaw slumps (e.g., Kokelj et al. 2005) in a number of lakes in the area between Inuvik and Richards Island, Northwest Territories, Canada. However, the role of such landscape-related slumping on sediment loading, chemistry, and benthic biota still remains unclear and is predicted to be more frequent in a warmer climate (Wrona et al. 2005). This study focused on investigating the hypothesis that retrogressive slumping can produce significant differences in sediment and water chemistry, submerged macrophyte biomass, and benthic invertebrate abundance between undisturbed (U) and disturbed (D) lakes in a similar geographical region.

Lake Selection and Sampling Methodology

To test the above hypothesis, a set of lakes were selected between Inuvik and Richards Island (N.W.T). Based on lake/catchment characteristics and water quality data from a 60-lake survey (Thompson, unpubl.) and field logistics, a final subset of 3 lakes not affected by retrogressive slumping

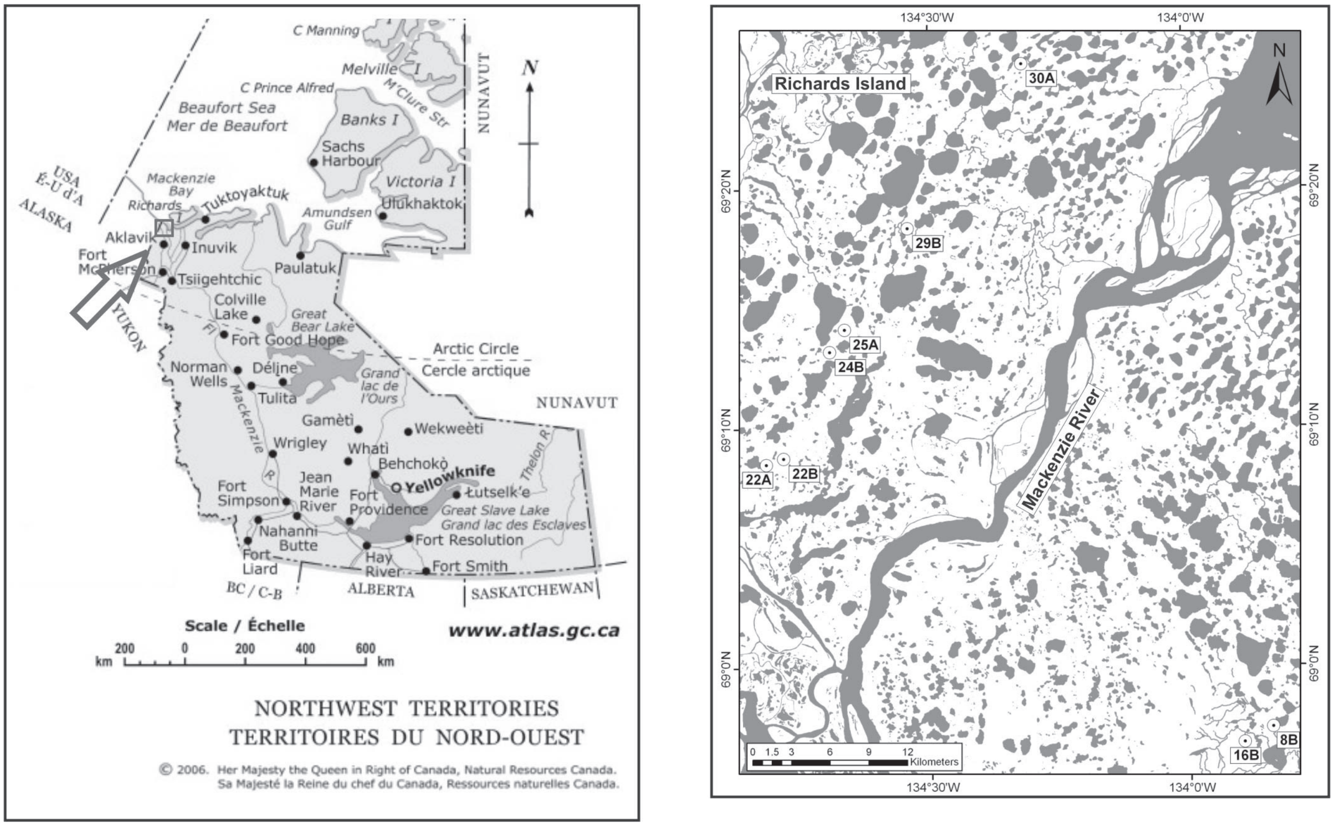

Figure 1. Geographic location of studied lakes. Source: Natural Resources Canada/CanVec (www.geogratis.gc.ca).

(undisturbed or *U* lakes) and 5 lakes affected (disturbed or *D* lakes) were selected for detailed study (Fig 1, Table 1). Disturbed lakes were sampled in two areas: one located at the opposite side (*Do*) of the physical disturbance caused by the slump, and another one in an area adjacent (*Da*) to the slump and thus directly physically affected by the disturbance. This allowed for testing whether undisturbed lakes are similar in their physical, chemical, and biological properties to disturbed systems (particularly with areas in disturbed lakes that are physically removed from the slump (*Do*).

Stratified radial transects starting from the shoreline towards the center of the lake were used as the main sampling unit (replicate) in the present study, and were distributed in order to encompass the different areas of each lake. Taking into consideration the focus on the littoral benthos, sampling points were randomly placed in 1 m, 2 m, and 3 m deep strata along the transects, yielding a maximum of 9 replicates (3 depths x 3 transects) in undisturbed lakes and a maximum of 18 replicates in disturbed lakes (9 in each disturbance zone - *Do* and *Da)*. However, due to logistical constraints in the field, some variables could not always be sampled at all strata depths in all lakes.

Between the end of August and the beginning of September 2006, samples of sediment, submerged macrophytes, benthic invertebrates, and pelagic water were taken from the selected lakes. In addition, interval measurements of underwater photosynthetic active radiation (PAR) (Li-cor LI-192) were taken at each of the transect points from the near surface to the maximum depth of one meter or before reaching the top of macrophytes. The results were used to calculate the light underwater attenuation coefficient (K_d) at each point in accordance with Kalff (2001).

Submerged macrophytes were collected at 1 m, 2 m, and 3 m deep strata with a telescopic macrophyte sampler (Marshal & Lee 1994) that covered an area of 0.164 m^2. The macrophytes were subsequently separated, washed, and oven-dried to a constant weight at 60°C for dry weight determination, and then extrapolated to represent a total biomass per m^2.

Sediment samples were collected with a sediment corer at 1 m and 3 m depths. Samples from the top 15 cm were transported to the laboratory, homogenized, and separated into two fractions. One fraction was frozen, freeze-dried, and sent for analysis of recoverable metals (i.e., environmentally available) and nutrients at the Environment Canada National Laboratory for Environmental Testing (NLET), Burlington, ON (Table 2).The remaining fraction was oven-dried and burned for calculations of loss of ignition (as a measure of organic matter content) in accordance with Hakanson & Jansson (1983).

Sediment samples for estimating invertebrate abundance were collected at 1 m, 2 m, and 3 m depths. Samples from the top 5 cm were washed through a 250 µm sieve, and the invertebrates were subsequently sorted, counted, and extrapolated to 1 m^2. Water physico-chemical parameters were collected at the deepest point in each lake previously determined from a bathymetric survey. A handheld

multiparameter Y.S.I was used to collect pH, temperature, and conductivity data. In addition, water samples were collected and sent to the NLET lab for analysis of particulate organic carbon (POC), dissolved phosphorus (DP), orthophosphate (OP), total phosphorus (TP), ammonium (NH_3N), nitrite-nitrate (NO_3NO_2), total dissolved nitrogen (TDN), particulate organic nitrogen (PON), and total nitrogen (TN).

Statistical analyses

All the variables were tested for normality using a Kolmogorov-Smirnov (K-S) test ($p<0.05$) and, when necessary, $\log_{10}$ transformed to fit the assumptions of parametric testing. General Linear Model (GLM) regressions were performed to test for differences in sediment chemistry and invertebrate abundance between undisturbed (*U*) and disturbed (*D*) lakes, using depth as a co-variate.

In cases where a significant difference (p<0.05) between disturbed and undisturbed lakes was found, a subsequent GLM with a Bonferroni simultaneous *a posteriori* test between lake/disturbance location (*U, Do* – opposite to slump, *Da* – adjacent to slump) and depth was performed. These analyses were used to ascertain whether the differences were related to in-lake processes (*Do* vs. *Da*) versus between lake (*U* vs. *Da*, *U* vs. *Do*) processes and physical proximity to the slump.

Since some sediment variables and macrophyte biomass data were not normally distributed even after transformation, the non-parametric Kruskal-Wallis test was used in these cases. As water nutrient data were only collected at one station per lake system, differences between undisturbed and disturbed lakes were analyzed using one-way Analysis of Variance (ANOVA). All the analyses were performed with MINITAB 13.1 (Minitab Inc. 2000).

Results

ANOVA tests for water nutrient data between undisturbed and disturbed lakes revealed no significant differences ($p>0.05$) for all measured constituents (POC, DP, OP, TP, NH_3N, NO_3NO_2, TDN, PON, TN). However, pH (mean = 7.6 in *U* vs. 8.19 in *D*) and specific conductivity (mean = 128.6 µS/cm in *U* vs. 516.7 µS/cm in *D*) were significantly different ($p<0.05$).

Table 2. List of key nutrient, metals and metalloids analyzed from sediment samples.

Carbon (organic/inorganic)	Sodium (Na)	Potassium (K)	Arsenic (As)
Nitrogen (organic)	Zinc (Zn)	Calcium (Ca)	Beryllium (Be)
Phosphorus (inorganic)	Cooper (Cu)	Magnesium (Mg)	Bismuth (Bi)
Phosphorus (P)	Nickel (Ni)	Iron (Fe)	Cadmium (Cd)
Manganese (Mn)	Molybdenum (Mo)	Cobalt (Co)	Gallium (Ga)
Antimony (Sb)	Lanthanum (La)	Chromium (Cr)	Aluminum (Al)
Thallium (Tl)	Lithium (Li)	Strontium (Sr)	Rubidium (Rb)
Uranium (U)	Lead (Pb)	Vanadium (V)	Barium (Ba)

GLM tests revealed significant differences (p<0.05) in only seven sediment variables between *U* and *D* lakes. Mg and Ca means showed highly significant differences, (p<0.01) with higher values in *D* lakes (Ca= 4.85 g/Kg in *U* vs. 9.44 g/Kg in *D*, and Mg= 5.74 g/Kg in *U* vs. 7.35 g/Kg in *D* (Fig. 2)).

Organic N and C, As, Ni, and Zn were also significantly different between *U* and *D* lakes ($p<0.05$). However, the highest mean values for these variables consistently occurred in undisturbed (*U*) lakes. The mean values of each of the variables for *U* and *D* were 7.29% and 4.90% of organic C, 0.61% and 0.34% of organic N, 0.02 g/Kg and 0.015 g/Kg of As, 0.052 g/Kg and 0.041 g/Kg of Ni, and 0.137 g/Kg and 0.106 g/Kg of Zn, respectively (Fig 2).

Bonferroni *a posteriori* testing revealed no significant differences (p>0.05) between in lake disturbance regions (*Da* and *Do*) and between disturbed regions and *U* lake comparisons for As, Ni, and Zn.

Mg and Ca were not significantly different between *Da* and *Do*, but were different between these regions and undisturbed lakes. In contrast, organic N content in *Da* (0.24%) was significantly different (p<0.05) from *Do* (0.24% vs. 0.44%), and highly significantly different (p<0.01) to undisturbed lakes (0.61%). Organic C was only significantly different (p<0.05) between *Da* and *U* lakes. These indicated that *Do*, a region within the disturbed systems, was similar to a "control" undisturbed lake for the variables organic N and C.

Kruskal-Wallis tests on Mn, Co, Sr, and ignition loss showed a significant difference ($p<0.05$) between *U* and *D* lakes. Median Mn concentrations varied from 0.83 g/Kg in *U* versus 0.42 g/Kg in *D*-lakes; Co ranged from 0.015 g/Kg on *U* to 0.013 g/Kg on *D*; ignition loss varied from 13.26% on *U* to 9.67% on *D*; and Sr, the only of these variables with

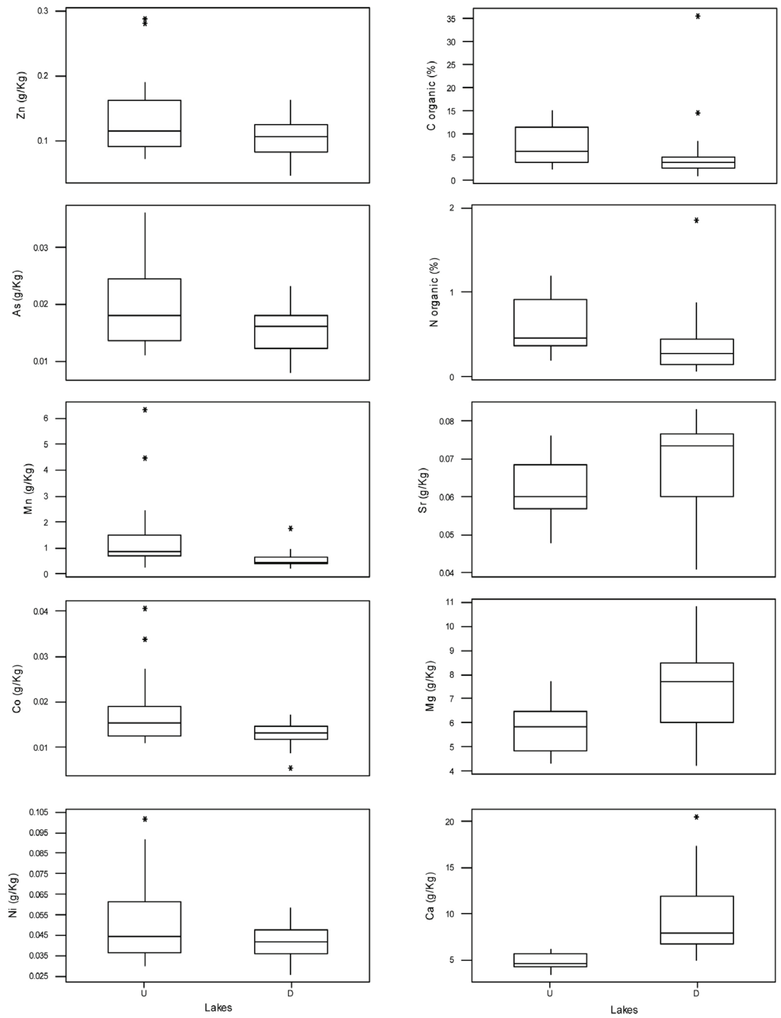

Figure 2. Box plots for sediment chemistry variables that were significantly different between undisturbed (*U*) and disturbed (*D*) lakes. All variables in g/Kg with the exception of C and N in %.

higher values in *D*, varied from 0.06 g/Kg on *U* versus 0.073 g/Kg on *D* (Fig2).

Mn, Co, and Sr were not significantly different between *Do* and *Da* regions ($p>0.05$) but were different to the undisturbed lakes. Ignition loss results had a similar pattern as found from the Bonferroni test for organic C. The K-W test revealed that only *Da* was significantly different from *U* ($p<0.05$). Correlation analysis showed a strong positive association between organic C and ignition loss ($r = 0.947$, $p<0.01$).

Although the median values for macrophyte biomass were the same (zero) at *U* and *D* lakes, the distributions were significantly different ($p<0.01$) according to Kruskal-Wallis test, with higher values on *D* lakes. This can be explained by the fact that macrophytes were more frequently found in *D* lakes (44%) than in *U* lakes (11%). The biomass present on *Do* was significantly different from *Da* and *U* lakes ($p<0.01$), while differences between *U* lakes and *Da* were not significant ($p>0.05$) (Table 3).

The difference in invertebrate abundance between *U* and *D* lakes was highly significant ($p<0.01$), with higher abundance values in *D* lakes. Differences between *U*, *Do* and *Da* were also significant, with *Da* having the highest abundance and being different from *U* ($p<0.01$), and from D*o* ($p<0.01$). Also, the interaction between *U/D* lakes and depth was significant ($p<0.05$), indicating a covariation between these two variables (Table 4).

Discussion and Conclusions

Significant differences were found between disturbed and undisturbed lakes for a variety of environmental variables. In general, disturbed lakes exhibited higher mean values of Mg, Ca, and Sr in sediments, and pH and conductivity in the water column. Undisturbed lakes had higher levels of organic C and N, As, Ni, Zn, Mn, Co, and organic matter in the sediment, and higher values of littoral underwater light coefficient of attenuation (K_d). The conductivity pattern is in accordance with previous observation by Kokelj et al. (2005), where lakes with catchments disturbed by thermokarst slumping had higher water ionic content and conductivity than undisturbed lakes in the same geographic area.

Macrophyte biomass and invertebrate abundance were higher in disturbed lakes, being postulated that this difference

Table 3. Macrophyte biomass (g/m^2) summary data from all lake, *U*, *D*, *Do*, and *Da*. Number of sample points (N), number and percentage of cases where macrophytes were present (N_p), minimum and maximum biomass (Min., Max.), median, and first and third quartiles (Q1, Q3).

Lakes/Areas	N	N_p and % presence	Min.	Max.	Median	Q1	Q3
All lakes	90	31 (34%)	0	705.5	0	0	19.21
Undisturbed lakes (*U*)	27	3 (11%)	0	24.268	0	0	0
Disturbed lakes (*D*)	63	28 (44%)	0	705.5	0	0	55.9
Opposite region (Do)	33	24 (72%)	0	705.5	28.7	0	104.1
Adjacent region (Da)	30	4 (13%)	0	76.22	0	0	0

is related to higher water transparency and concentrations of key chemical elements originated from the slump and transferred to the sediment. Thus, it is expected that a higher availability of nutrients for the growth and maintenance of macrophyte community produce a structurally more complex benthic habitat, having a positive effect on benthic invertebrates.

Previous studies have suggested that the sediment is the primary source of N, P, Fe, Mn, and other micronutrients necessary for macrophyte metabolism (Barko et al. 1991). However, the present study did not find macrophytes predominant at lakes with higher levels of organic N and Mn (undisturbed lakes). A possible explanation is that higher amounts of organic matter found in the sediment of undisturbed lakes could be affecting nutrient availability and uptake processes (Barko & Smart 1986).

In addition to decreased nutrient availability due to complexation with organic matter in organic sediments, macrophyte growth can be disrupted by the presence of phytotoxic compounds produced during anaerobic decomposition (Barko et al. 1991) For instance, accumulation of large quantities of refractory organic matter in sediments are shown to decrease nutrient availability and the growth of rooted submerged macrophytes, while additions of low quantities of labile organic matter in sediments may benefit macrophytes, especially on coarse textured sediments in oligotrophic systems (Barko et al. 1991).

With the exception of organic N, all the sediment variables and the light attenuation coefficient values were not significantly different within disturbed lakes, leading to the question of what factors might be influencing the absence of macrophytes in areas adjacent to the actual slump (*Da*). Since submerged macrophyte biomass is documented to be related more to underwater substrate slope at depths where irradiance is not the primary limiting factor (Kalff 2001), slope and related substrate stability is postulated to be the major factor influencing the almost complete absence of macrophytes in *Da* areas.

Based on preliminary results of bathymetric surveys and field observations, the underwater substrate slope near the slump disturbance is consistently higher than observed in opposite areas in the same lake or in undisturbed lakes. More detailed field analyses need to be conducted to determine the possible causal physical mechanism for this observation. It is possible that macrophyte colonization in disturbed areas is being constantly subjected to burial by soil and vegetation from the lakeshore slump.

Table 4. Invertebrate abundance (individuals/m^2) summary table from *U*, *D*, *Do,* and *Da*. Number of samples (N), minimum and maximum abundance (Min., Max.), mean, and standard deviation (S.D).

Lakes/Areas	N	Min.	Max.	Mean	S.D
Undisturbed lakes (*U*)	26	3215	39460	13232	8786
Disturbed Lakes (*D*)	68	2037	119549	28630	24482
Opposite region(Do)	35	2037	97334	22247	22818
Adjacent region (Da)	32	4584	119549	35631	25055

The observed water transparency and related light penetration values (PAR) in the littoral zone of disturbed lakes also contradicts what would be expected in a scenario of higher suspended sediments and color (dissolved organic carbon) arising from the input of landscape material into the lake water.

Two possible mechanisms could be operating individually or jointly to produce these observed patterns. First, higher ionic concentrations supplied to the lakes from the enriched slump runoff as those shown in Kokelj et al. (2005) could be adsorbing to organic compounds on the water column, causing them to precipitate and "clearing" the water. Secondly, adsorption of organic substances to the exposed mineral soils could be producing runoff with low concentration of colored material in disturbed catchment, while in undisturbed ones colored runoff would be a result of water flux through the shallow organic soils (Carey 2003, Kokelj et al. 2005). Further process-based research is necessary to elucidate the relative importance of these two possible processes and some preliminary experiments examining possible causal mechanisms can be found in Thompson et al. (2008).

In general, benthic invertebrates were found to be more abundant in disturbed lakes. However, while it was expected that areas with more macrophytes would support higher number of invertebrates, areas adjacent to slumps were found to have the highest mean abundance. Other factors, such as periphyton and bacterial abundance, pH, and oxygen, could be influencing benthic invertebrate communities and this needs to be further explored.

In summary, a warmer climate regime accompanied by enhanced seasonal thawing of the active layer will significantly affect benthic macrophyte and invertebrate communities of upland tundra lakes. The present work shows that in addition to the changes in water column characteristics already documented in previous studies (Kokelj et al. 2005), thermokarst retrogressive slumping also affects sediment chemistry and water transparency relationships in upland tundra lakes. In addition to influences related to input of enriched runoff, deposition of landscape material (i.e., soil and terrestrial vegetation) at the littoral zone can have an impact in macrophyte colonization rates and littoral complexity, affecting benthic invertebrates and upper level consumers.

Complementing the mentioned processes, other environmental changes need to be taken into consideration when projecting the effects of a warmer climate on upland tundra lakes. Active layer deepening could act synergistically with higher temperatures, higher UV penetration in lakes, changes in biota composition/ metabolism, and changes in runoff input due to alterations of biogeochemical cycles at landscape level which could all ultimately lead to a variety of different balances. Contrary to the expected increase in pelagic productivity and decreased transparency associated with permafrost degradation (Wrona et al. 2005), it is suggested that at an earlier stage, increases in the macrophyte biomass associated with higher transparency could be a possibility, being later followed by greater disturbance of littoral zone and decrease of macrophyte communities.

Abstract

The Vault Creek (VC) gold mining tunnel north of Fairbanks, Alaska, is the deepest and longest permafrost tunnel ever made available for periglacial research. The VC tunnel sedimentary profile includes loess and fluvial gravels above bedrock and is, thus, comparable to the famous Fox permafrost tunnel. AMS ^{14}C dates from the VC tunnel indicate that loess accumulation took place around 40–50 ka BP, whereas the fluvial sediments show mostly infinite ^{14}C ages, confirmed by IRSL dates around 55–85 ka. However, the pollen record of the VC tunnel reflects very warm and unambiguously interglacial climate conditions with the occurrence of *Abies* and *Tsuga* in large parts of the spectra. The stable isotope composition of ice wedges also reflects warm climatic conditions in the lower part of the profile. Consequently, a very warm phase occurred in Central Alaska, whose timing is uncertain due to conflicting age determinations and proxy indications.

Keywords: Central Alaska; climate reconstruction; ground ice; permafrost dating; Quaternary environment.

Introduction

Permafrost consists of sediment and ground ice preserving suitable signals for the reconstruction of Late Quaternary environment and climate. Thermokarst, thermoerosion, and slumping often prevent the possibility of resampling a permafrost outcrop. Therefore, underground excavations and permafrost tunnels such as the Fox and Vault Creek (VC) tunnels, may serve as three-dimensional natural laboratories for permafrost studies including dating techniques.

Especially in Central Alaska, where the chronology of sediments is still insufficiently known for the interval between 25 and 100 ka BP (Berger 2003), such revisitable sites are valuable for regional environmental reconstruction. Dating of deposits in this region is based upon a variety of methods including thermoluminescence (TL), infrared or optical stimulated luminescence (IRSL, OSL), fission track (FT), and ^{14}C, which led (and may further lead) to a substantial improvement of the knowledge on timing and duration of Late Quaternary warm and cold phases in Central Alaska. Here we present new data from the Central Alaskan Vault Creek permafrost tunnel near Fairbanks.

Study Area

The Fairbanks area is characterized by discontinuous permafrost and a continental climate with mean annual air temperatures of about -3.0ºC and precipitation of 263 mm (at Fairbanks airport, 1971–2000). Presently, spruce-birch-aspen taiga dominates the vegetation. Permafrost may reach a thickness of up to 120 m and is relatively warm with ground temperatures about -0.8°C at 2 m below ground surface at the tunnel site. The active layer reaches about 0.3 to 0.4 m.

Figure. 1. Study site: The Vault Creek tunnel north of Fairbanks. Additionally, an open pit near Fox was sampled.

Permafrost usually dominates valley bottoms and north slopes, but is largely absent on south-facing slopes. The VC tunnel is situated on a north-facing slope. Frost cracking activity is presently reduced in Interior Alaska. In Wisconsin times, when mean air temperatures were 4°C lower, ice wedge formation was a more common process. In the

Fairbanks region, permafrost is generally considered to have thawed and reset after Sangamon interglacial (Pewe 1975).

The VC tunnel is situated about 40 km north of Fairbanks, Alaska. It was established in 1990 by a local private gold miner and is, to our knowledge, the deepest (>40 m) and longest permafrost tunnel (>200 m) for periglacial research. The entrance of the VC tunnel is secured by a 30 m long steel tube, which makes the uppermost part of the section inaccessible (Fig. 1). This part has been sampled in a 3.0-m-deep auger hole (26 inches or 0.65 m in diameter) located about 50 m ENE of the tunnel's entrance (Fig. 2).

Results

The methodological approach applied to the permafrost sequence of the VC tunnel includes different dating techniques, sedimentology, and palynology, as well as stable isotope geochemistry ($\delta^{18}O$ and δD) of ground ice.

Sedimentology

The sedimentary and geocryological sequence is similar to that of the Fox research tunnel constructed in 1963 by the US Army Corps of Engineers (CRREL). About 40 m of Quaternary deposits overlie weathered schistose bedrock ("Birch-Creek schist"). The Quaternary deposits are: **(1)** at the bottom, 17.5 m of fossiliferous ice-bonded fluvial gravels with several sand and peat lenses, as well as numerous wood remains (depth: 22.5–40.05 m). No ice wedges occur in the gravel horizon; **(2)** in the upper part, about 12 to 15 m of ice-rich silty sediments are found (depth: 3–15 m). These are loess-like, organic-rich, and contain fossil bones, as well as relatively large ice wedges. The silt horizon has a very uniform unimodal grain size distribution (mean 52 µm). Between these two units: **(3)** a 7.5 m thick transition horizon of fluvial gravels interbedding with loess-like silt and relatively small ice wedges was distinguished (depth: 15–22.5 m).

The general sequence is characterized by mean total organic carbon (TOC) content of about 3%. Two horizons of higher TOC content (of up to 18%) are found at about 7.5 m and 23.5 m depth, respectively. C/N ratios are around 8, but significantly higher (reaching 20) at the TOC-enriched horizons. Carbonate contents (Cc) are, in general, below 1.5% (mean Cc 1.1%), but reach a maximum of up to 4.3% at 22.5 m depth. The mass-specific magnetic susceptibility (MS) is low in the transition and gravel horizons (mean MS: 24 and 30.10^8 SI, respectively), whereas the silt displays higher mean MS of almost 70.10^8 SI. The ice contents are significantly higher in the silt (up to 60 wt%) as compared to the gravels (max. 20 wt%). Both ground ice and sediments were significantly deformed by post-depositional slope processes, especially in the upper part of the sequence.

Two 1 to 3 mm thick layers of tephra were detected in the tunnel at about 2 m depth and at about 15.4 m depth. These white ash layers are yet unidentified. Especially the upper tephra is disturbed by creeping or sliding of slope material. At 15.7 m, three up to 20 cm thick ice bands intersect with sediments and ice wedges. Contacts between ice wedges and

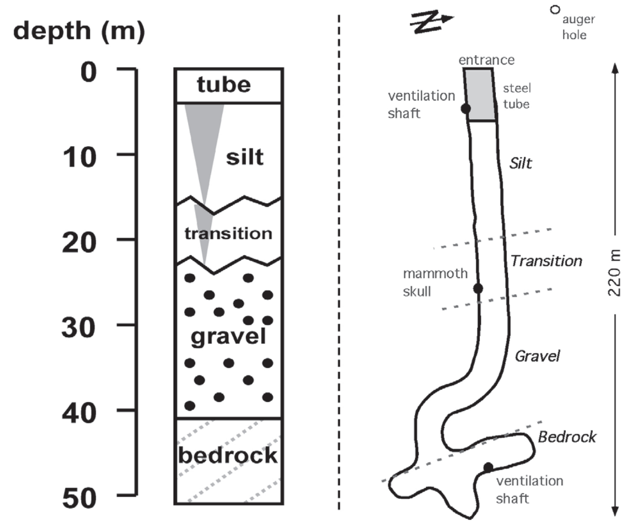

Figure 2. Schematic sedimentary profile of the VC tunnel and top view of the VC tunnel (schematic).

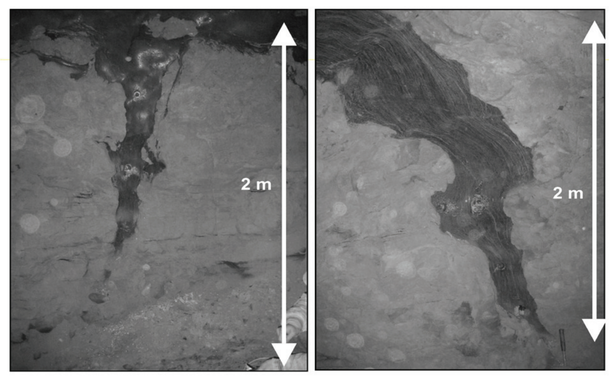

Figure. 3. Ice wedges of the VC tunnel of the silt horizon (left) and transition horizon (right). Note: deformation structures.

ice bands are similar to features interpreted as thermokarst-cave ice in the Fox tunnel (Shur et al. 2004) following melt and erosion of a part of an ice wedge by running water. No frost cracking occurred after refreezing of meltwater, so ice wedges were or became inactive after the melt event.

Geocryology

The different types of ground ice in the VC tunnel include massive ice such as: **(1)** ice wedges, the most important type of ground ice in the VC tunnel. These are associated only with the silt and transition horizons (Fig. 3).

They are wider (up to 3 m) and more strongly deformed in the upper section than in the transition horizon, where only small, vertically oriented ice wedges of 0.1-0.4 m in width were observed. Ice wedges in the silt horizon show signs of syngenetic growth. The inclination of ice wedges is stronger at the topmost part of the profile reaching up to 45–50° from the vertical line. This indicates a post-depositional transport of material e.g., by slumping or, more likely, by creeping without melting the wedge ice, which reacted plastically. Tops of ice wedges are visible in several cases, especially in the transition horizon; (2) thermokarst cave ice as also recognized in the Fox tunnel (Shur et al. 2004); and (3) a strange type of clear ice is observed at the wall with huge

Table. 1. Summary of all Radiocarbon and IRSL dated sediment and ice wedge samples of the VC tunnel, Fairbanks, Alaska

crystals of several cm in diameter, most likely related to mining activity. These locations were avoided while sampling in the tunnel. Intrasedimental ice includes segregated ice, as thin layers of ice often bound upward near ice wedges, and finely dispersed pore ice, as well as ice lenses.

Dating

To assess the stratigraphic position of the VC tunnel, several dating techniques were applied (AMS ^{14}C, IRSL, U/Th). The results are summarized in Table 1 and Figure 4. Radiocarbon analyses were carried our at Leibniz laboratory in Kiel, IRSL dating at the Technical University of Freiberg and U/Th dating at GGA Institute in Hannover, Germany. A first stratigraphic scheme is mainly based upon ^{14}C dates.

Samples taken from the auger borehole show a Late Holocene sediment accumulation and soil development around 2.5 to 3.5 ka ^{14}C BP. These dates are similar to those of an open pit near Fox, where peat and ice wedges grew in the second half of the Holocene. The uppermost sample in the VC tunnel (silt horizon) was dated to 25.3±0.2 ^{14}C ka BP. Seven finite ^{14}C dates were measured in the sediments of the silt unit, all between 40,000 and 50,000 ^{14}C BP with a relatively large error bar. Two radiocarbon ages in the silt horizon are beyond dating range. One ice wedge of the silt unit was dated to 34,400+4,390/-2,820 ^{14}C BP. Ice wedges are vertical features, thus, younger organic remains might reach deeper parts of the profile, if the ice wedge was active after sediment accumulation.

From the transition and gravel horizons, three infinite ^{14}C ages of older than 50 ka BP were retrieved, among them one age from a mammoth skull. Only one finite age of 49,550 +2,190/-1,720 ^{14}C BP was measured in the transition horizon. Two IRSL ages in the transition horizon of 57±4.4 ka and 75±10 ka were measured between 20 and 21 m depth confirm the hypothesis of a Wisconsin age of transition and silt horizons. The fluvial gravel might be even older. The attempt to date peat material from the gravel unit by means of U/Th failed due to open system conditions and the subsequent loss of uranium and only an unreliable age (of 360–460 ka) was obtained.

Palynology

Pollen spectra from the VC tunnel can be subdivided into 5 main pollen zones (PZ-I to PZ-V). Oldest pollen spectra (PZ-I, below 27 m) reflect that spruce-birch forest with dwarf birch and shrub alder dominated at the site during that time. The climate was wet and warm, and the studied pollen spectra are unambiguously pointing to “interglacial environmental conditions” similar to Holocene ones.

Pollen spectra of PZ-II (17.5-27 m) are composed of Cyperaceae, *Picea*, *Betula*, Ericales and *Sphagnum* spores showing that spruce forest with some birch trees dominated

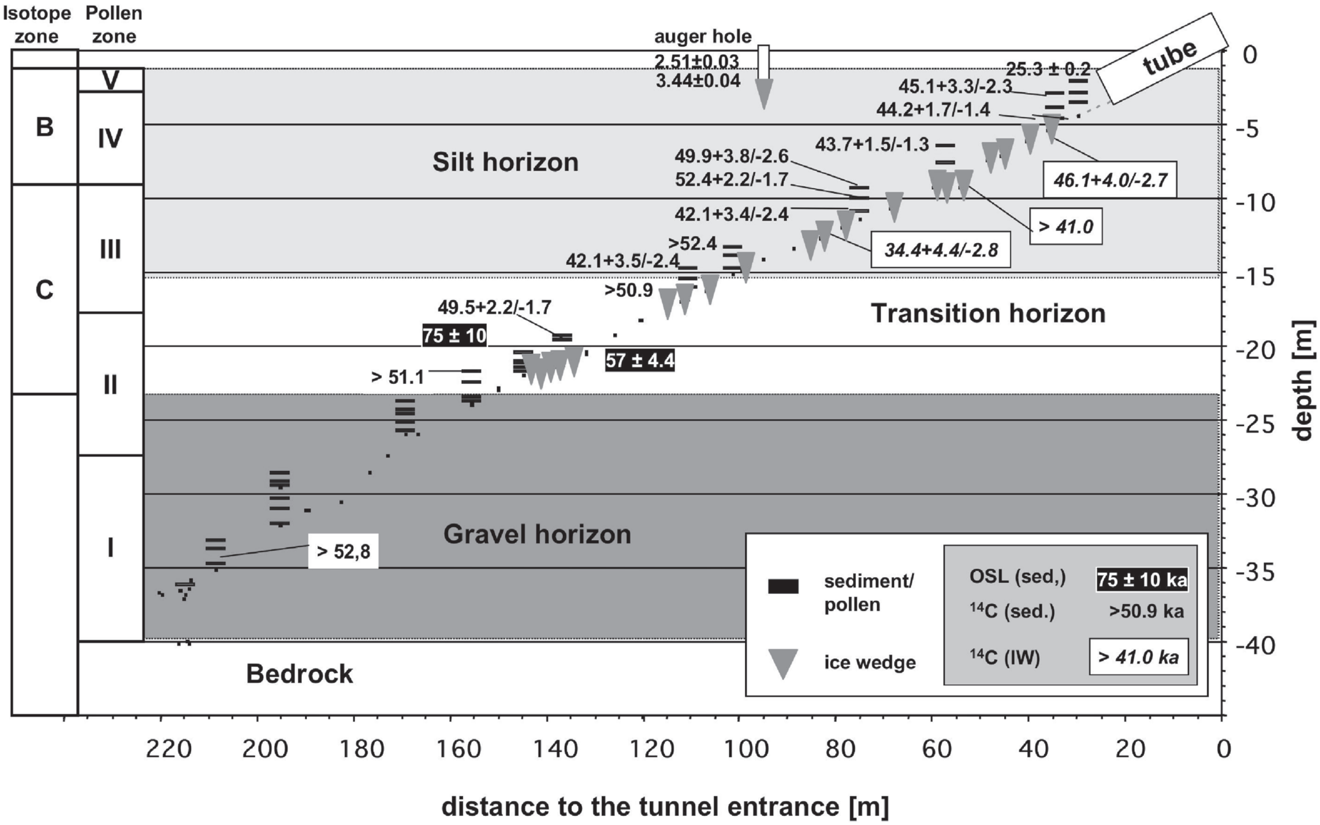

Figure. 4. Stratigraphic position of all sampled sediment profiles and ice wedges as well as their respective sedimentary horizon, pollen zone and isotope zone. Results of all IRSL and radiocarbon AMS ^{14}C dated samples are positioned at their right depth.

at the site during that interval. The find of relatively heavy pollen not readily transported by wind, such as hemlock (*Tsuga*) and fir (*Abies*) may reflect their presence in the local vegetation. The pollen spectra of PZ-III (8–17.5 m) are dominated by *Picea* and Cyperaceae pollen reflecting that spruce forest still dominated at the site. The permanent presence of hemlock and fir in the spectra reflects, most likely, that these trees grew around or not far from the site. Nowadays, these taxa occur in Alaska only in the rather moist coastal areas, where annual precipitation reaches at least 600 mm and winter and summer temperatures range from -6°C to -2°C and 13°C to 16°C, respectively (Viereck & Little 1972). Thus, during the PZ-III interval, climate conditions were probably wetter and warmer than today, e.g., such as in a warm stage of an interglacial. It should be stressed that redeposition seems unlikely due to the good preservation of pollen grain, even though both taxa are known from Tertiary deposits in Alaska (Ager et al. 1994).

A decrease of *Picea* and an increase of Cyperaceae pollen content in the pollen spectra of PZ-IV (depth: 2.8–8 m) may reflect a slight deterioration of the environmental conditions. However, spruce forest still dominated in the local vegetation. The presence of few hemlock and fir pollen shows, however, that climate conditions were still wet and warm during the PZ-IV interval. In pollen zones PZ-I to PZ-IV, typical cold indicators are missing.

Pollen zone PZ-V includes two samples from the uppermost part of the VC tunnel (2.0–2.7 m, near the entrance) reflecting a treeless environment and a significant deterioration of the climate conditions, which were extremely dry and cold during this time. A radiocarbon age of 25,320±240 a BP reflects a Late Wisconsin age of PZ-V.

Stable isotope geochemistry

Ice wedges are periglacial features giving information about winter temperatures which may be derived by stable oxygen and hydrogen isotopes (e.g,, Vaikmäe, 1989, Vasil'chuk 1992, Meyer et al. 2002). Ice wedges are fed by snowmelt or snow directly entering frost cracks, and thus are directly linked with atmospheric moisture. The isotopic composition of single ice wedges and other types of ground ice has been measured with a Finnigan Delta-*S* mass spectrometer using equilibration technique with a precision of ±0.1‰ for $\delta^{18}O$ and ±0.8‰ for δD. Significant differences have been observed in the isotopic composition of single ice wedges as well as in the other types of ground ice. Ice wedges have been subdivided into main isotope zones (A), (B), and (C).

The ice wedge of an open pit near Fox (A), directly dated to 3.6 ka ^{14}C BP, shows a mean $\delta^{18}O$ and δD of -21.8‰ and -172‰, respectively. This is a typical isotopic signature for ice wedges of Holocene age and may therefore be used as equivalent for interpretation of ice wedges in the VC tunnel.

The stable isotope composition of ice wedges in the tunnel displays two zones of varying winter temperatures: (B) 2.8–8 m depth. Ice wedges are characterized by lowest respective mean $\delta^{18}O$ and δD of about -26.5‰ and -210‰, thus, by relatively coldest winters. This estimate is based upon 8 single ice wedges with mean oxygen isotopic composition between

-29.3‰ (at 2.8 m, auger hole) and -23.6‰ (at 6.3 m). This indicates a certain degree of variability of winter climatic conditions, but nonetheless glacial conditions especially in the uppermost part, where lightest (most negative) isotopic composition is reached.

(C) 8–22 m depth. A much higher mean $\delta^{18}O$ and δD of about -22‰ and -175‰, respectively, is observed in the 14 ice wedges of isotope zone C. Mean oxygen isotopic composition in single ice wedges varies from -24.2‰ (at 10.2 m) and -20.5‰ (at 21 m). This could reflect winter temperatures similar to the present ones or, in parts, even warmer as today. Especially in the transition horizon, relatively heavy isotopic composition in ice wedges between -20‰ and -21‰ are common. This relatively clear subdivision is possible despite the fact that ice wedges, predominantly vertical features, propagate downward into older sediments. Between 13.5 and 15 m depth, ice wedges might have a limited climatic relevance. In this depth range, low d excess (below -2‰) points to secondary fractionation. This might be caused by evaporation/sublimation of snow or the participation of reprecipitated water. Therefore, the relatively variable isotopic composition of ice wedge in this depth range is considered with caution.

The mean isotopic composition of thermokarst-cave ice is $\delta^{18}O$ = -22.1‰, and is thus similar to that of ice wedges in isotope zone C. This points to an event of local melt of ground ice, which was subsequently refrozen as thermokarst-cave ice. Intrasedimental ice (both pore and segregated ice) displays highly variable isotopic composition all over the permafrost sequence due to the fact that this type of ice includes not only winter precipitation. Consequently, the isotopic composition of intrasedimental ice is heavier ($\delta^{18}O$ = -19.8‰, N = 23), with lightest values observed at the top of the silt horizon and heaviest values at the bottom.

Discussion

The environmental history reconstructed from sediments and ground ice of the Vault Creek tunnel revealed a series of new results for Central Alaska. The youngest part of the regional history was derived from samples of an auger hole (as well as of an open pit near Fox) and dated to the 2nd half of the Holocene, where peat accumulation took place, ice wedge growth was common and the climate was relatively wet and warm according to palynology and isotope geochemistry of ice wedges. Obviously, the top of the VC tunnel reveals a part of the environmental history around 25 ka ^{14}C BP. Pollen indicate a cold and glacial climate and treeless vegetation. Lightest isotopic composition in ice wedges (and in intrasedimental ice), also point to coldest climatic conditions for the whole sequence. This section was dated to an interval just some thousand years before Late Glacial Maximum. It also states clearly that at VC tunnel, loess accumulation continued at least until 25 ka BP. At the Fox tunnel, a hiatus was observed between about 14–30 ka BP (Hamilton et al., 1988).

The organic remains in fluvial gravels at the bottom of the sequence show infinite ^{14}C ages, which is also supported by the IRSL dates in the transition horizon. Consequently, fluvial activity must have been strong in Early Wisconsin or even before. At this time, summers must have been warm and wet, leading to the intensification of fluvial activity in the area.

Conflicting dates and proxy indications are especially related to the silt unit, which was AMS ^{14}C dated between 40 and 50 ka BP. Unfortunately, these dates are not always in the right order with increasing ages with depth and display relatively large error bars. Hence, it raises the question how the ages around 40 - 50 ka BP correlate with the extremely warm temperatures derived from pollen analyses (especially PZ-II and PZ -III).

This interval has not been known as very warm until now, whereas around 30 to 40 ka BP, interstadial conditions have been described for various sites. For instance, thaw unconformities in the Fox tunnel (the so called ”Fox thermal event”) have been dated to 30 to 35 ka BP (Hamilton et al., 1988). In northwest Canada, a mid-Wisconsin Boutellier non-glacial interval with temperatures similar to the present ones has been dated to between 30 and 38 ka BP (Schweger and Janssens, 1980). Three ^{14}C dates from ice wedges fall into this time interval (two from Fox, one from VC tunnel), confirming that in the region, frost cracking was active at that time. For about the same interval, temperatures similar to the present ones have been derived by pollen analysis for a sediment record of the Isabella basin, near Fox (Matthews et al. 1974). In Matthews' study, pollen zone Ab indicates climatic conditions as warm as today around 32 ka BP.

There are only few examples for Alaskan climate records extending beyond this interstadial phase. For instance, pollen spectra at Imuruk Lake, Seward Peninsula were interpreted differently by various authors. Pollen zone i was dated to >37 ka and >34.4 ^{14}C BP and attributed to the Sangamon by Colinvaux (1967). However, Shackleton (1982) assumed a Mid Wisconsin interstadial for this pollen zone. This re-estimate is based, among other methods, upon the assumption that the Old Crow (OC) tephra (predating pollen zone i) is about 80 ka old. New data yield an age for the OC tephra of about 142.3±6.6 ka BP (Berger 2003). Therefore, the pollen spectra at Imuruk Lake must be re-interpreted and at the moment, pollen zone i is more likely interglacial (Sangamon) than interstadial.

Nonetheless, in no other palynological study in Interior Alaska have such warm climatic conditions as in the VC tunnel been derived by means of pollen analyses (Ager & Brubaker, 1985). This is not only valid for a small part of the VC tunnel, but for almost the complete periglacial sequence. This reflects the difficulty of interpreting environmental data beyond radiocarbon dating range and the need to understand more about the environmental history in Alaska. This makes the VC tunnel exceptionally valuable for a more detailed study of this time interval.

To summarize, there are three possibe interpretations of our data: (1) trust the radiocarbon ages. In favor of this hypothesis is the high number of similar and finite ages of the silt horizon, as well as two IRSL ages from the transition horizon predating the loess. This points to a Wisconsin age of both transition and silt horizons. Additionally, the AMS method applied at Leibniz laboratory in Kiel, expanded the dating range back to about 50–70 ka BP (Nadeau et al. 1997, 1998). This assumption would lead to a very warm and as yet unknown interval in mid-Wisconsin times.

The fact that trees grew close to the site allows a second (hypothetical) interpretation, that (2) a small forest existed in the Vault Creek area due to locally different climate conditions (e.g., close to a hot spring) and survived through Wisconsin times. Finally, we can (3) disbelieve the ages, which are near the dating limit, and assign the whole sequence to the Sangamon (or other) interglacial based on interpretation of pollen spectra. A warm phase is supported by relatively heavy isotope composition of the ice wedges. Acceptance of this hypothesis would contradict Pewe's ideas of no ground ice surviving the Sangamon interglacial in Interior Alaska. In any case, winter temperatures must have been cold enough for frost cracking, and summers not so warm as to melt ground ice. This paradox of extremely warm summer temperatures at a presently discontinuous and relatively warm permafrost site, with predominantly loess accumulation in which ground ice was formed and survived, cannot be solved completely. It is likely that sediment transport downslope, redeposition, and burial of ground ice played a key role for the pre-existence of permafrost. At least once, melting influenced the sequence when thermokarst-cave ice was formed after lateral melting of ground ice. This displays the vulnerability of these deposits, but also the possibility of contaminating older deposits by younger organic material.

Conclusions

The late Quaternary record of the Vault Creek permafrost tunnel near Fairbanks spans more than 75 ka and indicates varying environmental conditions from rather fluvial (gravelly) to aeolian (silty) environmental conditions.

Fluvial activity was intensive in the Vault Creek area in or before Early Wisconsin, leading to the deposition of 17.5 m of fluvial gravels. Climate conditions were warm and wet during that time. There are no signs of frost cracking activity at that time.

AMS ^{14}C dates point out that silt accumulation and ice wedge growth took place in the vicinities of the VC tunnel from 40 to 50 ka BP to at least 25 ka BP. A very warm phase with spruce forest environment occurred in Central Alaska, whose timing and duration is still uncertain due to conflicting age determinations and proxy indications. However, a climate deterioration is evident at the top of the section (around 25 ka BP), when the climate was colder than today and a treeless tundra environment prevailed as indicated by pollen and ice wedge isotope geochemistry. During the second half of the Holocene, peat accumulation and ice wedge growth took place.

Acknowledgments

We thank Mr. Sam Skidmore for the field support and valuable suggestions. We also thank Melanie Sierralta from the GGA Institute in Hannover for U/Th dating and Matthias Krbetschek from Freiberg Technical University for providing two IRSL dates.

Abstract

We studied eroding coastline soils at 6 points along the beach exposure of Elson Lagoon near Barrow, Alaska. Exposures consisted of an average 37 cm of thawed soil and 103 cm of permafrost soil. Sediments were Holocene in origin with basal organic matter dating from 4,820 to 6,650 ybp. Exposures contained large amounts of organic carbon and nitrogen (45–112 kgOC m^{-2}, 2.5–6.1 kgN m^{-2}). These amounts are among the highest found for exposures of similar heights across the north coast of Alaska. We estimate large amounts of water, sediment, organic C and N (1,144, 1,002, 98, and 6 kgx10^3 km^{-1}, respectively) are exposed to erosion each year along the lagoon. Methane released from the thawing exposure soils ranged from 0.06–1.66 gCH_4 m^{-2}, and soil horizons nearest to the top of the permafrost and bottom of the active layer released the largest amounts in all exposures.

Keywords: Alaska; coastal erosion; sediment transfer; methane; trace gases; soil organic carbon.

Introduction

Changing wind and sea ice conditions along the Alaskan arctic coast have been associated with increases in observed rates of coastal erosion. Brown et al. (2003) reviewed previous erosion rate studies of the arctic Alaska coastline. Long-term rates for the Beaufort Sea coast calculated for the latter part of the 20th century (1951–1983: Reimnitz et al. 1988, Barnes et al. 1992) showed that the finer sediments of the coastline in the Barrow region are eroding most rapidly at an average rate of 5.4 m yr^{-1} compared with an average rate of 1.4 m y^{-1} for the coarser-based sediments of the eastern two-thirds of the Alaska coastline. A more detailed photogrammetric study for one area of the Elson Lagoon near Barrow for the period 1979–2000 revealed erosion rates for different exposures varying from 0.69 to 2.75 m yr^{-1} with an average rate of 1.27 m yr^{-1} for the whole lagoon (Brown et al. 2003). The Brown et al. study found that the 1979–2000 erosion rates along lagoon segments had increased up to 47% over the previous 40-year period. These increases were for the exposures with fine-grained sediments, whereas the erosion rates of gravel beach segments of the lagoon remained lower at 0.5 m yr^{-1}. Sediment and carbon transfer rates along Elson Lagoon were estimated by Brown et al. (2003) using the erosion rate determined in the study combined with soils data from the 1957 soils map of the area. We studied actual soils profiles of exposures along Elson Lagoon and detail the soil materials exposed as they vary along the lagoon in order to characterize load and range of materials that are being released to the near-shore lagoon environment. Work at Elson Lagoon was part of a larger study to assess the fate and transformation of soil carbon eroding into the Beaufort Sea (Jorgenson et al. 2005).

Methods

Sites

Study sites were located along beach segments identified by Brown et al. (2003) for sites 1–4 and extending further southeast along the coastline for sites 5 and 6 (Fig. 1).

The soils at the exposures (Table 1) represent those of the major mapping units that covered over 80% of the area near Barrow, including south of Elson Lagoon as reported by Bockheim et al. (1999). Exposures sampled were typical in morphology for each respective beach segment.

Sampling and analysis

Soil profiles were excavated from the surface down to sea level to remove slumped and refrozen materials at each of the 6 beach exposure sites along Elson Lagoon (Fig. 1). Soil layers were identified (Schoeneberger et al. 1998) and sampled using cut blocks in the active layer and drill cores in permafrost. These dimensional samples were at regular depths to include all soil horizons identified down to sea level. Samples in permafrost were kept frozen and all samples were stored frozen until analysis at the UAF-AFES Plant and Soils Laboratory at the Palmer Research Center. Soil bulk density and water contents were determined by weight difference upon drying at 100°C of dimensional samples. Total organic C (TOC) and N were determined using a LECO CHN analyzer with carbonates removed by acid pretreatment. The sediment, water, TOC, N, nutrient contents, and gas contents of the exposures were determined using the exposure description and analysis by the method of Kimble et al. (1993) to account for cryoturbation. Available soil N, P, and K were extracted by 2M KCl, Mehlich-3, and neutral 1M ammonium acetate solutions respectively (Soil Survey Staff 1996). Methane and carbon dioxide gases evolved from

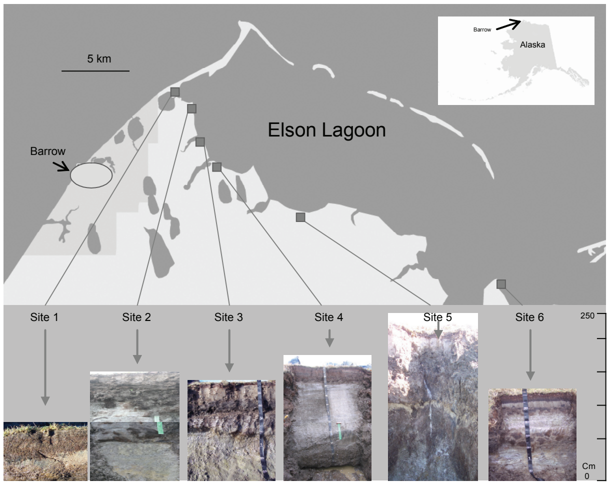

Figure 1. Study site locations and exposure profiles.

samples were determined by thawing dimensional samples for 5–10 hours in a sealed chamber attached to a Columbus Instruments Micro Oxymax respirometer. Radiocarbon dating was performed at NOAMES Laboratory, Woods Hole Massachusetts.

Results and Discussion

Soil characteristics

Exposure soils were either in alluvial-marine (sites 1 and 3) or drained lake (sites 2 and 4–6) deposits that contained inter-bedded peat and fine minerals of sandy loam to silty clay in texture (Fig. 1 and Table 1). The two alluvial marine exposures (sites 1 and 3) and one of the drained lake basins (site 5), showed little cryoturbation of organics within the layers and were Orthels while the majority of drained lake exposures had significant cryoturbation or frost mixing of organic matter and mineral materials and were Turbels under the U.S. soil classification system (Soil Survey Staff 1998). But all soils had uneven distribution of organic matter throughout their profiles (%OC in Table 1) contributing to increase OC stores to depth. Turbels are common to the area around the southern lagoon, as Bockhiem et al. (1999) mapped over 70% of the area as Turbels. Basal peat ages at sites 2 and 6 were 6650 ybp (125 cm) and 4820 ybp (60 cm), respectively.

Materials eroding at the exposures

Coastline exposures averaged 74% water and ice by volume ranging from 51% at site 4 to 90% at site 6 (site data in Fig. 2). An average of 69% was reported by Michaelson et al. (2006) for 29 exposures along the coast east to Colville River delta. Active layers along Elson Lagoon averaged lower at 67% volumetric water compared to the permafrost that averaged 77% volumetric ice. This is consistent with higher water holding capacities of organic horizons that elevate water contents in the active layer and the permafrost-encased organic horizons along with additional water in permafrost stored as ice lenses and massive ice. Water contents found in this study are generally higher than the 50% estimate used by Brown et al. (2003) to calculate erosion volume transfers along the lagoon. The mass of water in exposures studied here ranged from 431 to 1735 kg m^{-2} (average: 901 kg m^{-2}). The average mass of water in the Elson exposures tends to be somewhat lower than the average of 1200 kg m^{-2} found for 29 exposures along the coast from Barrow to the Colville River delta reported by Michaelson et al. (2006). However the 29 exposures across the larger coastal section averaged 175 cm in height compared to 140 cm in this study (Table 2). There is less than a 10% difference if considered on a per–cm-exposure height basis.

The mass of sediments available for transfer from the Elson Lagoon exposures were somewhat lower than that of water and ranged from 395–1032 kg m^{-2} (average 789 kg m^{-2}, Table 2). These sediment amounts encompass a greater range than found for three study-transects along the Beaufort Lagoon in the northeastern North Slope of Alaska, but the average of 789 kg m^{-2} is within the range of 871–998 kg m^{-2} found there (Jorgensen et al. 2003).

Carbon and nutrients at the exposures

Organic carbon (OC) and nitrogen transfer from the coastal tundra to the nearshore environment is of particular interest for terrestrial-aquatic carbon partitioning and budget analysis. Even with this interest, there are little data on carbon and very little on nitrogen in coastal tundra especially to depth (Ping et al. 2007). The soils of the coastal plain have been found to hold high amounts of organic carbon compared to the foothills region on average about 50% more (Michaelson et al. 1996). Exposure soils at sites 1–6 along Elson Lagoon ranged from 45 to 112 kgOC m^{-2} (Table 2), averaging 78 kgOC m^{-2}. Jorgensen et al. (2003) found similarly high stocks ranging from 54 to 136 kgOC m^{-2} in coastal exposures of the Beaufort Lagoon on the northeastern coastal plain. Exposures studied there averaged 240 cm in height compared to the Elson sites average of 140 cm, and average OC stocks there were 85 kgOC m^{-2} compared to 78 kgOC m^{-2} for the Elson Lagoon sites. Still, on average, the Elson exposures held about 60% more OC cm^{-1} of exposure height (0.56 compared to 0.35 kgOC cm^{-1} of exposure height) compared to the Beaufort Lagoon. When 29 exposure sites were considered from Barrow to the Colville River delta (Michaelson et al. 2006) exposures averaged 175 cm in height and contained on average 69 kgOC m^{-2} (0.39 kgOC cm^{-1} of exposure height,).

More OC data for the area is available for soils to a 100-cm depth in a study by Bockheim et al. (1999). They estimate the average Barrow area soils (around Elson Lagoon) to hold 50 kgOC m^{-2} to a depth of 100 cm with soils in mapping units containing from 27 to 73 kgOC m^{-2}. When OC stocks were calculated to only 100 cm for each site (including site 1 with only a 63 cm exposure measured) Elson sites 1–6 of this study averaged 63 kgOC m^{-2}. This average is the same as estimated as average for coastal plain soils by Michaelson et al. (1996).

The major organism-available nutrients nitrogen (NH_4+NO_3-N), phosphorus (PO_4-P), and potassium (K^+)

(Table 2) are important for organisms to utilize carbon energy sources in coastal waters as well as on land. They have been little-studied in relationship to coastal erosion transfer in the Arctic. We found considerable variation in amounts across the 6 exposures. Nitrogen was high at site 4, phosphorus at site 2, and potassium in the intertidal site (site 1). Average organic or Total N transferred per km of coast was over 100 times the magnitude of the available NH_4+NO_3-N form (bottom Table 2). Although the amounts of OC and N available at the exposures were considerably higher on Elson Lagoon (over 80%) than the Alaska Barrow to Canada coastal averages found by Dou et al. (2007), the C:N ratios were the same at 17.7, an indication of similar average organic matter quality. Potassium was in the highest in magnitude of the three nutrients for all 6 sites.

Gas content of eroding soils

Trace gas release from eroding coastline is of particular interest because it could serve as a positive feedback to climate change with increased methane and carbon dioxide emissions. Tundra is known to release significant amounts of methane upon melting as has been measured in thermokarst lakes (Walter et al. 2006). Similar thawing of permafrost is occurring along the coastline. Warming and thawing of soils already containing methane under saturated conditions can be expected to release trace gasses. We measured methane and carbon dioxide released from frozen samples taken from the Elson Lagoon sites 1–6 (Fig. 2). Site exposures released an average of 0.61 gCH_4 m^{-2} exposure (range 0.06–1.66 gCH_4 m^{-2}) and 67 gCO_2 m^{-2} (range 43–78 gCO_2 m^{-2}). For the 29 sites along the coast to Colville River delta, Michaelson

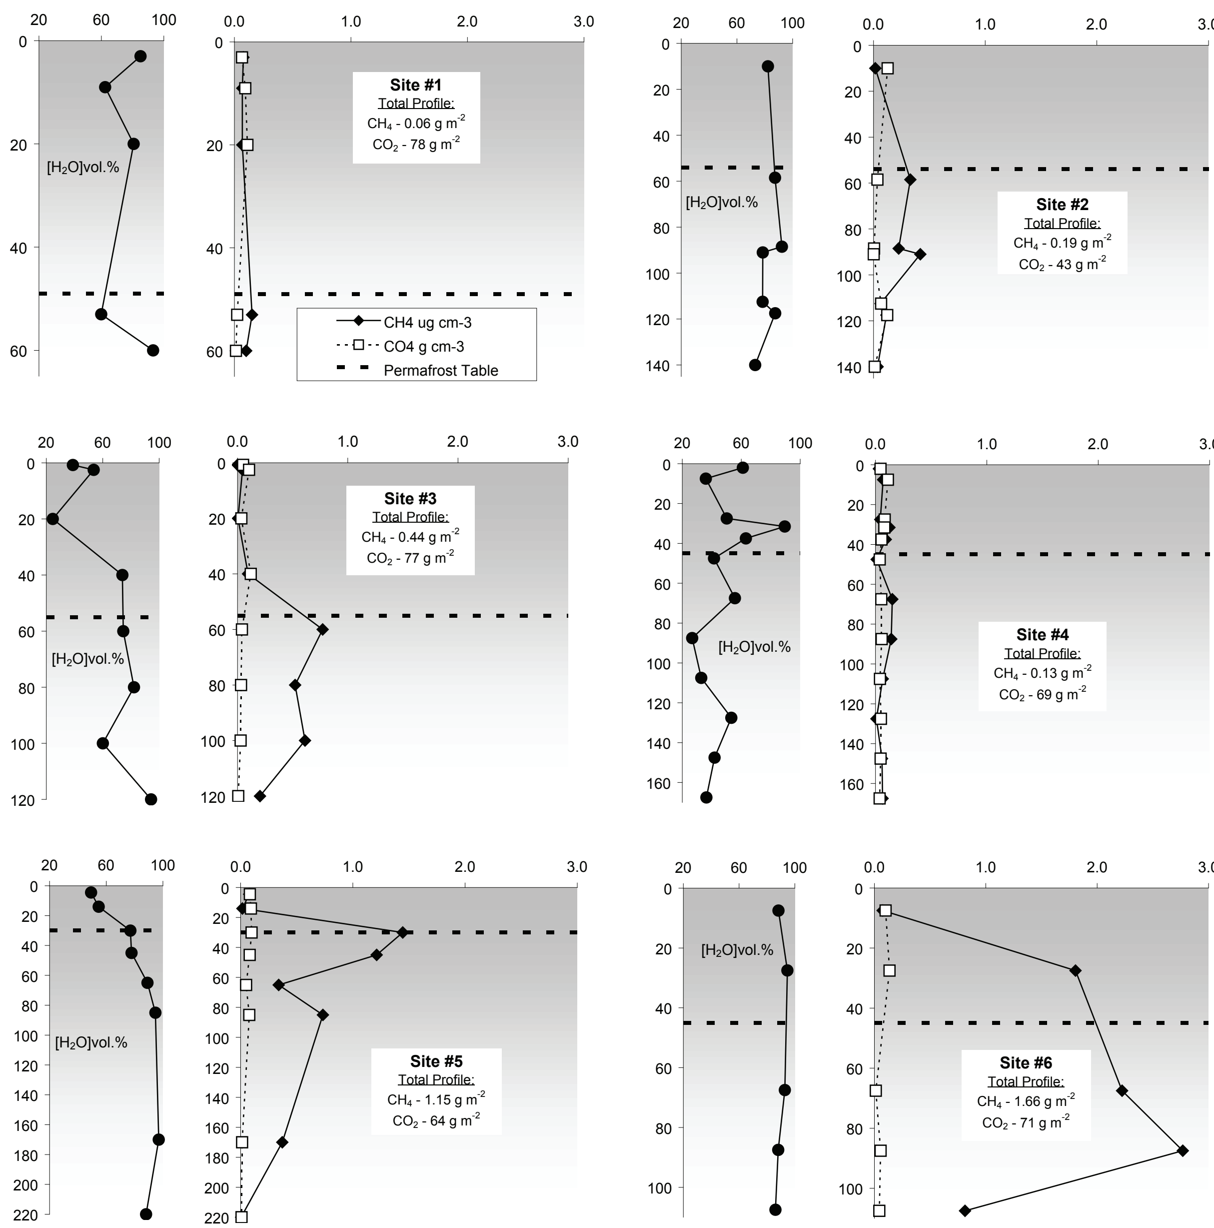

Figure 2. Volumetric water content ([H_2O]$_{vol.}$%) and methane/carbon dioxide gas release of soil profiles (lines are measured for cubic centimeters along the profile and totals are given as contained in a square meter of profile).

et al. (2006) reported average releases of 1.1 gCH_4 m^{-2} and 89 gCO_2 m^{-2} with an average exposure of 175 cm. The average methane release of the Elson sites was 0.43 gCH_4 m^{-1} of exposure height compared to the 29 sites to the east that averaged 0.63 gCH_4 m^{-1} of exposure height that is within the range found for the Elson sites (0.04–1.19 gCH_4 m^{-1} of exposure height). Carbon dioxide released had less variation with an average of 48 gCO_2 m^{-1} of exposure height for Elson sites. This compares closely to an average of 51 gCO_2 m^{-1} of exposure height found for 29 sites to the east by Michaelson et al. (2006).

As could be expected, methane releases tended to be higher in the permafrost and near permafrost (lower active layer, Fig. 2), while carbon dioxide release tended to be higher in the active layer. This is consistent with methane formation conditions more favorable in the saturated or frozen saturated organic horizons with limited contact to the atmosphere, while carbon dioxide would be favored in aerated near-surface layers. These relationship trends can be observed for nearly all site-exposure profiles. Methane increases at or near the top of the permafrost table, reaches a maximum in the permafrost, and decreases again at depth. Sites with the greatest water contents (sites 5 and 6) had the greatest methane contents. On an aerial basis the releases of methane are on the order of one-tenth those observed for wet tundra on the North Slope (Vourlitis et al. 1993).

Conclusions

Exposure heights along Elson Lagoon are near average for the North Slope, Alaska, coastline. However, Elson exposures contain larger OC stores than the average for the whole North Slope, Alaska, coastline. These larger OC stores are due to the presence of soils with both cryoturbated organic matter and layered peat or muck horizons. These OC rich horizons are a result of the drained-lake sequence history and the medium-textured soils of the lagoon's nearshore area. The history of the tundra, alternating from moist to aquatic conditions, allows for cryoturbation causing an increase in the OC storage in the moist condition, while peat development and sedimentary accumulation increases OC during wet or aquatic conditions. There is more OC eroding from exposures than would be predicted from the currently available local soil survey map of Bockheim et al. (1999).

The TN of exposures can also be expected to be higher than for other North Slope shore areas, as most of the nitrogen is associated with the eroding organic matter. The higher TN of eroding organic matter can be expected to positively affect the nutrient status and biotic activity of the nearshore area with N often limiting activity.

The stratification of peat by cryoturbation and by aquatic-sedimentary accumulation has resulted in layers of organic-enriched materials near the surface of the present-day permafrost table and just above it in the lower active layer. Both layers are under water-saturated conditions that favor accumulations of methane as organic matter decomposes. In exposures with these saturated organic layers, methane has accumulated presumably from subzero-temperature soil respiration and/or encasement of gases produced under previously thawed conditions with permafrost table fluctuation. Carbon dioxide present will be released along with methane upon thaw due to thermal erosion at the shoreline. This release upon thaw is in relatively small amounts, but could become a significant amount with increased rates of erosion and or with increased methane production due to changing soil thermal regimes.

Acknowledgments

This study was conducted as part of NSF grant OPP Grant #0436179. Field work was through the assistance of Yuri Shur, Mikial Kavansky, Daniel Fortier, Vladimir Tumskoy, Sabine Fiedler, Prothap Kodeal, and BASC staff at the Barrow Ilisagvik College.

The Application of Tritium in Permafrost Ground-Ice Studies

F.A. Michel
Dept of Earth Sciences, Carleton University, Ottawa, Canada

Abstract

Tritium, a radiogenic isotope of hydrogen with a half-life of 12.43 years, can be utilized as a natural tracer in water (ice) investigations. Anthropogenic tritium released into the atmosphere during nuclear testing from the 1950s to 1970s created peak monthly concentrations as high as 10,000 T.U. Recent values for Arctic Canada monitoring stations are below 30 T.U. Seasonal variations indicate higher tritium values occur during summer. Infiltration of precipitation into the thawed active layer during the summer produces elevated tritium concentrations within the soil profile. Elevated tritium levels also occur in ground ice below the permafrost table and have been interpreted previously as indicative of downward migration of water into the permafrost along a thermal gradient. Re-evaluation of data suggests that this tritium within the permafrost may in part represent the preservation of active layer water within a zone of aggrading permafrost during climatic cooling in the 1950s to 1980s.

Keywords: climate change; ground ice; permafrost; tritium.

Introduction

Although permafrost refers strictly to a thermal ground condition, many investigations of permafrost consider the distribution of water and ice in the soil as an important component due to their effects on the soil structure and stability. The accumulation of ice in the near surface can cause frost heave, while melting of excess ice can lead to thaw settlement; either can result in severe geotechnical problems. In addition, over time landforms and landscapes can be altered due to the freezing and melting of excess ice (e.g. pingos, palsas, ice wedges, patterned ground, thaw lakes, and excessive shoreline erosion) caused by changing climatic conditions. As the climate at any site changes, the seasonally frozen and thawed active layer can increase or decrease in thickness (CALM 2008) and as a result the position of the permafrost table will fluctuate.

Tritium, a radiogenic isotope of hydrogen that was produced in large quantities during atmospheric testing of nuclear devices in the 1950s and early 1960s, has been utilized by several researchers to investigate the incorporation of modern precipitation (since the 1950s) into ice contained within the active layer, the upper permafrost, and permafrost related features, such as ice wedges and frost blisters. Michel (1982, 1986) and Michel & Fritz (1978, 1982) first identified the presence of tritium within permafrost in northern Canada, while Russian investigations in Siberia were reported by Chizhov et al. (1983, 1985) and Chizhov & Dereviagin (1998). Other studies include reports by Livingstone (1988), Burn & Michel (1988), and Lewkowicz (1994). In these studies tritium has been employed as a marker to identify the presence of young water (ice) and to investigate the mechanisms for transferring this water into the permafrost from the active layer. The purpose of this paper is to examine the effects of climate change on the distribution of tritium in permafrost.

Distribution of Tritium in Precipitation

Tritium is naturally produced in low concentrations in the upper atmosphere through the interaction of cosmic radiation with ^{14}N and has a radiogenic half-life of 12.43 years. The distribution of this natural tritium in the stratosphere of the northern hemisphere is poorly understood, but is expected to be higher toward the poles; the natural concentration is considered to be in the range of 10 to 20 tritium units (T.U.; 1 T.U. = 1 atom of tritium in 10^{18} atoms of hydrogen). Testing of nuclear devices injected large quantities of anthropogenic tritium into the atmosphere, primarily in the northern hemisphere, with peak concentrations in precipitation occurring in 1963. Figure 1 displays the 1963 average monthly concentration data from North American monitoring stations. Average tritium concentrations over the polar region in 1963 (5000 T.U.) were 2 to 3 times that of the southern part of the continent and the highest recorded monthly values reached 10,000 T.U. in Whitehorse, Yukon and Nord, Greenland (IAEA 2007). Since 1963, the concentration in precipitation has decreased so that typical values today are in the range of 10 to 25 T.U. (Figure 2). At some localities, new sources of radiogenic emissions, such as nuclear facilities, may periodically give rise to increases in the tritium concentration of local precipitation.

There is also a seasonal variation at any given locale that is related to the ‘leakage’ of tritium from the stratosphere into the troposphere during the spring (Payne 1972). This causes the tritium concentration in precipitation to rise during the spring, peak in the summer and decline during the fall and winter, as shown in Figure 3 for the monitoring station at Alert.

The tritium concentration in precipitation peaks during the warmest part of the summer (July) when the active layer is rapidly thawing. The summer months also receive the highest amount of precipitation.

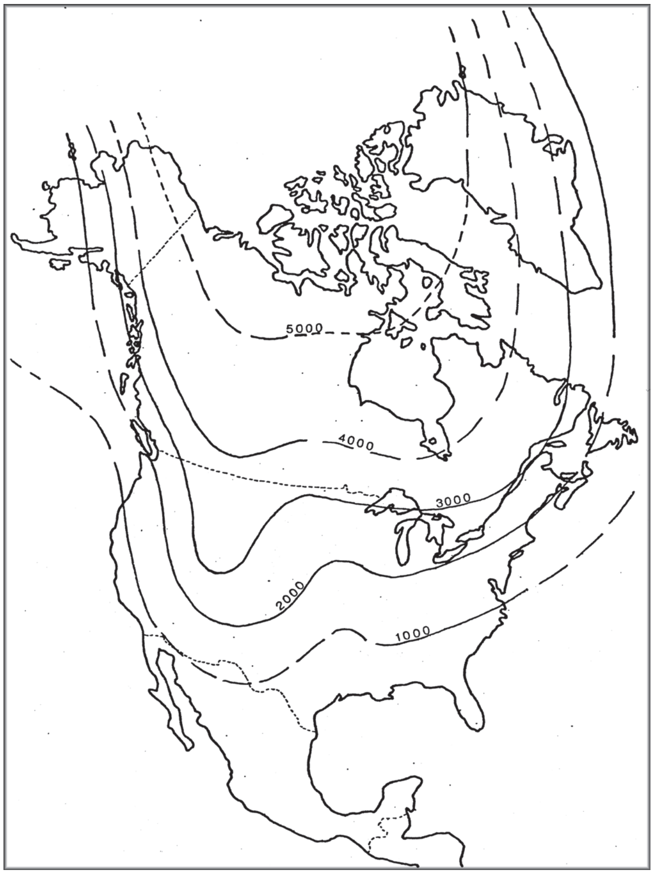

Figure 1. Distribution of average monthly tritium concentrations (in T.U.) for precipitation in North America during 1963. Dashed lines indicate uncertainty due to lack of station data (Michel 1977).

Distribution of Tritium in the Active Layer and Upper Permafrost

Tritium concentrations, for water (ice) contained within the active layer and upper permafrost, have been measured since the 1970s. Chizhov & Dereviagan (1998) summarize over 250 tritium data from a number of sample sites throughout Siberia, with measurements as high as 352 T.U. in the active layer and 323 T.U. in the upper permafrost. The author has measured numerous samples from cores collected along the various proposed pipeline routes in northern Canada and from a detailed study site (Illisarvik) in the outer Mackenzie Delta (Michel 1982). The highest concentration measured at Illisarvik was at a depth of 30 to 40 cm (269 T.U.), while the highest overall tritium value (370 T.U.) was measured from a site south of the Baker Lake community in Nunavut. Peak concentrations throughout the Canadian arctic are generally in the range of 200 to 250 T.U. for samples collected in the mid to late 1970s and early 1980s and are usually found in the lower portion of the active layer or the upper 30 to 50 cm of permafrost. These concentrations are higher than the contemporary average annual precipitation values shown in Figure 2 and must either represent older precipitation recharged during the late 1960s to early 1970s, or summer precipitation recharge that was not mixed (diluted) with snowmelt from winter precipitation. Many active layer tritium concentration values are similar to the average precipitation values.

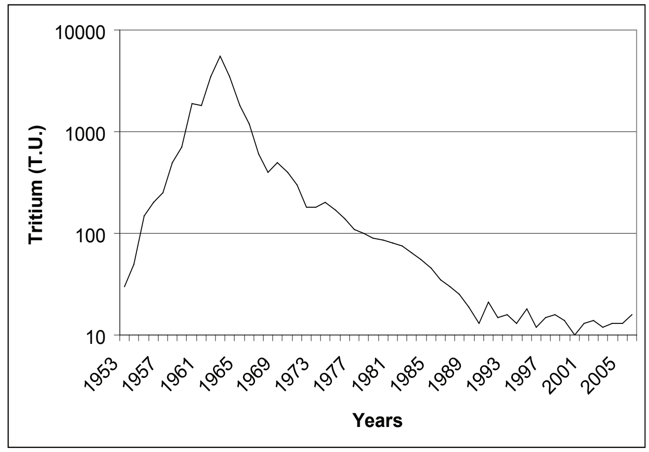

Figure 2. Estimated average tritium concentration for precipitation in the Canadian Arctic. Modeled on data from Ottawa, Canada, plus shorter term records from various Canadian (1955-1969), Greenland (1962-1971), and Alaska (1962-1971) stations (IAEA 2007). Also includes author's spot data from 1975 to 1989 and the author's arctic precipitation network data from 1989 to 2006.

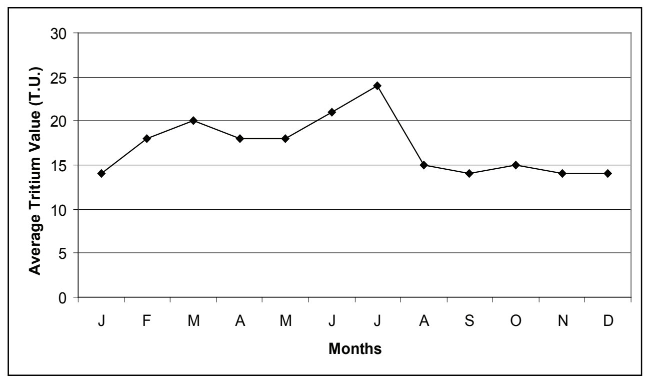

Figure 3. Average monthly tritium concentration in precipitation at Alert, Canada, for the period 1990-1999. Note the spring and summer increase.

Chizhov et al. (1983) and Chizhov & Dereviagan (1998) concluded from their investigations that the presence of tritium in the upper permafrost indicates that extensive moisture exchange takes place between the active layer and permafrost. A study by Burn & Michel (1988), where test plots were irrigated with water containing elevated tritium concentrations, also concluded that the transport of tritiated water into the upper permafrost was due to mass flow rather than molecular diffusion. In all of these studies, the transport of water into the upper permafrost was considered to be due to water migration along a thermal gradient. Most of these investigations involved the collection of spot samples from shallow pits or cores.

Detailed profiling was conducted in May 1979 for two cores at Illisarvik; one within the limits of the lake drained in 1978 (79-4) that subsequently froze to a depth of 2.45 m during the winter of 1978-79, and the other just outside the lake basin (79-3) (Figures 4a and b, respectively). Tritium in

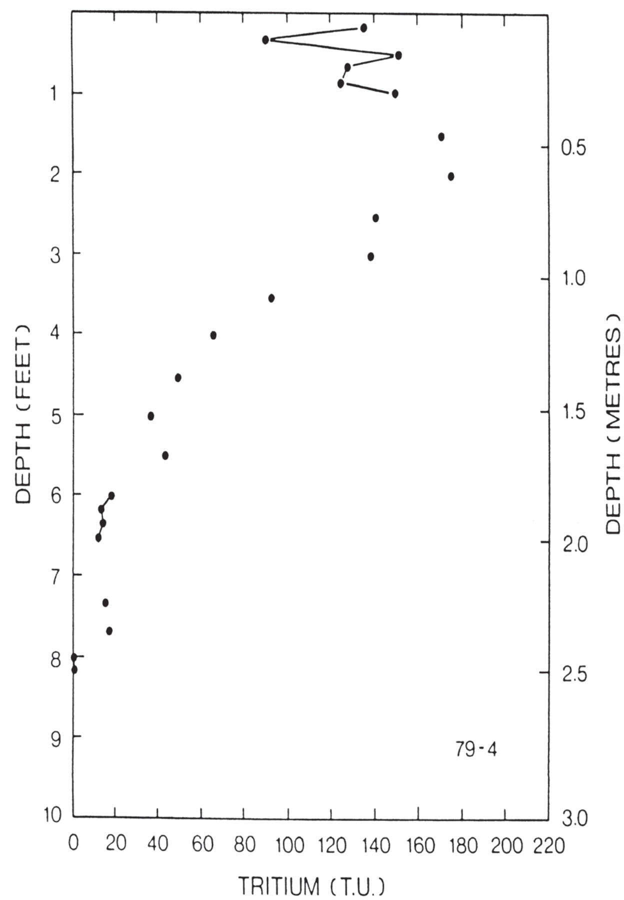

Figure 4a. Tritium concentration profile for lake-bottom sediments at Illisarvik in the Mackenzie Delta (Michel & Fritz 1982).

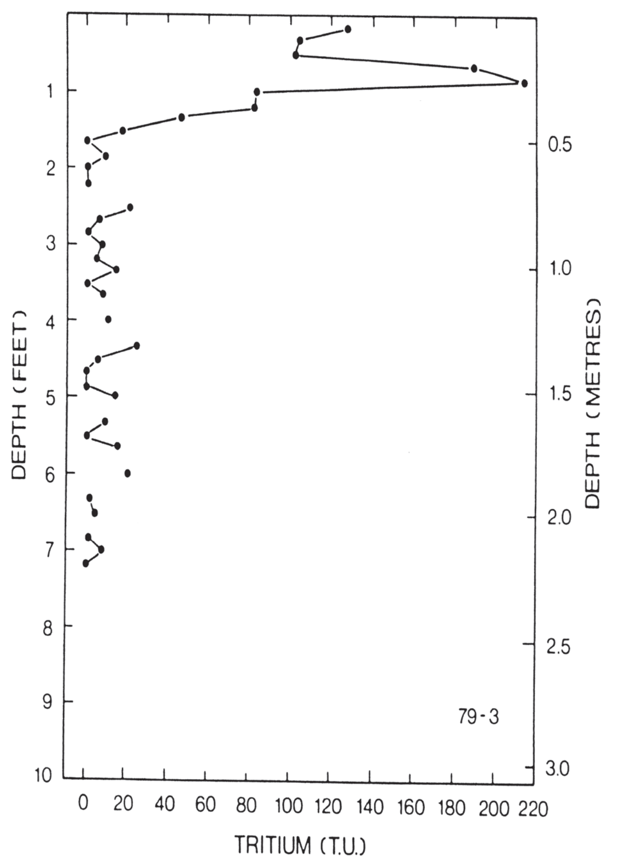

Figure 4b. Tritium concentration profile for frozen ground adjacent to the drained lake at Illisarvik in the Mackenzie Delta (Michel & Fritz 1982).

water from the shallowest lake sediment sample (136 T.U.) in core 79-4 closely reflects the tritium concentration of the lake water just prior to drainage (141 T.U.), while deeper samples display a gradual increase in tritium concentration to 177 T.U. at a depth of 40 cm. Below 40 cm the tritium profile displays a gradual decline to background concentrations at a depth of approximately 2 m. This profile is what would be expected for downward diffusion from a point source (the lake) and developed while the lake sediments were unfrozen (as a lake talik). Since the lake had no discharge creek and was surrounded by ground containing permafrost, there was little if any hydrologic gradient within the unfrozen sediments and thus little physical water migration within the lake sediments. The relatively low peak concentration of 177 T.U. is only on the order of 10% of the expected 1963 peak value (accounting for radiogenic decay) that would occur if the tritium were moving downward as plug (mass) flow. Therefore, through the diffusion process, the tritium concentration is reduced.

In contrast, tritium concentrations for core 79-3 waters peak at a depth of 25 cm (214 T.U., Figure 4b) which corresponds to the base of the active layer as determined from the stable isotope fractionation pattern measured for the pore water profile (Michel 1982). The tritium concentrations drop rapidly to 83 T.U. immediately below 25 cm and reach background values by a depth of 50 cm. Moisture contents throughout this 50 cm interval averaged 300% by weight, with the 20-25 cm interval the lowest at 125%. The sediments in the upper 50 cm of core 79-4 were also saturated, with moisture contents exceeding 500% by weight. This excess water resulted in the formation of ice lenses throughout the depth profiles of both cores.

Another core (NWD-1), collected near Norman Wells in the Mackenzie Valley, was sampled in detail to study its stable isotope (^{18}O) distribution, but was also analysed for tritium. As shown in Figure 5, elevated tritium concentrations were detected more than 50 cm below the level of maximum thaw. Furthermore, the stable isotope profile displays evidence of isotope fractionation generated at the time that the pore water froze.

Infiltration of young tritiated water after this ground was frozen, either by diffusion or mass flow along a temperature gradient, would have altered the stable isotope profile and thus the tritium must have been incorporated prior to permafrost forming in this soil. Since the tritium is related to anthropogenic sources, the presence of tritium in the permafrost indicates that this particular section of ground froze within the previous decade as a result of permafrost aggradation. Livingstone (1988) also found tritium within a section of aggrading permafrost that was caused by the continued deposition of sediments at his study site.

Tritium analysis of other ground ice bodies in Siberia

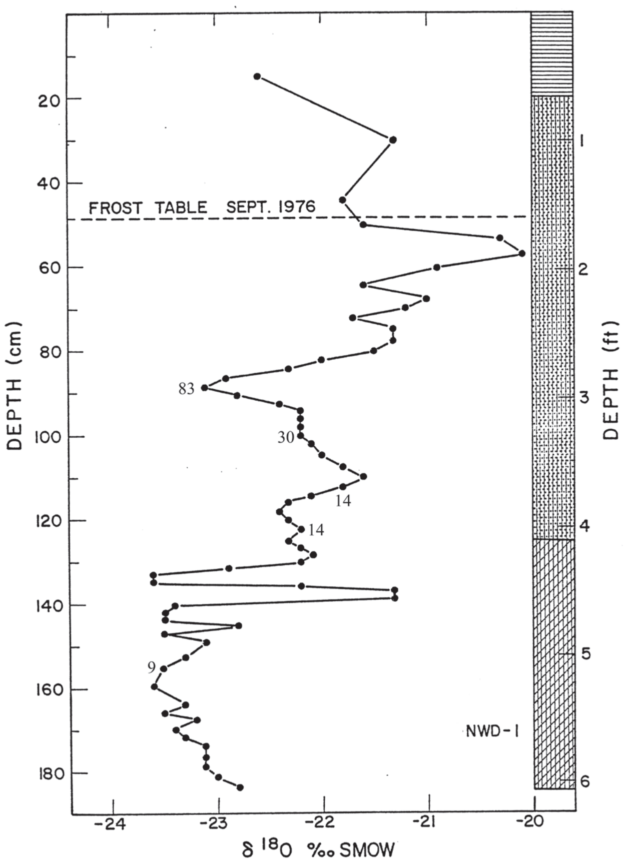

Figure 5. ^{18}O profile for frozen and unfrozen sediments near Norman Wells with spot tritium concentrations (in T.U.) shown below the frost table. Soil profile from top down consists of peat, sandy silt, and silty clay. (Modified from Michel & Fritz 1978.)

and in northern Canada also have been successful in identifying ice formed within the latter half of the 20th century. Identification of active ice wedge growth has been demonstrated in several studies, including Lewkowicz (1988) and Chizhov & Dereviagan (1998). It must be remembered that the source water for ice wedges, winter snowmelt, will contain tritium concentrations that are below the annual average precipitation value. Chizhov & Dereviagan (1998) have also reported tritium data for massive ice from a variety of settings and have been able to determine whether the ice is young (tritium bearing) or relict (pre-1953).

Tritium concentrations for local surface waters will reflect average precipitation values while groundwater retains a tritium signature from precipitation at the time of recharge (Michel 1977) and thus can be useful in distinguishing water sources. Michel (1986) found that the tritium concentration of massive ice within frost blisters at a site in Yukon reflected the age of the source water (local springs) rather than direct precipitation at the site. The tritium concentration within the ice core was considerably higher than water (ice) contained within the overlying organic cover and active layer. The tritium did not appear to have undergone fractionation during freezing of the ice as had been observed for the stable isotopes of the water. Without a clear understanding of how the massive ice formed, an incorrect age could have been assigned to the frost blister. It is important therefore to be careful with the age interpretation of tritium data.

Effect of Climate Change on Tritium Distribution

The active layer only begins to thaw once the snow cover has disappeared and solar radiation is absorbed by the darker ground surface. Excess water, frozen into the active layer during the previous winter as pore ice or ice lenses, will gradually drain down slope through the active layer and enter the local surface water system. Relatively warm summer rains can run off over the ground surface or infiltrate into the unfrozen portion of the active layer and enhance the rate of thaw. By the time the active layer begins to refreeze in the fall, there has been considerable drainage and flushing of the water originally in the active layer, as well as some mixing with the summer precipitation. This will result in a tritium signature for water in the unfrozen active layer that reflects a combination of the tritium concentrations found in the summer precipitation and that of water retained from previous years.

During the fall as the active layer refreezes, unfrozen tritiated water within the active layer will migrate along thermal gradients, both upward toward the ground surface and downward toward the permafrost table, leaving a relatively moisture deficient central zone within the active layer as observed at Illisarvik. If the following summer is cooler and the active layer does not thaw to the same depth as the previous year, some of the tritiated water will be retained in ice formed at or immediately below the permafrost table. Successive years of cooler temperatures would result in an aggrading permafrost table and the preservation of tritiated ice, while a series of warmer summers with greater active layer thaw would result in the formation of a thicker active layer and melting of ice previously accumulated at the permafrost/active layer boundary.

Average annual air temperatures have varied throughout the 20th century. From the 1910s to the early 1940s global temperatures rose such that the highest temperatures of the 20th century were recorded in the 1940s. A cooling trend followed, during the period from the late 1940s to the early 1980s, which has been followed in turn by another warming trend through the 1990s (Hardy & Bradley 1996). The cooling trend in the middle of the 20th century led some scientists to predict the start of a new ice age, while the latest warming trend has spurred the recent global warming debate.

All of these sustained periods of cooling and warming will have an impact on the depth of thaw and the thickness of the active layer. Maximum thaw depths should have been attained during the 1940s. The first part of the subsequent cooling trend corresponds to the period of atmospheric nuclear testing (1953 to 1962). During this period of cooling, the thickness of the active layer should have been decreasing and the permafrost table should have been aggrading upward. Precipitation infiltrating the active layer would have contained significant concentrations of tritium, which would then be preserved within the aggrading permafrost. Of course, variations in the active layer thickness also will occur due to site-specific microclimate effects that could differ from regional climate trends.

Although significant downward diffusion of tritium can occur at unfrozen sites, such as the Illisarvik lake sediments, and moisture migration along thermal gradients can aid in the transport of tritium into the upper permafrost, much of the tritium preserved in the upper 30 to 50 cm of permafrost is probably due to permafrost aggradation under a cooling climate regime. This preservation of tritiated water (ice) in the upper permafrost provides an independent estimate of the maximum active layer thickness developed since the 1950s with which to compare changes occurring in the active layer today due to the current warming trend. Many of the samples analysed for tritium were collected during the last cooling trend when active layers were thinning and therefore tritium was preserved within the upper permafrost. Calculated tritium decay rates for older precipitation from the 1960s and 1970s indicates that preserved precipitation from this period of aggrading permafrost should still have a higher radiogenic signature compared to modern precipitation; however, dilution and mixing with older tritium-free water may have lowered the concentrations to near background levels.

Conclusions

Previous studies have demonstrated that tritium can be utilized as a natural tracer in permafrost investigations and can help to distinguish between water sources of different ages. The presence of tritium in ground ice is indicative of water that recharged into the subsurface during the last half of the 20th century when significant anthropogenic tritium was injected into the atmosphere due to nuclear testing.

Although downward migration of moisture along thermal gradients or due to diffusion is possible, the majority of tritium detected within the upper 30 to 50 cm of permafrost is most likely the result of aggrading permafrost due to climatic cooling during the 1950s to 1980s. The identification of thaw depths caused by warming climatic conditions earlier in the 20th century will permit comparison with modern active layer development caused during the current warming trend.

Abstract

Since 1988, long-term monitoring of the Furggentälti rock glaciers (Western Alps, Switzerland) has revealed significant changes in process dynamics. The changes include large seasonal and interannual variations of rock glacier activity, superimposed by an exponential increase of overall rock glacier creep velocity. During the monitoring period, the largest of the rock glaciers (located at 2450 m a.s.l.) developed signs of decay, with some parts of the rock glacier becoming inactive and others showing patterns of collapse. Analysis of local climate data suggests a strong and surprisingly low-latency link between rock glacier activity and weather patterns. Even though some of the long-term developments in the kinematics of the Furggentälti rock glaciers are also influenced by other factors, such as topography and process feedback, the short-term response to climate signals points at ever warmer permafrost conditions at the site as the major cause for the changes observed.

Keywords: climate change; ground surface temperature; long-term monitoring; rock glacier activity; Switzerland; warm permafrost.

Introduction

Background

During the 2003 summer heat wave, the many rock fall events in the Swiss Alps—the most prominent one affecting the well known Matterhorn—have demonstrated the very immediate and very obvious impact of rising temperatures on permafrost present in rock walls.

Though slower and less obvious, the thawing of perennially frozen debris typically found in rock glaciers is now becoming visible at the lower limit of alpine permafrost.

For the last 20 years, the Institute of Geography of the University of Bern has been closely monitoring a small rock glacier located in the western parts of the Swiss Alps. During the monitoring period, the rock glacier has undergone rapid changes in shape and process dynamics, which are coupled with the development of the local climate.

Situated at the lower limit of Alpine permafrost, the Furggentälti rock glacier is a textbook scenario for the impact of a warmer climate on rock glacier activity and evolution.

The project site

The Furggentälti (46°24.5′N, 7°38′E), a small valley near the Gemmi pass, is located in the western part of the Bernese Alps between Kandersteg and Leukerbad (Switzerland). The valley stretches over a range of approximately two square kilometers from west to east, from an altitude of approx. 2450 m to approx. 2850 m a.s.l.

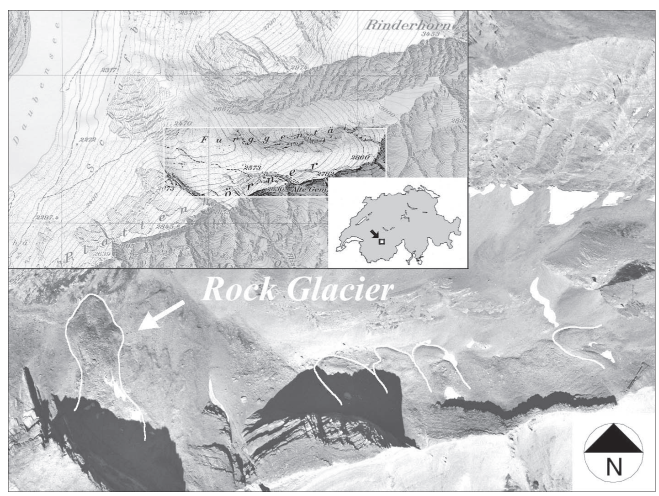

Figure 1. Geographic location and aerial view of the Furggentälti Valley (© Swiss Federal Office of Topography).

Most of the surface of the valley is covered by vast layers of periglacial debris, forming large talus cones on the foothills of the steep northern slope.

The Furggentälti Valley is home to many periglacial forms, including solifluction lobes and several small active and inactive rock glaciers on the north exposed slope. Typical periglacial patterned ground is also present in a flat region of the valley.

The focus of interest lies on an approximately 250 m long tongue-shaped rock glacier in the lower western part of the valley (Fig.1). The rock glacier is situated on a slope of about 20° of northern aspect, its front protruding into the bottom of the valley, at an altitude of approx. 2450 m a.s.l.

The research project

Initiated in 1988, the long-term monitoring project consists of several measurement programs recording meteorological data, ground temperatures, ground surface temperatures (GST, recorded by ultra miniature temperature loggers UTL, www.utl.ch), and rock glacier activity data through aerial and terrestrial survey. The time series recording air and ground surface temperatures represent the longest such measurement series in a periglacial environment in the Alps.

The project is funded by the Institute of Geography of the University of Bern (www.giub.unibe.ch), the PRO GEMMI foundation of Bern, and by the PERMOS program (Permafrost Monitoring Switzerland, www.permos.ch).

Changes in Rock Glacier Activity

Multi-decadal trends

Photogrammetric survey of the Furggentälti rock glacier spans over nearly five decades, the first set of small scale aerial photographs dating back to 1960. Since 1990, large scale aerial imagery was flown at five year intervals, and since 2001 in a two year interval.

A first photogrammetric assessment of the Furggentälti rock glacier in 1996 (Krummenacher et al. 1998) revealed unusually high surface velocities and a rapid increase during the late eighties and early nineties. Further photogrammetric surveys (Mihajlovic et al.2003) confirmed this multi-decadal trend, which was also observed in neighboring rock glaciers in the valley. The survey also found indications for a slowdown in surface velocities in the peripheral parts on the left and right side of the rock glacier (Fig. 2).

The latest data (Mihajlovic et al., in prep.) confirm both trends, with increased surface velocities found along the centerline of the rock glacier and a slowdown on the sides. The data have also detected the inactivation of peripheral parts of the rock glacier (Fig 3).

Interannual variations

Since 1994, terrestrial survey campaigns provide a more detailed picture of the development of rock glacier activity and process dynamics.

Annual survey campaigns have uncovered interannual variations in the activity of the rock glacier, showing a clear pattern of thermally induced acceleration and deceleration of surface velocities (Fig. 4).

The pattern clearly reflects the development of the warming conditions at the site, with some attenuation during 2005 to 2007.

Seasonal activity pattern

A seasonal activity pattern was detected during a series of repeated survey campaigns from August 1998 to October 1999 (Mihajlovic et al. 2003). After a continuous slowdown during winter, the permafrost creep process accelerates rapidly at the beginning of the Zero Curtain phase in spring, when water infiltrates into the frozen active layer and rock glacier material, triggering an instant warm-up of the thermal conditions there (Fig. 5).

New clues

The results (Nussbaum 2008) of geophysical soundings (GPR and refraction seismic) in 2007 are providing new clues for the unusual shape and rheology of the Furggentälti rock glacier, which are also affected by the special arrangement of rock glacier material on the underlying bedrock topography (Fig. 6).

The observed long-term acceleration of rock glacier activity could be partly the result of this arrangement or of process feedbacks such as the increasing surface area exposed to irradiation due to the extending rock glacier footprint. However, similar findings on neighboring rock glaciers in the Furggentälti, together with the thermally induced short-term variations, point at the warmer climate as the main cause for the long-term development.

Similar developments across the Alps

During the last years, similar observations on other rock glaciers have provided a clearer picture of changes in rock glacier activity in different parts of the Alps. Delaloye et. al. (2008) gives an overview of data from 17 rock glaciers. Several studies mention a similar increase of rock glacier surface velocities during the past decades (e.g., Roer 2005), as well as interannual variations (e.g., Ikeda et al. 2003).

Impact of a Warmer World

Ice temperature and permafrost creep

Lab experiments using centrifuges to assess the mechanical stability of rock glacier material have shown that the plasticity of rock glacier material increases rapidly with ice temperatures approaching 0°C (Arenson 2003). The reason for this non-linear behavior was found in the exponential increase in the presence of liquid water in the material, when increasing from approximately -2.5°C to 0°C.

Ice temperatures in the Furggentälti rock glacier cannot be measured directly, as the high surface velocity of several meters per year prevents the installation of a borehole or the retrieval of other (wired) equipment. Instead, the winter equilibrium temperature (WEQT) is used as an estimation for the permafrost temperature at its coldest state in the year. The WEQT is derived from continuously recorded ground surface temperatures (GST), which are measured by ultra miniature temperature loggers at several locations on the rock glacier surface.

During most of the 13 year monitoring period, winter equilibrium temperatures recorded on the Furggentälti rock glacier were within the range of -2.5°C to -1.5°C, with the exception of two distinct cooling events that led to a significantly lower WEQT in early 1996 and 2006.

Influence of weather patterns and snow cover

A comparison of ground surface temperatures of several years (Fig. 7) shows the broad variation of the atmospheric influence on the active layer.

The GST monitoring period (1994 to 2007) contains both positive and negative interannual WEQT fluctuations, which coincide with positive and negative variations of rock glacier activity. In the positive case, atmospheric conditions during the preceding year led to a general increase of ice temperatures, whereas in the negative case an overall cooling occurred. This information can be used as a simple pointer to assess the direction of the energy flux integral at the ground surface, for the corresponding interval.

The main factor controlling direction and magnitude of the energy flux is the snow cover (Keller 1994, Krummenacher et al. 1998, Mittaz et al. 2002) which acts both as a shortwave radiation shield and as a thermal insulator. Timing, duration and depth of the snow layer modulate the energy balance of the ground surface, and as a consequence the thermal conditions in the active layer.

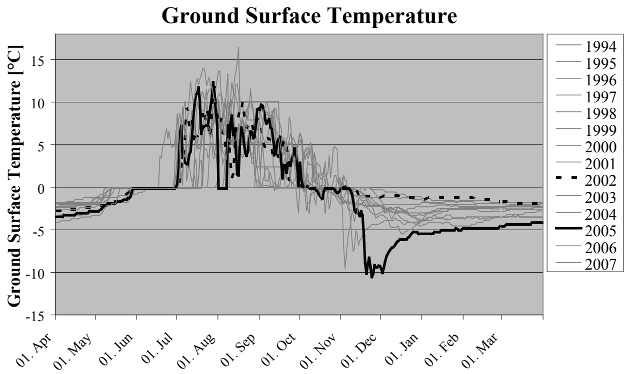

Figure 7. Bandwidth of fluctuations in ground surface temperatures from 1994–2006. Dotted line: 2002/2003; black line: 2005/2006. Recorded by UTL data logger #3 on the Furggentälti rock glacier surface.

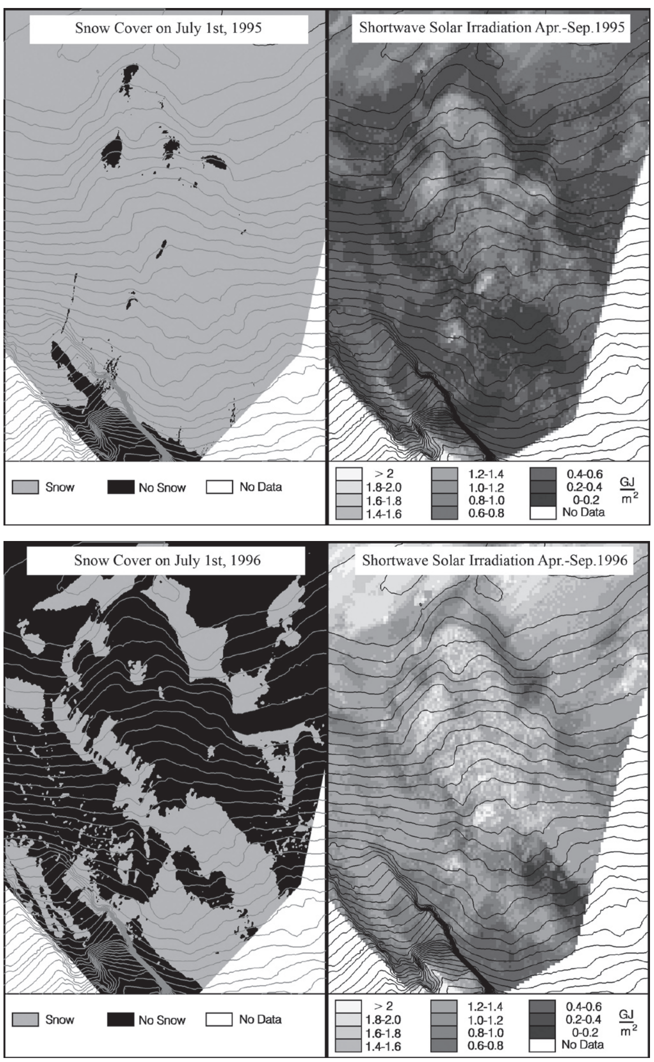

Figure 8. Snow cover variations (July 1 1995 and 1996) (derived from terrestrial orthophotos) and net shortwave solar irradiation April to September 1995 and 1996 on the Furggentälti rock glacier. Based on daily snow cover maps and shortwave radiation (1-hour interval), high resolution elevation model.

A study (Mihajlovic et al. in prep.) using local shortwave irradiation data and snow cover maps (derived from digital orthophotos of an automated camera taking daily photographs of the site) assessed the total shortwave irradiation on the rock glacier surface during the summer of 1995 and of 1996, which corresponds with the distinct positive variation between the WEQT in 1996 and 1997 (Fig. 6). During the period from April 1 to September 30, 1995 the average net shortwave irradiation on the true surface of the rock glacier amounts to 38 W/m^2, compared to 108 W/m^2 during the same period in 1996 (Fig. 8). This enormous difference is in large part caused by the different duration of the snow cover during spring and summer, whereas the total shortwave irradiation sum only differed by approximately 9%.

Analyzing the influence of the snow cover in GST data

In order to get a better picture of how different temporal patterns of snow cover occurrence influence permafrost temperature variations, a simple method was developed which allows extracting more specific parameters from existing GST measurement series. The basic idea is to skip from looking at GST time series in fixed intervals (e.g., annual intervals like MAGST Mean Annual GST, or monthly intervals etc.) to intervals which take into consideration the different states of thermal insulation properties of the snow cover.

For this, the annual cycle of snow cover ablation and development is divided into four phases, where each represents a different role of the snow cover on the energy flux between ground surface and atmosphere:

- Phase Z: Zero Curtain (springtime); GST shows 0°C, direct energy flux between atmosphere and ground surface is suppressed.
- Phase N: No Attenuation; during the absence of snow, GST shows big daily temperature fluctuations while the energy flux between atmosphere and ground surface is unhindered.
- Phase L: Low Attenuation; in this phase, a snow cover of limited depth is present. Energy flux between atmosphere and ground surface is attenuated, but not suppressed. Daily temperature fluctuations are still visible in the GST, but clearly attenuated.
- Phase H: High Attenuation; in this phase, the ground surface is covered by a thick and thermally insulating layer of snow, through which the energy flux is highly attenuated and therefore only minimal. No daily temperature fluctuations visible in GST.

To extract the beginning and end of these phases, the GST data is processed through a series of simple signal processors which act as band pass filters on the daily fluctuations showing up in the data. While the *Zero Curtain* (no daily fluctuations and 0°C) and the *No Attenuation* phase (large daily fluctuations) are easily distinguishable, the *Low Attenuation* phase (daily fluctuations below a certain threshold value) is less clearly defined and can vary by a few days, depending on the actual filter settings (Mihajlovic, in prep.). Figure 9 shows a typical arrangement of the phases.

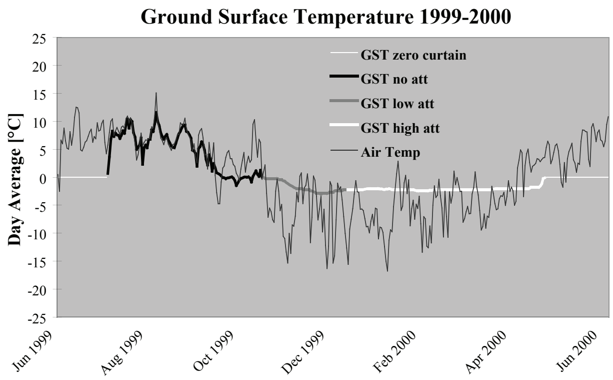

Figure 9. GST data divided into four phases which roughly represent different states of the thermal insulation properties of the snow cover; thin white line: Zero Curtain (phase Z); black: no attenuation of the atmospheric signal by the snow cover (phase N); gray: low attenuation phase (phase L); thick white line: high attenuation phase (phase H); thin gray line: air temperature (2 m).

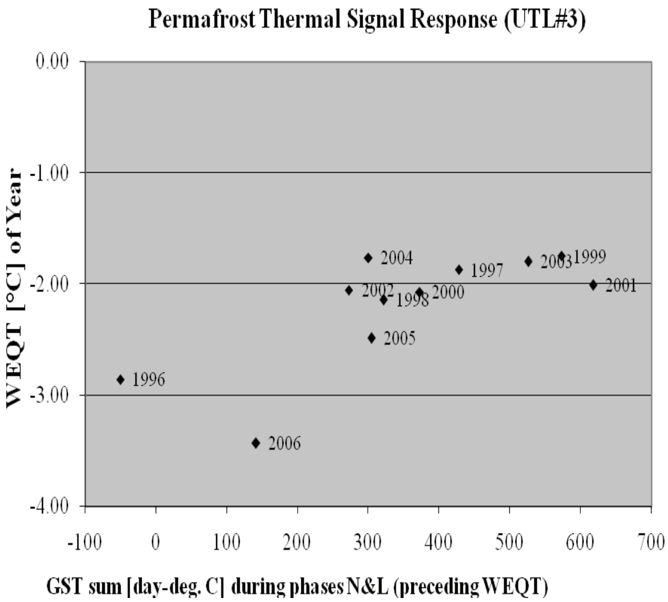

Figure 10. WEQT compared to the ground surface temperature sums of the preceding *No Attenuation* and *Low Attenuation* phases.

During Phase N and L, the ground surface temperature recorded is influenced by the energy flux between atmosphere and active layer, whereas during the *Zero Curtain* the temperature recorded is that of the snow cover. During the *High Attenuation* phase H, the data reflects the thermal "response" of the permafrost to the thermal "signal" applied to the surface of the active layer during the preceding phases N and L.

Comparing different years of GST data by adding temperatures sum for N and L phases only, the relation between thermal "signal" and the thermal "response" becomes more obvious (Fig 10).

The non-linearity in the relation shows how the thawing of ice in the rock glacier material is acting as a thermal buffer in warmer years with a high energy input. Doubling the thermal signal from, for example, 300 day-degrees C to 600 will not lead to substantial increase of the WEQT (and,

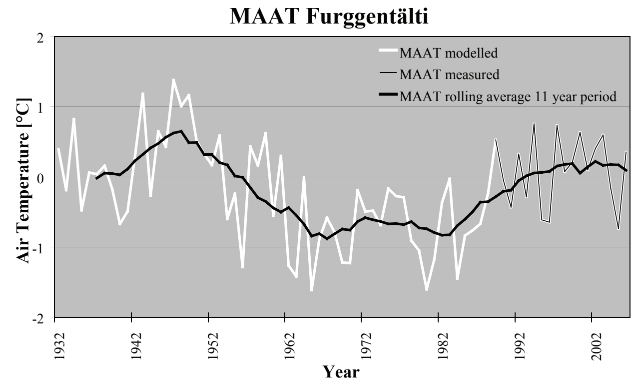

Figure 11. Modeled and measured air temperature in the Furggentälti; based on data of the nearby MeteoSwiss (www.meteoswiss.ch) meteorological station Montana 1932 to 1988, local measurements since 1988.

therefore, permafrost temperature), as the excess energy input of the warm season is leaving the rock glacier system as melt water. In contrast to this, reducing the thermal signal to 150 day-degrees C leads to a significant drop in permafrost temperature.

Long-term trend

Between 1988 and 2007, the trend in the air temperature data measured at the site shows a clear rise in average air temperatures during the first decade of measurements, which is then followed by a series of both extremely high and low temperatures during recent years. Long term temperature records of the nearby Meteoswiss meteorological station of Montana have been used to model air temperatures for the preceding decades (Fig. 11). The data suggest a general increase in air temperatures since the mid-1960s, preceded by a significantly warmer period during the forties and fifties.

One of the changes witnessed during the monitoring period is the increasing lack of snow. The clustered occurrence since the early nineties of winters with only little snow did not lead to a general cooling of the permafrost present in the rock glacier, as could be expected in higher regions with MAAT<<0°C. At the comparably low altitude of the site (average air temperature 1988–2006 = 0.1°C), the importance of the snow cover acting as a radiation shield during early summer is exceeding the "cooling effect" of the absence of snow during the cooling phase in early winter, as typical winter temperatures and the typical timing of snow falls do not a allow a profound cooling of the thermal conditions in the early winter of an average year.

The two WEQT cooling events recorded in the 13 year GST series (Fig. 10) find their explanation in abnormalities in the occurrence of snow; while an unusually long duration of a thick layer of snow on the Furggentälti rock glacier during the cold summer of 1995 led to the cold WEQT recorded in early 1996, the 2006 negative WEQT variation was caused by a lack of snow combined with exceptionally cold air temperatures during the preceding weeks of early winter.

Preliminary results based on long term snow depth and air temperature data of Montana station suggest that the depth and timing of snow cover in combination with air temperatures did not lead to a significant cooling of the permafrost conditions in the Furggentälti rock glacier during most of the past 75 years (Mihajlovic, in prep.).

Conclusions

The 20-year period of monitoring has amassed a large amount of scientific data about the sensitive environment in the Furggentälti Valley. The rather low cost methods used in the monitoring program such as the UTL data logger, which was especially developed for the project by B. Krummenacher (Krummenacher et al. 1998), have allowed uninterrupted data series over many years, despite limited funds.

The monitoring data is offering clues to a deeper understanding of the link between seasonal weather patterns on permafrost temperatures and subsequently on rock glacier activity.

The changes in shape and activity of the rock glacier during the last five decades reflect the development of the local climate during that period, which follows a general trend to warmer air temperatures and an increasing lack of snow. The changes also confirm the scenario of increased rock glacier activity before the onset of inactivation.

The findings of the monitoring program provide a graphic example for the impact of a warmer climate on the lower limit of alpine permafrost.

Convective Heat Exchange Between Rivers and Floodplain Taliks

V.M. Mikhailov
North-Eastern Research Station of the Melnikov Permafrost Institute, SB RAS, Magadan, Russia

Abstract

The results discussed are estimates of convective heat exchange between rivers and floodplain taliks. Heat balance calculations were made for large sections of six rivers of northeastern Asia. Heat flux from rivers peaks in June, rarely in July, 100–200 W/m^2. Total heat transfer during summer is 700–1000·10^6 J/m^2; thus taliks obtain larger amounts of heat from rivers than from soil surface. In autumn, heat flux changes its sign, and rivers begin to receive heat back. This slows down their cooling, detains water freezing (for up to 10 days or even more), and sustains numerous glades in winter. These features demonstrate that convective heat exchange is not just capable of upholding floodplain taliks; it is far excessive for this task even in the coldest region of the Northern Hemisphere. Obviously, climatic conditions are not a limiting factor for geographical distribution of such taliks.

Keywords: convective heat exchange; floodplain taliks; heat balance; rivers; seasonal dynamics; thermal regime.

Introduction

Concerning the origin of floodplain taliks, the majority of authors agree that they exist due to convective heat exchange with rivers, though until recently no attempts were made to obtain quantitative characteristics of this process. Based on traditional approaches this problem is virtually unsolvable. The only practical way is to calculate a river heat balance. Accounting for all commonly considered components, the residual is convective heat flux into the ground. Using this approach, a number of estimates of this quantity were made for streams of III–IV orders (Mikhailov 2003); the data for calculations were received by *in situ* observations. Since the study process is highly dynamic and strongly dependant on hydrometeorological conditions, these results represent only short periods of time. Besides, it remained unclear whether it is possible to extrapolate them to larger watercourses. Dealing with such rivers, the investigated reaches should be several kilometers long or more, depending on water discharge. In such cases, it is usually impossible to obtain adequate data on the channel width for a given time span; that is why previous calculations could have been made only for one river during one ten-day period (Mikhailov 1998).

Profound research of convective heat exchange is not feasible without studying its seasonal dynamics. The most appropriate way is by using long-term means. While such hydrological and meteorological data are provided in reference books, the average width of extensive river sections can be estimated only for the date of the aerial mapping used to make the corresponding sheet of a topographic map. A special research program was carried out in order to solve this problem (Mikhailov & Ushakov 2002). It turned out that in braided rivers, correlation between channel width and water discharge is close enough to fulfill heat balance calculations with sufficient accuracy. Such rivers prevail in mountainous areas of northeastern Asia and are also associated with floodplain taliks (Mikhailov 1995).

The aim of this work is to investigate the main regularities of seasonal dynamics of convective heat exchange between floodplain taliks and rivers of medium and higher orders and its influence on a number of hydrological processes and phenomena.

Materials and Methods

The general pattern of estimations is the same as in the previous study (Mikhailov 1998): the intensity of heat exchange between rivers and adjoining grounds was calculated using stepwise approximation, so as to achieve identity of the simulated and actual river temperatures in the studied river sections. The calculations of temperature increments were carried out successively from one confluence node to another, with presumed instant water mixing in nodes.

Methods of calculations

The heat balance equation for a river segment, dx, under considered conditions is as follows (Vasilyev & Voyevodin 1975):

$$\Omega \frac{\partial T}{\partial x} + \frac{\partial}{\partial t}(sT) - \frac{B}{C}\sum q_i = 0 \qquad (1)$$

where x and t are distance downstream and time, respectively; Ω and T are, accordingly, water discharge and temperature; B and s are river channel width and cross-sectional area, respectively; C is water volumetric heat capacity; $\sum q_i$ is the sum of all heat fluxes influencing water temperature. Hereafter all dimensions are in SI if not specified otherwise.

The sum $\sum q_i$ includes the resultant of energy exchange on water surface (q_s); the heat of dissipation of kinetic energy of the flow (q_{diss}); the heat of thawing solid precipitation (q_m); and total heat flux into ground (q_{gr}), which is the sought quantity. Thermal influence of liquid precipitation is negligible; in large rivers; the same is true for the dispersed inflow. The working equation for estimations of river temperature increments between outfalls of tributaries is as follows:

$$T = T_0 + \frac{B\Delta x}{C\grave{U}}(q_s + q_{diss} - q_m - q_{gr}) - \frac{\Delta x}{\grave{U}\Delta t}\left(s\Delta T + T\Delta s\right) \qquad (2)$$

Hereafter the symbol « Δ » stands for the finite increment of the according quantity; index «0» implies that the labeled quantity is related to the upstream cross-section of the segment Δx. In calculations by formula (2) made with a specially designed computer algorithm, the step Δx was specified as approximately equal to the river width and so, as the number of steps to the next node, was an integer.

The constituents of q_s are generally known, e.g. (Pavlov 1984):

$$q_s = S\left(1 - A\right) + I_a - I_s - P - LE \qquad (3)$$

where S is total shortwave radiation; A is albedo of water surface; I_a and I_s are long-wave radiation of air and water surface, respectively; P and LE are sensible and latent heat fluxes accordingly. The methods of estimations of all these quantities are minutely elaborated and well-known. Though somewhat diverse empiric formulae are in use, the results obtained differ but a little (Mikhailov 1998).

The quantity q_{diss} is usually defined as the product $\rho gIVH$, where ρ is water density; g is gravitational acceleration; I is river inclination; H and V are mean values of the river velocity and depth, respectively. In calculations it is more appropriate to use the equivalent formula $q_{diss} = \rho gI\,\Omega/B$. Finally, q_m is evaluated by the dependency $q_m = L_m p/n$, where L_m is specific heat of ice thawing; p is monthly solid precipitation in millimeters; and n is the number of seconds in a given month.

Studied river sections and time span

The most suitable river sections for heat balance estimations are those between two stations, where full-scale hydrological and meteorological observations are implemented. It is essential, of course, that the river has a floodplain talik. Despite a fairly well-developed monitoring network and an abundance of such taliks, the first requirement is fulfilled only for one of six chosen sections. Besides, some necessary information is absent in principle. The lacking data were compensated using interpolations and various kinds of empirical dependences discussed in the next subsection.

The general information on the sections is given in Table 1. The first three are situated on the largest rivers of northeastern Asia; the others, in the Upper Kolyma basin (Fig. 1). All of them belong to the subarctic zone characterized by a severe, extremely continental climate. Those characteristics, which are the most important for the aim of the research, vary in close limits; thus the July mean air temperature ranges from 13.7 C to 15.6 C, and the total shortwave radiation ranges from 218 to 228 W/m^2.

In the selected sections, the rivers have braided channels and vast floodplains covered with mixed forest, which is a generally accepted indicator of floodplain taliks. The only exception is the Debin River, which is degrading over almost one-third of the section length and has no accumulative floodplain. In computations, convective heat exchange in such segments was specified as zero. Thus, the final result for this river, q_{gr} value, relates only to the reaches with floodplain taliks.

Table 1. Overview information on the studied river sections.

River	Length, km	Drainage area, km^2	Mean July discharge in the upper cross-section, m^3/s
Kolyma	190	11000	2210
Indigirka	113	32100	842
Anadyr	100	3400	964
Debin	89	2300	27.0
Detrin	63	2140	81.6
Berelekh	50	2180	119

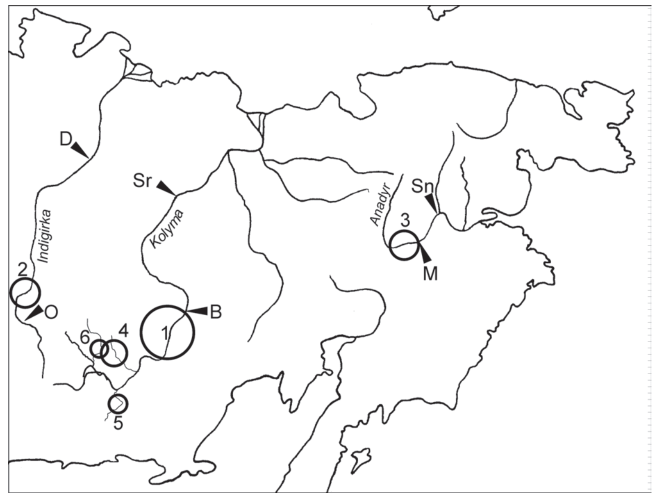

Figure 1. Locations of the studied river sections (circles) and gauging stations (triangles). Rivers: 1–Kolyma; 2–Indigirka; 3–Anadyr; 4–Debin; 5–Detrin; 6–Berelekh. Gauging stations: B–Baligichan; Sr–Srednekolymsk; M–Markovo; Sn–Snezhnoye; O–Oimyakon; D–Druzhina.

In May and October, the thermal regime of the studied rivers is considerably affected by freeze-thaw processes, which cannot be taken into account because of the lack of data. This limits the study period to four months.

Basic data

The values used in computations were monthly means in summer and ten-day means in September. The latter, except for water temperatures, were obtained via interpolation (using smoothed seasonal change curves). In this month, which is of particular interest for this study, a monotone decrease occurs of all quantities affecting water temperature; therefore such technique could not cause significant errors.

Most of the necessary information was obtained from reference books (Reference Book 1966; Long-Term Data 1985, 1987). The lacking data were acquired in the following ways.

Water discharges in the studied river sections were estimated using the data from the nearest gauging-stations, corresponding values of unit discharges, and increments of drainage areas. In five cases out of six, the upstream cross-sections were provided with discharge data, which minimized errors. The exception is the Kolyma River, but there the drainage area over the whole section increases less than 8%; this reduces the errors originating from the next discussed approximation.

Water discharges and temperatures of tributaries: The former quantities were calculated using drainage areas (measured on topographic maps) and unit discharge means estimated for each river section. To compute water temperatures, as well as in the previous study (Mikhailov 1998), empirical dependences "discharge–temperature" were derived via statistical treatment of data from 59 gauging-stations belonging to the investigated watersheds. All of these formulae were of the form $T = a\lg\Omega + b$ with a and b parameters calculated separately for each summer month and each ten-day period of September. When using long-term data, the correlation between temperatures and discharges is closer than in the case studied earlier, when the estimations were made for a short time span. While in that period 70% of T values were beyond the interval of ±1 C from the regression line; for mean July temperatures, the relation is inverse. In June, the range of temperatures is a little wider, but by the end of the season, it becomes sufficiently more narrow.

Climatic data used were obtained at the weather stations located, as a rule, in close vicinity to the gauging-stations, or not more than 100 km away from them. All weather stations, as well as gauging-stations, are situated in wide river valleys where local peculiarities are minimal. As it was mentioned above, the values of climatic characteristics vary within close limits all over the vast territory embracing the studied river sections, so the differences within short distances are negligibly small.

River channel width and cross-sectional area: To estimate B, traditional empirical formulae $B = \alpha\Omega^{\beta}$ were used (Park 1977). Values of a and β for braided rivers had been obtained earlier (Mikhailov & Ushakov 2002). Due to similarity in relations of B and H to water discharge (Park 1977), s values obey the dependence of the same form: $s = s_0\left(\Omega/\Omega_0\right)^{\beta}$, where s_0 is the cross-sectional area at the upstream station determined by hydrologic yearbook data. The β values were evaluated by analysis of information from the reference book (*Atlas of the Kolyma River* 1931) based on previously obtained results (Mikhailov & Ushakov 2002).

Discussion

The ultimate results of computations are shown in Table 2. To evaluate their reliability, a series of additional computations were made in which the values of quantities not provided with precise data differed from those used in the main version. Deviations were specified so as to be the maximum reasonable possible. If it is assumed that all errors do not compensate each other and affect the final result in the same direction, then it might change most significantly in June by 25 W/m² on average; in the Debin River, by 33 W/m². Further on, absolute values of errors decrease monotone,

Table 2. Mean monthly and ten-day period values of q_{gr}, W/m² and total heat transfer into ground over the study period (Q_{gr}), 10⁶J/m².

River	June	July	August	September 1	September 2	September 3	Q_{gr}
Kolyma	166	109	101	47	−23	−71	1033
Indigirka	152	111	95	36	−19	−65	906
Anadyr	171	207	145	69	−3	−81	1445
Debin	150	113	77	42	−7	−49	934
Detrin	99	101	55	17	−28	−62	689
Berelekh	111	147	86	22	−24	−70	931

and in the first ten-day period of September, respective values are 9 and 13 W/m². Relative errors are minimal in July (12 and 18%, correspondingly).

In fact, as the fluctuations in values of each of the said quantities are governed by combinations of numerous independent factors, and furthermore, an impact of each individual fluctuation is not overwhelming; their net effect most likely does not exceed a few W/m².

The quantity q_{gr} includes convective and conductive components. According to Braslavsky & Vikulina (1954), monthly means of the latter in shallow reservoirs decrease from June to August from 15 to 4 W/m² and become negative in September. As seen from Table 2, seasonal changes of both components are qualitatively similar, conductive one's share being mostly less than 10%. Actually, its contribution is still smaller, because in watercourses, cooled by both convective heat exchange and by inflow of tributaries, water temperatures are lower than in such reservoirs. In the Kolyma River, the difference in July is more than 3 C, and in the Debin River, it increases to 6 C. Obviously, this reduces conductive heat flux into the river bottom, and q_{gr} may be regarded as a close estimate of convective heat flux.

For further discussion, it is important to emphasize that convective heat transfer develops as a result of groundwater flow along a general valley slope, and so concentrates in a slightly inclined plane. Of course, in this flow a vertical circulation develops as well, but its role is limited because, as a rule, not deep under river thalwegs, the ground is either bedrock or immobile silted sediment having very low permeability. Therefore, first, it is warmed virtually by conductive heat transfer alone; second, groundwater flow cannot substantively influence heat flux from the soil surface.

Total heat transfer from rivers to floodplains: Obviously, the values in the last column of Table 2 are lower estimates of this quantity (some amount of heat adds up in May). As it is known, mature rivers in mountainous territories have floodplains which are 5–10 times wider than their channels. Accounting for river sinuosity, the relation of surface areas is at most 10:1. Therefore, during warm periods, taliks receive from rivers no less than $70–100·10^6$ J/m^2 (the lower margin being more likely atypical). Judging by the available data, it is more than the amount of heat supplied from soil surface. In the open woodlands of Central Yakutia, where the climate is warmer, the last-named quantity does not exceed $80·10^6$ J/m^2 (Pavlov 1984). In floodplain taliks, the soil surface is cooler due to the thick vegetation cover and subsurface, undoubtedly, warmer; both differences diminish heat supply from the surface. Also, some of this heat is spent on "useless" (for a talik existence) warming up of an aeration zone. Therefore, convective heat exchange with rivers is not only a unique factor of floodplain talik formation, it is also the major income source of their heat balance.

The value of Q_{gr} in the Anadyr River is almost 1.5 times greater than the maximum of all other such quantities (see Table 2). The reason is that in the Markovo Depression (to which the lower half of the studied section belongs) the river is aggrading and has an outstandingly large talik, up to 7 km wide (Vtyurin 1964). For comparison, the Kolyma River has twice as large July discharge, but its talik is approximately twofold narrower. This is why convective heat transfer from the Anadyr River to its floodplain is maximal. Since the results obtained are mean values over the whole river section, then in the depression itself heat flux is still greater.

The Detrin River, on the contrary, stands out against all others by substantially less intensive heat exchange with its floodplain. Based on the data available, there is not an adequate explanation for this phenomenon; one of the possible reasons may be degradation of the talik.

Heat flux direction change occurs, on average, within a short period of time, September 5–15, irrespective of a river size. The rivers begin to receive heat back while still having comparatively high temperatures (4–7°C); i.e., their thermal potential is not fully used. In other words, convective heat exchange with rivers is excessive in relation to sustaining floodplain taliks even under extremely severe climatic conditions. Summarizing all of the above-said, climate can hardly limit both the size of floodplain taliks and their geographical distribution.

The floodplain talik of the Anadyr River not only accumulates the largest amount of heat, but also spends it at a maximal rate: the third part of September q_{gr} is again the greatest by absolute value.

Convective heat exchange with floodplain taliks causes a number of peculiarities of thermal and ice regimes of rivers which earlier could not be adequately explained (Table 3). The most striking of them were first noticed by Shvetsov (1952) in the Indigirka River and named thermal anomalies. In summer, maximum river temperatures are observed not in places with the warmest air, but far downstream, while in autumn, temperature increments (of both water and air) change signs.

"Anomalies" (actually a pattern) are due to the fact that in all pairs of gauging-stations shown in Table 3, the upstream stations (see Fig. 1) are located on floodplain taliks which downstream pass away. In summer an intensive heat exchange with taliks decreases river temperature; in autumn it delays its cooling and ice phenomena, despite low air temperatures. Noteworthy, these peculiarities are best manifested in the Anadyr River.

Notwithstanding huge energy expenditures in autumn, the remnants of heat accumulated in taliks earlier are sufficient to sustain numerous glades during the whole winter. They are very typical for rivers of northeastern Asia, quite often stretching, one after another, for tens and hundreds of kilometres (Kuznetsov 1961); as this author rightly pointed out, these phenomena could not be explained by discharges of subpermafrost water. Obviously, such sequences of glades reveal plentiful and abundant outlets of groundwater from floodplain taliks.

General dynamics of convective heat exchange: On the whole, during the study period, a monotone decrease of q_{gr} values prevails. This is readily explained by the thawing of the seasonally frozen layer, which consumes very large amounts of heat even at low water temperatures. Also, energy flux to water surface diminishes during the warm season. Since during most of May the rivers remain covered with ice, q_{gr} as a rule reaches a maximum in June. The exceptions are the Anadyr and Berelekh Rivers, which

Table 3. Characteristics of thermal regime and freezing processes in the studied rivers.

River	Gauging station	Mean water temperature, °C		Average dates of:			
		July	October 1–10	drop of water temperature below 0.2 C	beginning of freezing process	beginning of ice drifting	beginning of freezing-up
Kolyma	Baligichan	14.5	1.4	Oct 11	Oct 7	Oct 9	Oct 17
	Srednekolymsk	15.4	0.8	Oct 6	Oct 5	Oct 10	Oct 13
Anadyr	Markovo	11.1	2.7	Oct 16	Oct 8	Oct 13	Oct 22
	Snezhnoye	15.1	1.4	Oct 7	Oct 6	Oct 7	Oct 10
Indigirka	Oimyakon	11.7	1.2	Oct 7	Oct 4	Oct 9	Oct 23
	Druzhina	15.1	0.3	Oct 3	Sept 30	Oct 3	Oct 12

display maximal values in July and require a more thorough analysis.

Convective heat exchange between rivers and taliks is due to intensive water exchange; the latter, in its turn, to concentration of groundwater flow in networks of preferential pathways with extremely high water-transmitting capacity (Mikhailov 1999). Experiments on indicator injections into observation wells have shown that after ice drifting in spring, a partial blocking of these pathways occurs resulting in a substantial decrease of alluvium effective permeability. The blocking was observed mainly at the beginnings of pathways and most probably is caused by entrainment of small ice particles. The research was carried out in the Kolyma River floodplain, which is covered with mixed forest. The studied sections of the Anadyr and Berelekh Rivers are distinguished by relatively sparse vegetation and an abundance of bare ground. In the former case, it is caused by frequent inwash of fresh sediment, the river being at the aggrading stage; in the latter case, by forest clearing and placer exploitation (Fig. 2). In both cases, the result is deep winter freezing, promoting the blockage of preferential pathways and diminishing convective heat transfer in early summer. After recovery of alluvium permeability, heat flux sharply increases and peaks in mid-summer.

As strong land disturbances, such as in the Berelekh River floodplain, are infrequent, there is an even smaller number of aggrading watercourses. In other studied rivers, the July values of q_{gr} , despite large differences in water discharges (almost by two orders of magnitude), are quite similar; in this month, even the Detrin River does not stand out. Taking into account the results of numerous observations in the valleys of smaller streams (Mikhailov 2003), in northeastern Asia these values in all typical floodplain taliks fall in the narrow range, probably not wider than 100–120 W/m^2; this opens up a possibility to estimate the distributions of such taliks over large river basins.

Conclusion

Based on heat balance calculations made for representative sections of six rivers of northeastern Asia, the main regularities of seasonal dynamics of convective heat exchange in river valleys have been ascertained. Usually heat flux is maximal at the beginning of summer, ranging from 100–170 W/m^2, but under conditions causing deep winter freezing of soil, the peak is shifted to July. The warming up of floodplains continues with decreasing strength up to and including the first ten-day period of September, on average. As a result, taliks receive from rivers very large amounts of heat; only since June, not less than 70–100 10^6 J/m^2 related to soil surface area. Comparison with published data demonstrates that heat exchange with rivers is not only crucial for the existence of taliks, it is a main income source of their heat balance (at least under climatic conditions close to the extreme ones).

The reverse side of intensive summer warming of floodplains is their rapid pre-winter cooling. In early autumn,

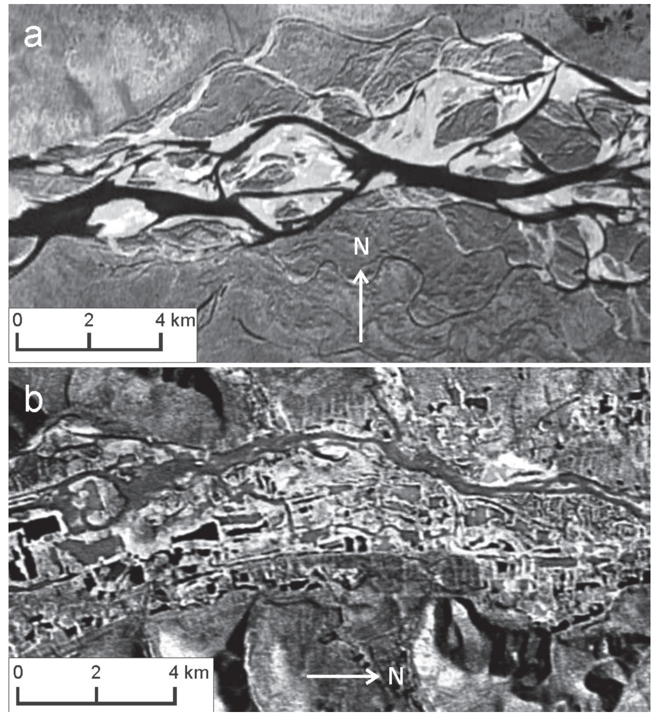

Figure 2. Satellite photographs of the valleys of Anadyr (a) and Berelekh (b) Rivers.

at relatively high temperatures of river water, heat flux changes its sign, and taliks start returning the accumulated heat to rivers. This process continues till the spring flood.

Convective heat exchange with taliks causes a specific distribution of water temperatures along the rivers ("thermal anomalies"); considerable delay of freezing-up and preceding ice phenomena (up to 10 days or even more) sustains numerous glades and successions of glades.

The results obtained lead to the conclusion that climatic conditions can hardly be a limiting factor for geographical distribution of floodplain taliks or their size. For further research, it is very important that in rivers at grade, which prevail in northeastern Asia, and in the absence of heavy soil-cover damage, mean July values of heat flux into taliks lie in a narrow range of 100–120 W/m^2, the same as in small streams or very close to it.

Abstract

For the last decade at a number of Hydro Units in Western Yakutia, we have observed subsurface seepage processes that compromise their structural stability. A number of geophysical techniques are discussed for verification of the permafrost state near Sitikan and Viluy Hydro Units, including electric, electromagnetic, ground penetrating radar, hydro location, thermal, and radiowave down-hole measurements. Ground-level and down-hole geophysical surveys focused on detecting thawing zones (talik) in dams, dam flanks, and tail-water zones. Long-term geophysical monitoring shows the spatio-temporal permafrost evolution and talik development in the flank shore of the Sitikan dam. Detection of the inflow zone and seepage velocity was performed for the right-bank contiguity of Viluy HPS-1. Numerically analyzed conditions causing the initiation and development of the talik near the reservoir are discussed.

Keywords: cold regions; dams; geophysical monitoring; permafrost; talik; thermal field.

Introduction

Permafrost covers about 70% of the territory of Russia, most of the territory of Alaska, as well as a significant part of Canada and mountain Alpine regions. Regular water and energy supplies in permafrost areas are vitally important conditions for inhabitants of the large northern territories of Russia, Canada, the U.S., and Alpine areas of China. Artificial reservoirs in permafrost terrain create the formation and development of talik zones in the adjacent flanks. Dam and flank shore stability is the key consideration in reservoir safety (power pool, water supply, tailing pit, etc.). Similar problems may also occur with natural basins in cold regions; climate change may activate lake drainage and changes in permafrost.

To avoid water loss and ensure the Hydro Unit stability in the permafrost zone, we need to use geophysical tools, including long-term monitoring for the detection of talik development. Along with required temperature control, different geophysical methods give information about variations in rock physical properties caused by thawing-freezing effects. Integrated geophysical monitoring allows observing time-space variability of the physical fields that reflect the evolution of frozen-thawed dam bed and flank shores.

Geophysical Observations

Study area

This study was conducted in the Aichal-Mirni region of Western Yakutia, which is an area of potential development of different types of anthropogenic development (Fig.1). They are connected with the exploitation of kimberlitic pipes, construction and operation of hydro facilities, injection and dumping of underground waters, underground storage facilities for toxic waste, and tailing dumps. Permafrost is very sensitive to natural and human-caused influences. In consequence of these circumstances, thawing-filtration processes were observed in a number of hydro technical projects in Western Yakutia: Marha, Irelyah, Viluy, Anabar, Sitikan, Kieng, and Iyraaas-Yuryah. We present two examples of geophysical observations from the Sitikan Hydro Unit and the Viluy Hydroelectric Power Station.

The Sitikan Hydro Unit (frozen type dam) provides the water supply for the city of Successful (near the diamond pipe "Udachnaya"). An underflow talik-zone developed in the dam basement in 1995 after 20 years of reservoir operation (Kronik 1999). As a result, there is currently significant water loss from the reservoir and a serious problem with water management.

Construction of the Viluy Hydroelectric Power Station (VHPS-1) was finished in 1967. It was the world's first large Hydro Unit with a rock fill dam on permafrost. More information about Viluy Hydro Units Cascade can be found at http://regtime.spb.ru/lenhydroproject/e_vil01_02.html. In August 1996, a temperature jump was observed in the right-bank contiguity of VHPS-1. During a few days, seepage was formed (Velikin & Snegirev 2004). This seepage continues to the present time despite special antifiltration efforts. For the last 15 years, various geophysical investigations were carried out on many engineering constructions in Western Yakutia by Viluy Permafrost Station (VNIMS). Priority interest was connected with the methodology of geophysical surveys of the permafrost state and its change near the hydro units. Some examples of this work are presented below.

Methods

Geophysical surveys focused on several main tasks: (1) eliciting and checking the position of inflow seepage near the dam and boundaries of dams, and detecting the location of most intensive thawing and seepage from the reservoir; (2) investigation of talik geometry in the frozen earth fill;

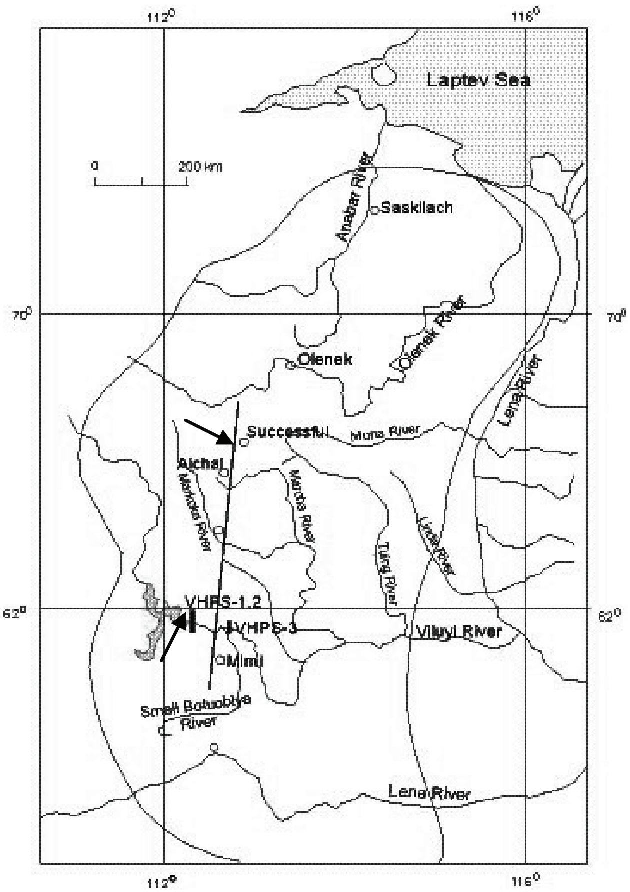

Figure 1. Case study areas: Sitikan Hydro Unit near Successful (Pipe Udachnaya) and Viluy HPS-1, 2 (shown by arrows).

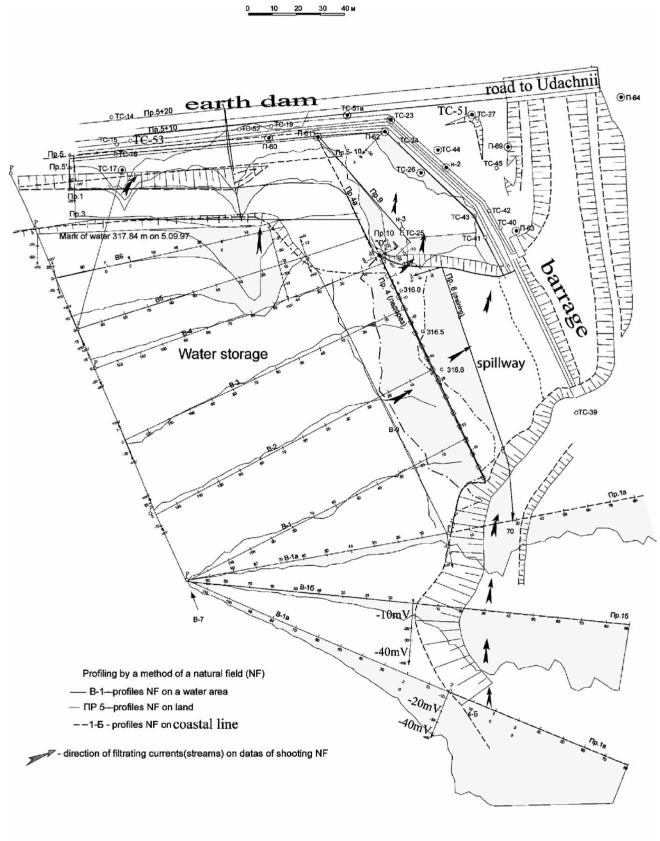

Figure 2. Natural Field profiles on water, land, and coastal zone of Sitikan Hydro Unit; negative NF anomalies indicate inflow seepage zones.

and (3) monitoring the progressive seepage dynamics in space and time.

From the many surface-based geophysical methods (Zikov 1999), the most useful for solving these tasks were selected including the Natural Field method (Semenov 1968) or Self Potential method (Erchul & Slifer 1989), Capacitive-Coupled Resistivity profiling or VCHEP method (Timofeev 1980, Hunter & Douma 2007), and Ground Penetrating Radar (GPR) (Arcone et al. 1998).

Down-hole observations near hydro units included long-term temperature measurements. Logging systems (electrical, flow meter survey, gamma logging, neutron-gamma logging, caliper measurement) (Zikov 1999) were used for petrophysical studies. The Radio Wave Geo-Introscopy (RWGI- ORWP) method (Istratov & Frolov 2003) with thermometrical data provided the opportunity to monitor talik development.

Talik detecting and monitoring

Natural field (Self-Potential) method: In this case, the natural field (NF) technique has an electrokinetic nature resulting from the transportation of charges by flowing water. Inflow zones correspond to negative values of electrical potential, while outflow zones have positive values of the NF (Semenov 1968, Zikov 1999, Erchul & Slifer 1989). A network of profiles (observation step of 2.5 m along profile) was established, covering the lower toe and upper heel, the adjacent banks, and the crust of the earth dam of the Sitikan Unit (Fig.2). Measurements were made relative to one of two stationary reference electrodes in the head race. In particular, NF data obtained in the head race of Sitikan detected (by negative anomalies) infiltration zones in the earth dam, below the spillway and along the boundary of the right bank.

Among the many applied surface geophysical studies, the Capacitive-Coupled Resistivity profiling method (VCHEP) and Natural Field (Self-Potential) methods were the main source of information about propagation of inflow zones and talik identification. The theory governing the VCHEP method has been discussed by Timofeev (1980). Advantages of the VHCEP method are high productivity and simplicity of measurements in cold region. There is no need for direct electrical contact between the transmitter and the ground (Hunter & Douma 2007). Specially-developed optional equipment VCHEP was used for the survey. This capability allowed us to determine effective resistivity (ρ_{ω}) values directly during field observations via conversion of measured electric field parameters for ω = constant and the selected unit configuration (Timofeev 1980, Zikov 1999). Later on, this approach was realized in the development of the “Ohm Mapper” device (Hunter & Douma, 2007). The VCHEP survey on the Sitikan Unit was done in April 1997 with two frequencies (8 and 12 kHz) and a square

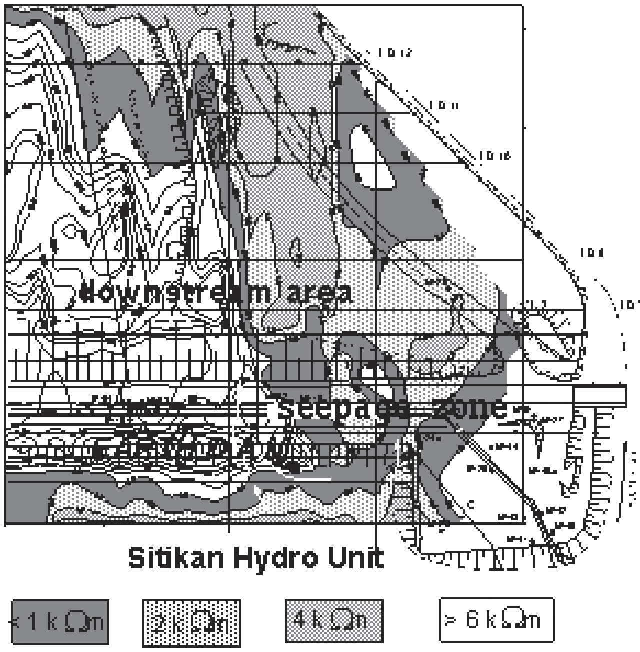

Figure 3. Spatial distribution of effective resistivity, ρ_ω kΩm (dipole length = 10 m, dipole-dipole spacing = 20 m, sampling step = 2.5m, ω = 8 kHz). Thawed zone determined with Capacitive-Coupled Resistivity profiling method (VCHEP) on Sitikan dam and tailwater. Shaded zones (low effective resistivity) correspond to talik's contour.

waveform signal. At that time, snow cover and frozen rocks did not permit the use of any galvanic ground connection. Boundaries between frozen and thawed zones—the shaded zones in Figure 3—are reflected in the effective resistivity (ρ_ω) field for ω=8 kHz.

The Self Potential (NF method) survey was conducted with the "ERA-MAX" instrument along the water profile in the Viluy HPS-1 head race and on its bank. Several years of observations along these profiles showed significant changes in form and amplitude of the natural field associated with different water levels in the head race and discrepancy of observation lines. Nevertheless, in the zone adjoining the right-bank contiguity, the abnormal part was well detected by signal form and amplitude. As a rule, seepage originates from structure and head race contact. It would be logical to suppose that just this anomaly was caused by seepage processes. Later on, test methods proved this to be true.

Two contactless surveys were performed on water with the use of inflatable boat in a head race of VHPS-1 using Ground Penetrating Radar (Arcone et al. 1998): above-water GPR survey with "SIR2000" and at the Side Plan Hydro location (Velikin & Snegirev 2004) using the "GBO" instrument. Both methods confirmed the anomalous zone that was distinguished using the self-potential data in the head race area. GPR- reflecting boundaries associated with water-filled cracks, typically horizontal and vertical cracks, can be recognized on the radargram. On bottom-surface images obtained with hydrolocation, the anomalous site was distinguished by the occurrence of small depressions (slots) perpendicular to the shore. In the geological structure of the berm adjoining the head race, a number of similarly-oriented (orthogonal to shore zone) cracks were also marked. It is important that close spatial coincidence of anomalous zones found by Self-Potential, GPR, and Side Plan Hydro location methods was established. Detected zones at 242–238 m elevation, coinciding with the depth interval of intensive seepage, was established also by thermometry (Velikin & Snegirev 2004).

Borehole observations: The first warning information (in 1995) about talik nucleation at the base of Sitikan dam was from long-term temperature measurements initiated in 1990. Seasonal temperature field dynamics for the flank of Sitikan dam with active talik zone are presented in Figure 4. The network density of thermometric holes and the irregularity of observations have hampered estimation of the spatial distribution of the talik and seepage development. For processing, all previous available temperature data were used.

In addition, measurements were conducted in piezoborehole and on a water area, where earlier temperature observations were lacking. This has allowed us to "fill in" the missing periods of observations in individual holes, and to derive the general evolution of the talik zone. An example of the active stage of talik evolution for the period 2000–2006 is shown in Figure 5. Without going into details of the contingency of the Sitikan dam, it is necessary to say that for the last decade many efforts (grouting, air and kerosene cooling, enrockment, etc.) were implemented to prevent the consequences of seepage. Some results are shown in Figure 5 on the left part of the earth dam. We also can see the progressing talik in the right bank contiguity due to development of bypass filtration (Figures 4 and 5). For controlling the in situ situation in the seepage zone, tracer techniques (with colorings and electrolytes) were used to determine the flow rate (Velikin & Snegirev 2004). NaCl solution was used as a tracer. Resistive potentiometers installed in observation boreholes on a particular selected

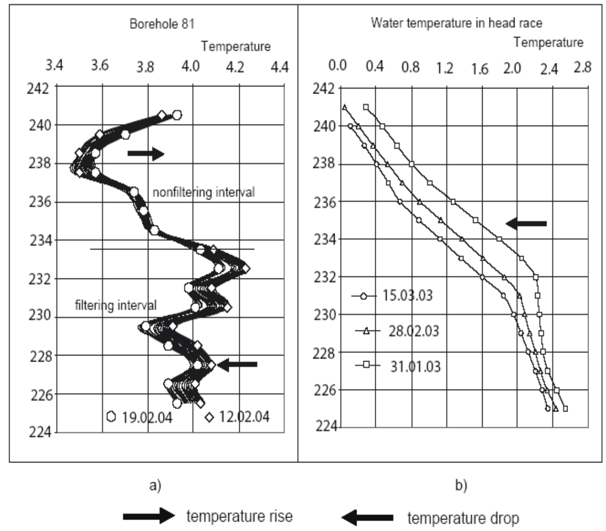

Figure 6. Revelation of percolation layers by logger measurements: (a) temperature measurements in piezometric borehole No. 81; (b) water temperature in head race.

interval were used as a recorder for continuously measuring water resistance filling the borehole.

Observations were carried out in two ways: (1) injecting a tracer into piezoborehole No. 80 and then measuring in piezoborehole No. 81 downstream; (2) injecting a tracer near the shore of the head race of the right-bank abutment and collecting measurements in piezoborehole No. 80. According to obtained data, the flow rate was estimated at approximately 50–60 m per hour. This is a fairly significant value and should be considered when developing anti-seepage measures.

Automatic temperature measurements in the boreholes using loggers are of special interest, insofar as they permit us to obtain information about the position of seepage horizons and their characteristics. Figure 6 illustrates logger measurements in piezometric borehole № 81 of the right-bank abutment in comparison to water temperature dynamics in the head race of the dam. Figure 6 shows that a general reduction of reservoir water temperature determines a temperature decrease in the filtration zone (236-232 m) of the embankment. In the upper part of the borehole, the logger data indicate a null or small temperature increase. The analysis of available data shows the high information content of logger temperature measurements. They may help to reveal reservoir intervals in thermometric boreholes based on analysis of temperature dynamics, identify the intervals where, despite the presence of positive temperatures, filtration flows are absent, and also to study the interaction peculiarities between the rocks and water.

For geophysical monitoring in a permafrost zone, the Radio Wave Geo-Introscopy (RWGI) profiling and cross-borehole measurement method, as well as the One-hole Radio Wave Profiling (ORWP) method, was used. Theory, tools and measuring techniques are described in Istratov & Frolov (2003). The purpose of radio wave investigations was as follows: First, to control the frozen rock thawing within the coastal zone of the reservoir and to assess the dynamics of the process; and second, to identify and locate the places of most intensive thawing and seepage from the reservoir. Thawing processes lead to a decrease of electrical resistivity (ρ); the saturation of the filtering layer must be reflected as an increase of relative dielectric permittivity (ε) within the same interval. If measurements are taken repeatedly at two frequencies along the borehole profile, the lower frequency data can give a picture of the rock electrical resistivity changes with space and time, thus providing insight into the process of frozen rock mass thawing under the influence of the reservoir. Measurements performed at high frequency permit the calculation of effective values of relative dielectric permittivity (ε); the higher values will indicate layers of most active filtration from the reservoir.

Monitoring in the Sitikan area began in 2000 and continues today (the last measurements were in March 2007). As an example, we consider the data obtained in 2001–2002 near the Sitikan Hydro Unit in Figure 7. In March and August 2001 and in March 2002, temperature measurements (Fig. 4) were made in boreholes 4 to 10, oriented perpendicular to the embankments of the Sitikan water resevoir. In additon, gamma logging and one-hole radio wave profiling (RWGI-ORWP) with the frequencies 1.25 and 31 MHz were conducted. Repeated ORWP data were interpolated between the holes (Fig. 7). The holes are 35 m to 45 m deep, with polyethylene casing and inside diameter of 65 mm. Sections based on repeated temperature measurements of

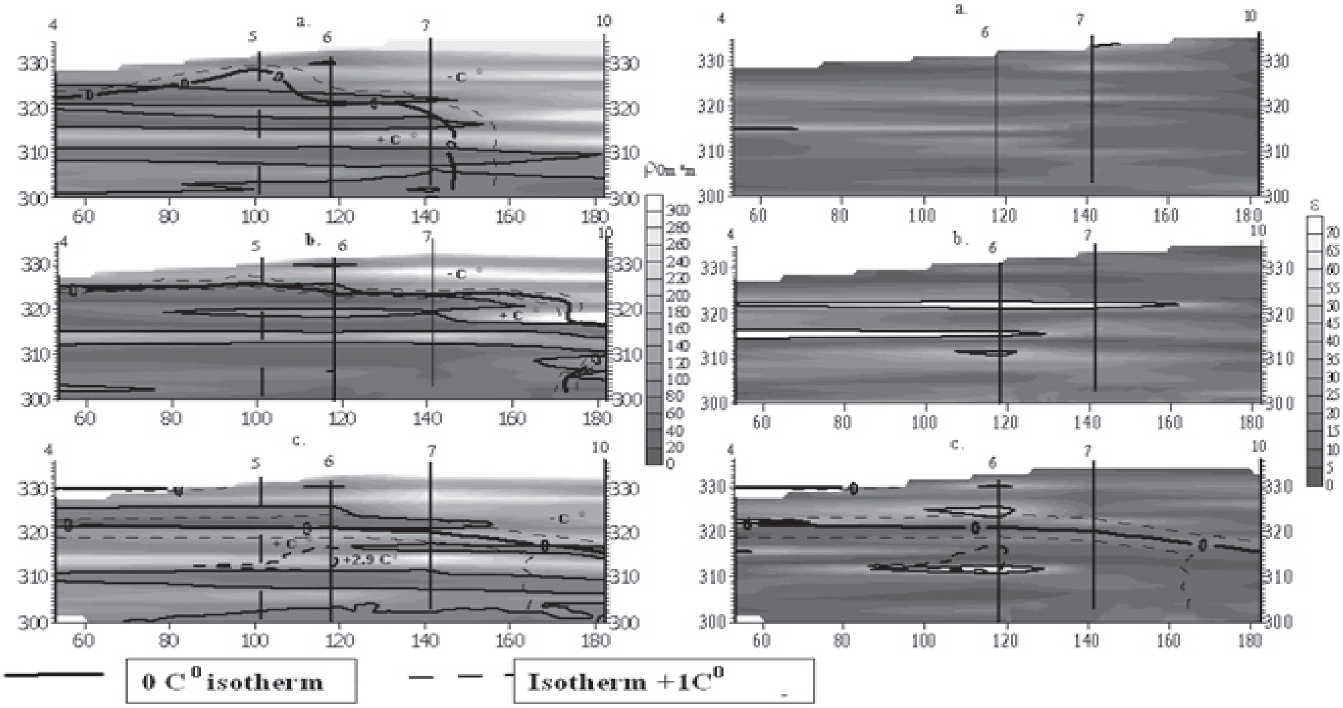

Figure 7. Examples of geoelectric sections of (left) effective electric resistivity (ρ) and (right) relative dielectric permittivity (ε) along boreholes profile (4 -5 -6 -7 -10) in a frozen embankment crosswise shoreline of the Sitikan Hydro Unit (Western Yakutia, Siberia). Replicated RWGI-ORWP observations in (a) March 2001; (b) August 2001; and (c) March 2002.

the fractionally thawed coastal frozen embankment in March and August 2001 show the dynamics of ground temperatures within the reservoir flank (Figs. 4 and 7). The geological section consists of carbonate rocks (limestone, dolomites and marbles) varying in fissured zones and clay content.

Comparing the results from March and August 2001, it is possible to see not only the general propagation of the "front" of lowered specific electric resistivity in the direction of borehole 10, but also to identify horizons at 309–311 m, 314–317 m, and 321–324 m, in which these changes occur most intensively. In August, a sharp decrease of resistivity was observed in these layers, and the first positive values of temperature were observed. Apparent on Figure 7 is the zero degree isotherm passage of 324–326 m on a sub-face of stratum of high resistivity. High resistivity gradient here marks the border of frozen and thawed rocks. In the section of effective dielectric permittivity, layers with the highest values of ε (intervals 311–314 m and 317–319 m, and near hole 6 at 306–309 m) correspond to a high gradient zone of positive temperature. Along these permeable layers, water from Sitikan penetrates deep into the coastal embankment, working over time like a "secondary" heat source by distributing heat and accelerating thaw of frozen rocks. However, in March 2002 (Fig. 7), the resistivity of rocks in a section increased. This phenomenon is connected with maximum freezing (frost penetration) of rocks, and minimum water temperature in Sitikan storage. Visually, it is tracked between holes 4 and 7 in a layer (314– 317 m) in which there is a relative increase of resistivity (ρ); below 314 m a reduction of ρ is observed. In March 2002 (at the time of minimal temperature of the entire rock embankment), the areas with heightened ε values are narrowed and located near borehole 6 at horizons 310–312 m and 322–325 m. This is connected with seasonal freezing of the embankment. However, the presence of local zones with heightened values of dielectric permittivity (ε) suggests the existence of "year-round" liquid water at the non-percolating level (322–325 m) and with bypass seepage from the water storage through the originally frozen embankment at level 310–312 m, corresponding to the Sitikan water level in March of 314 m.

The good correlation of geoelectric sections with the temperature data shows not only the direct dependence of electric properties on the frozen-thawed state of the embankment, but also the essentially higher sensitivity and resolution of electric methods for detecting the liquid water phase. Accurate interpretation of these data must also take into account the seasonal water level change of Sitikan.

Thermal Modeling

In the case of water storage, we have pressure headwaters constrained by a frozen dam with a set of engineered constructions. The non-steady problem of heat-mass transfer in fractured and porous saturated frozen Stratum (II) (Fig. 8), situated between frozen impermeable adjacent Stratam (I, III) is discussed. There is a pressure head acting from the Aquifer, explicating in thawing saturated Stratum (II) with allowance for seasonal variations of air-water temperatures on ground-water surface and within the Aquifer (Fig. 8). According to Petrunin & Milanovskiy (2005), from numerical analysis it follows that the process of thermal evolution of the frozen strata can conditionally be separated

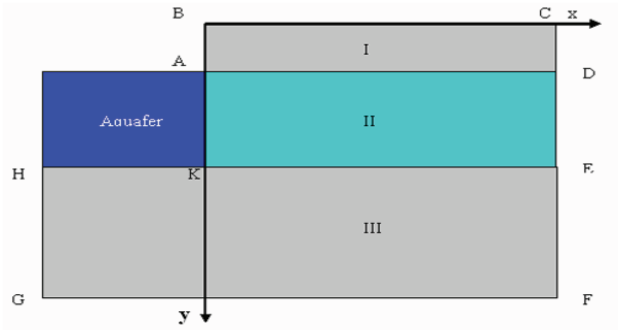

Figure 8. Schematic geometry of the model.

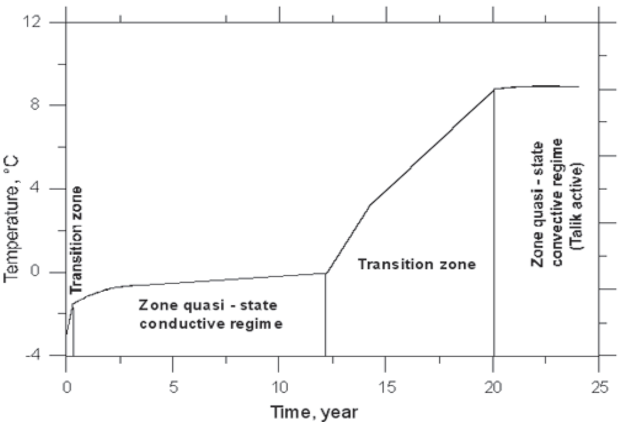

Figure 9. Variation of seasonal T-maximum in the mark-point situated in the middle of the top of permeable zone (talik zone) with time (from Petrunin & Milanovskiy 2005).

into two basic and two transient stages (Fig. 9). The first stage starts from the moment of water storage infill and represents initiation of thermodynamic equilibrium in the absence of convection. If it is quick enough; for 2–3 years it exhibits a quasi-state conductive heat regime in which seasonal variations in the thermal field quickly damp with depth according to Fourier's Law.

From Figure 9, the maximum seasonal temperature at the top of Stratum II (middle of AD) between 2–12 years ranges from -1°C up to 0°C, when the pore ice begins to thaw and permeability becomes distinct from zero. In this case, if there is hydraulic head, convective heat-mass transfer is initiated which is much more effective than pure conduction. This is the governing factor in our model for talik origination The results (Petrunin & Milanovskiy 2005) of 2-D thermal modeling indicate that talik development depends on specific thermal and hydraulic material parameters, water head, thickness of the frozen layer covering the talik, winter snow blanket insulating ground rocks, the seasonal temperature trend as well as on the presence of fractures in the frozen media. The observed evolution of the temperature field in the talik zone of the border part of the Sitikan Unit is in general agreement with the calculated temperature field.

Conclusion

Geophysical data testify about different types of talik zones. Nevertheless, they have a very common characteristic feature—the presence of a triggering mechanism for talik initialization. For identification of this mechanism, we need the pre-talik temperature history that leads to pre-heating of the strata, the existing fractures or pore channels (partly-open or ice cemented), and the reservoir water head. For example, in the Sitikan Unit case, the pre-talik history was about 20 years. An important factor for the stability of long-existing constructions like a Hydro Unit or waste confinement in the permafrost zone is global climatic change. The proposed simple model can be used for analyzing more complex situations. The results presented show the efficiency of a number of key geophysical methods for the study of permafrost peculiarities associated with talik formation and its development near Hydro Units in Western Yakutia. The proposed long-term geophysical monitoring of the permafrost state can be used for emergency situation prediction.

Abstract

It is well-known that temperature variation can impact the properties and performance of various materials utilized in civil structures. Much work has been performed to evaluate these impacts; however, limited work has been performed to evaluate the seismic performance of civil structures embedded in or surrounded by seasonally frozen ground. This paper presents a comparison study of seasonally frozen ground effects on two high-rise buildings in Anchorage, Alaska. The dynamic properties of a 14-story building have been evaluated under winter and summer conditions, and then correlated with frost depths quantified from temperatures recorded at a nearby airport. Further, these results have been compared with that of a nearby 20-story building. Discussions and conclusions are provided with regard to the impact of seasonally frozen ground on buildings with different configurations, specifically with or without a basement. These findings will provide insight into frozen ground effects on high-rise building design.

Keywords: dynamic response; earthquake engineering; frozen ground; soil-structure interaction.

Introduction

Even though the concept of frozen soil dynamic properties has been around for decades, very little work has been conducted to evaluate the seismic performance of civil structures with respect to frozen ground conditions, seasonally, or permafrost. Early investigations of frozen soil dynamics are rooted back in the 1940s as a by-product of the search for oil in permafrost-laden regions (Vinson 1978). Considerable changes in mechanical properties take place between unfrozen soil and frozen soil. Notably, the Young's Modulus, E, of frozen soils are larger, in magnitudes of tens and hundreds, than that of unfrozen soil (Tsytovich 1975). Experiments conducted by Tsytovich (1975) have concluded that the compressibility of frozen soils is so miniscule that it can be disregarded for engineering purposes. Other experiments, involving ultrasonic pulses, have revealed that the wave velocity of soil increased as the temperature decreased (Finn et al. 1978). Vinson (1978), by means of cyclical triaxial testing, determined that the dampening ratio of soil diminished with decreasing temperatures. All these parameters play a crucial role in evaluating seismic response and the soil-structure interaction of frozen ground versus unfrozen ground.

This paper will investigate the impacts of such changes in soil parameters to the dynamic response of a 14-story reinforced concrete office building in Anchorage, Alaska. Furthermore, findings from this building will be compared to those of a nearby 20-story building obtained in a recent study (Yang et al. 2007).

Project location and description

The subject, a 14-story office building known as the Frontier Building, is located in mid-town Anchorage, Alaska (61°11′15″N latitude, 149°53′05″W longitude). Anchorage, Alaska is an ideal setting for this project, since it is located within a seismically active region and is exposed to subarctic conditions with considerable annual frost penetration. The environment of the project site is that of a typical urban setting with asphalt concrete paved roads and concrete sidewalks surrounding the building. Minimal tree or vegetative cover can be observed around the general area. The topography is consistently flat and relatively level. The local climate has an average annual temperature varying from -1.6°C to 6.2°C and average frost penetration of 2.0 m (WRCC 2007).

Anchorage is located on one of the most seismically active regions of southcentral Alaska. According to national seismic hazard maps, the probabilistic peak ground acceleration of the Anchorage metropolitan area is around 0.4 g with 10% exceedance in 50 years (Wesson et al. 1999). The subduction of the Pacific plate underneath the North American plate, causes intense seismic activities in and around Anchorage. The Prince William Sound earthquake of 1964 (M_w=9.2) was one of the prominent examples of such subduction zone seismic activities which caused widespread damage in the Anchorage area. In addition to the subduction zone earthquakes, some prominent surface faults (Haeussler & Plafker 2003) surrounding the region, also contribute to the seismic hazard of the region. The Castle Mountain Fault is in the vicinity of the Anchorage area and has the potential to generate 6–7 magnitude earthquakes (Woodward-Clyde 1982).

Geologically, the soils underneath the project area consist of glaciofluvial, glaciodeltaic, and alluvial fan deposits (GF, sand and gravel) (Combellick 1999). The area is located on seismic site class C/D (Dutta et al. 2000; Martirosyan et al. 2002) with average site amplification around 2.5 times at 1 Hz. (Dutta et al. 2001)

The Frontier Building

The Frontier Building is a reinforced concrete building constructed in the early 1980s under the 1979 edition of the Uniform Building Code (UBC). The building is founded on a series of reinforced concrete strip footings running in the east-west direction. The footings on the north and south edges are 2.7 m wide and 1.4 m thick, while the interior footings are 3.4 m wide and the same thickness as the edge footings. Stemming from the footings are 1.2 m (north and south edges) and 0.9 m (interior columns) diameter reinforced concrete columns. A total of 14 columns make up the entire building. The typical floor level construction is 0.2–0.3 m thick reinforced concrete diaphragm. The first floor of the building is essentially a slab-on-grade atop the backfill of the strip footings. The bottom of the foundation is at a depth of 1.7 m below ground. The roof of the building is set at 50.6 m above ground level (first floor). The plan dimension of the building is 59.4 x 32.6 m in the E-W and N-S edges, respectively.

Geotechnical Characteristics

Site geotechnical properties

Existing soils investigation reports were utilized to assist with the determination of frost/thaw penetration. The soil characteristics down to 21.3 m are available from the boring report, conducted during the design and construction of the Frontier Building, which reveals the presence of a peat stratum of about 0.6 m thick overlying 2.4 m thick of very dense, damp, gray, slightly gravelly, fine to coarse sand (Combellick, pers. com.). The deeper formation consists of stiff sandy silts, but these layers are of no concern for the present study, since frost penetration is not expected to exceed 3 m in the area. The soil properties such as unit weight/density, moisture content, and groundwater level are taken from the boring reports of DOWL Engineers and Alaska Testlab (pers. com.) from a nearby site. The report showed a mass density, ρ, of 2002 kg/m^3 and a moisture content, ω, of 20% with the groundwater level at approximately 4.0 m below the surface.

Frost/thaw penetration

The Modified Berggren Equation, developed by Aldrich and Paynter, is a reliable method for quantifying frost/thaw penetration. The modified equation simply applies a correction coefficient, λ, to the widely used Steffan Equation (Andersland & Ladanyi 2004).

The surface freezing and thawing indices, I_{sf} and I_{st} respectively, were derived from air freezing (I_{af}) and air thawing (I_{at}) indices by relation of the surface *n*-factor values for the site environment as shown in equations (1) and (2).

$$I_{sf} = n_f \cdot I_{af} \text{ Freezing} \tag{1}$$

$$I_{st} = n_t \cdot I_{at} \quad \text{Thawing} \tag{2}$$

The air freezing and air thawing indices were calculated using daily average air temperatures from the Ted Stevens International Airport, approximately 4.8 km from the subject building. The I_{af} was calculated for each day starting from October 24, 2006 (the first day of freezing), to April 2, 2007 (day of maximum frost penetration or last day of freezing), and the obtained values were multiplied by the n_f-factor of 0.9 (pavement free of snow and ice) to determine the I_{sf}. The n_f-factor is consistent with the surrounding environment of paved roads and sidewalks. The daily I_{sf} values were added cumulatively to generate a day-by-day index, which was then used to quantify a day-by-day frozen ground thickness. A similar procedure was used to numerically track I_{st} into the frozen ground. The air thawing index, I_{at}, was calculated for each day starting from April 3, 2007 (the first day of thawing), all the way to June 24, 2007 (day of complete ground thaw out). The I_{at} value for each day was multiplied by the n_t-factor of 1.775 (average factor for asphalt pavement and concrete pavement) to produce I_{st}. The I_{st} values were then added cumulatively to generate a day-by-day index which, in turn, was used to quantify the day-by-day thaw penetration. The daily thaw penetration was added cumulatively until the summation was equal to or greater than the calculated frost penetration, which meant the frozen ground had completely thawed out.

The value of I_{sf} and I_{st} obtained above can then be used to numerically determine the depth (X) of frost and thaw penetration by means of the Modified Berggren Equation expressed as:

$$X = \lambda \cdot \left(\frac{172{,}800 \cdot k_{avg} \cdot I}{L} \right)^{1/2} \tag{3}$$

where X (m) is the depth of frost/thaw penetration, k_{avg} (J/(sec·m·°C)) is the soil thermal conductivity, L (MJ/m^3) is the soil latent heat, I (°C·days) is the absolute value of the surface freezing index or surface thawing index, and λ is the dimensionless correction coefficient.

We will numerically calculate the value of k_{avg}, L, and λ of equation. (3) as follows: To determine the soil thermal conductivity, k, we assumed that the peat layer was completely removed and replaced with excavated material displaced by the strip footing. This assumption will provide consistent soil properties down to 3.1 m. Applying the soil's mass density of 2002 kg/m^3 and moisture content of 20%, values of k_f (frozen) and k_u (unfrozen) were found to be 3.25 J/(sec·m·°C) and 2.00 J/(sec·m·°C), respectively, for an average k_{avg}, of 2.63 J/(sec·m·°C).

The volumetric latent heat, L, can be calculated by the equation:

$$L = \rho_d \cdot L' \cdot \left(\frac{\omega - \omega_u}{100} \right) \tag{4}$$

where L' = 333.7 kJ/kg is the mass latent heat for water, ω_u, is the unfrozen water in the frozen soil which is generally so small that it is considered to be at 0%, and the other variables are as before. Inserting the soil properties ρ_d and ω into equation (4) yields a latent heat value of 111,389 kJ/m^3.

The correction coefficient, λ, can be derived from the thermal ratio, α, and the fusion parameter, μ. The thermal ratio and fusion parameter can be expressed by the following equations, respectively:

$$\alpha = \frac{v_o}{v_s} = \frac{v_o \cdot t}{I_{sf}} \tag{5}$$

$$\mu = \frac{c_v}{L} \cdot v_s = \frac{c_v \cdot I_{sf}}{L \cdot t} \tag{6}$$

where c_v (kJ/m^3·°C) is the soil volumetric heat capacity, t is the time or duration of the freezing period, and v_o and v_s (°C) are surface temperatures initially above freezing and below freezing respectively.

Volumetric heat capacity, c_v, is the average of the unfrozen volumetric heat capacity, c_{vu}, and the frozen volumetric heat capacity, c_{vf}, which are expressed by the following equations:

$$c_{vu} = \frac{\rho_d}{\rho_w} \cdot \left(0.17 + 1.0\frac{\omega}{100}\right) \cdot c_{vw} \tag{7}$$

$$c_{vf} = \frac{\rho_d}{\rho_w} \cdot \left[\left(0.17 + \frac{\omega_u}{100}\right) + 0.5 \cdot \left(\frac{\omega - \omega_u}{100}\right)\right] \cdot c_{vw} \tag{8}$$

where ρ_w represents the density of water at 1,000 kg/m^3, c_{vw} represents the volumetric heat capacity of water at 4.187 MJ/m^3·°C, and all others are as before. Inserting the soil properties into equations (8) and (9) yields the values of 0.62 MJ/m^3·°C and 0.45 MJ/m^3·°C, respectively, for an average value, c_v, of 0.54 MJ/m^3·°C.

The time of freezing, t, is the number of days starting from October 24, 2007 to April 2, 2007, which comes out to 160 days. Average surface temperature, v_o, is derived by multiplying the average air temperature for the year by the average *n*-factor. This value was found to equal 4.35°C.

The thermal ratio and fusion parameter can then be solved by inserting the appropriate values into equations (6) and (7). In doing so, α equaled approximately 0.6 and μ, 0.04. These values are then inputted into the chart in Figure 1 to determine a correction coefficient, λ, of 0.94.

With all the variables determined, frost and thaw penetrations can be calculated via equation (3). The calculated seasonal frost depth was calculated for the days corresponding to dynamic data collection. The geothermal gradient for this area was examined to see if it had any substantial influence on the frost penetration. Without empirical data to determine the geothermal gradient, a rule of thumb approximation proved by Brown (1963) was used and determined the gradient to be 1.8 x 10^{-2} °C/m. This gradient was deemed negligible.

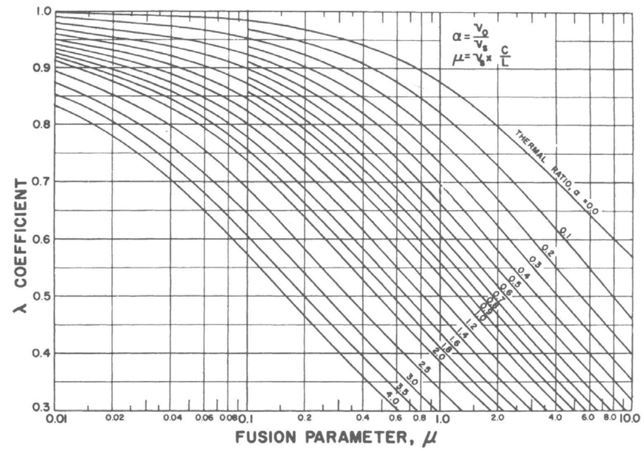

Figure 1. Correction coefficient (Andersland & Ladanyi 2004).

Strong Motion Instrumentation

Strong motion sensors

Installation of seismic sensors in the Frontier Building took place in early 2007. The seismic sensors used to measure the structural response of the building were the Kinematrics EpiSensor (Force Balance Accelerometer Model FBA ES-T, ES-U). Each sensor has a bandwidth of DC to 200 Hz and is capable of reading a user-defined acceleration spectrum of ±0.25 - ±4.0 g's with 1.25 V/g sensitivity (Kinemetrics 2005). A ±4.0 g range was selected for the sensors on this project. Three Altus K2 Strong Motion Accelerographs serve as the digital data recorders with 12 channels per data recorder. The recorders are located on the fourteenth floor of the building, within the communications closet. Thirty channels monitor lateral movement in 10 of the 14 floors of the building. Of the 30 channels, 20 channels are dedicated to the E-W direction and 10 channels to the N-S direction. The remaining 6 channels are set up for monitoring in the vertical direction. The vertically-oriented sensors are located only on the first and fourteenth floors. Nodes designated for biaxial sensitivity were composed of two ES-U2 sensors, with one oriented in the N-S direction and the other in the E-W direction. Uniaxial sensors oriented vertically were used for vertical measurements. Each of the sensors was installed on either the floor or the ceiling of the representative level of the building. The GPS antenna is installed on the rooftop of the building for accurate time (±0.5 ms) synchronization of the data recording devices (Kinemetrics 2002).

Data collection

We have measured the earthquake, as well as the ambient vibration, data of the building. In case of earthquake, the seismic system is preset to record any event that produces 1 gal acceleration at the base of the building (first floor) for a duration of 120 s. For the ambient vibration data, the recording duration was changed to 4–7 minutes. In both cases, the data were sampled at the rate of 200 samples/s and were processed in the same manner.

Data Analysis, Results, and Discussion

Data analysis

The recorded data from each sensor, after correcting for the baseline and instrument response, were filtered between 0.01–45.0 Hz using a fourth order bandpassed Butterworth filter. ARTeMIS Extractor was used to analyze the dynamic characteristics of the Frontier Building based on collected data. ARTeMIS Extractor is an Operational Modal Analysis (OMA), or output-only modal analysis software (Structural Vibration Solutions A/S 2007), and is a widely used program for strong motion dynamic analysis.

In ARTeMIS, a configuration file was first generated describing the structural geometry of the building. The generated model is shown in Figure 2. The arrows in the nodes represent the direction of sensor orientation. In the next step, the recorded time histories from each sensor were applied to the model and Spectral Density Matrix (SDM) were computed.

The generated SDM can then be decomposed into Singular Value Density (SVD) systems apparent to individual modes by means of either Frequency Domain Decomposition (FDD) or the Enhanced Frequency Domain Decomposition (EFDD) (Bai 2007). The dynamic characteristics of interest were the first and second modal frequencies (when available) and the corresponding mode shape. The data generated by ambient noise were enough to clearly depict the first two modes in the weak direction (E-W), the strong direction (N-S), and torsional direction. The data generated by the earthquake events had clear peak picking for only the first two modes in the weak direction (E-W) for the April 25, 2007, event and the first mode in the weak direction (E-W) and first mode in the strong direction (N-S) for the May 22, 2007, event. This was due to the direction of the earthquake's epicenter being mainly in the E-W direction relative to the building.

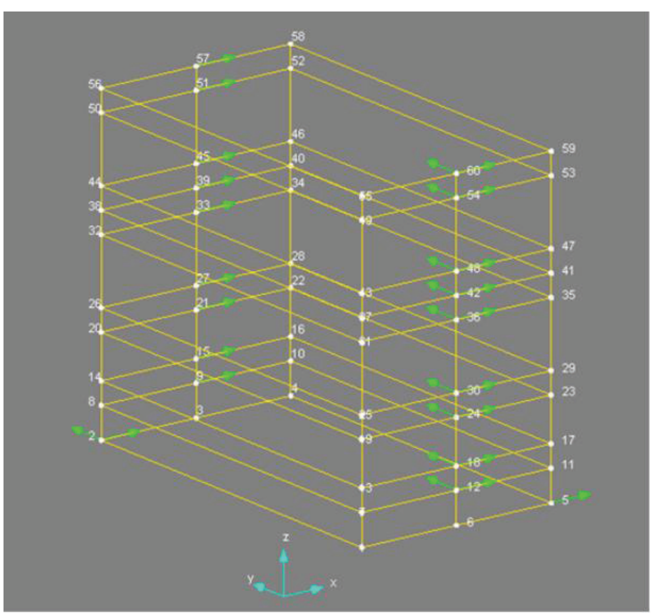

Figure 2. Geometric model of the Frontier Building generated by ARTeMIS.

The analyzed modal frequencies were then correlated with the calculated seasonal frost penetration. The relation between the first and second modal frequencies and frost depth can be seen tabulated in Table 1 and graphically in Figure 3. The data revealed minimal variation in the first and second modes with respect to varying frozen ground thickness. All fundamental frequencies for the weak axis were within 2% of one another and 3% for the second mode frequencies.

Discussion

The tabulated results do not reveal similar trends found in similar past projects conducted by Qi et al. (2006), Yang et al. (2007, 2008), and Bai (2007). These past projects, involving a pile foundation bridge, a 20-story office building (the Atwood Building) with an unheated parking garage basement, and an open, unheated, four-level parking garage yielded increases in the fundamental frequencies ranging from 4% up to 50% from summer to winter season. All these projects are anticipated to differ from the Frontier Building in that they all have foundation designs that allowed for the surrounding ground to freeze, whereas, the design of the Frontier Building allowed heat from the inside of the building to migrate to the foundation and prevent any ground freezing in the vicinity of the building. A thermal finite element model was generated for the Frontier Building, as well as for the Atwood Building, to examine and compare the two buildings' thaw bulbs.

It is appropriate to compare these two buildings, in that they are similar in shape and size, and they are relatively close to one another, and therefore, exposed to similar climate, as well as geotechnical, characteristics. They do, however, differ in configuration with respect to their foundations. As mentioned before, the Frontier Building has a footing foundation with the first floor directly on top of the foundation backfill. The Atwood building, on the other hand, has an unheated underground garage beneath the first floor of the building.

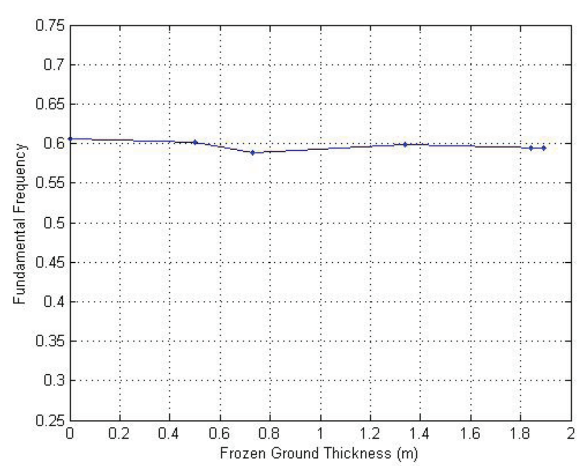

Figure 3. Frozen ground vs. fundamental frequency for the Frontier Building.

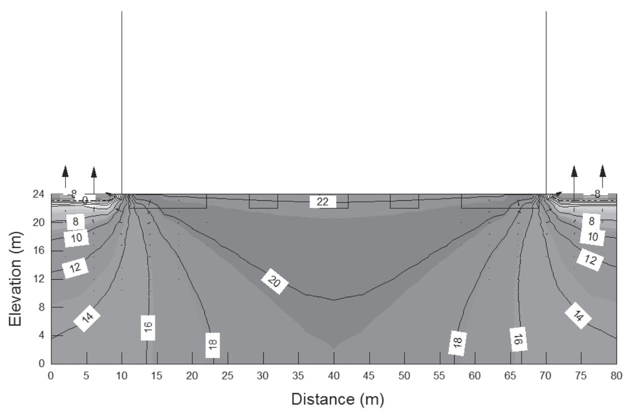

Figure 4. Thermal FE modeling results of the Frontier Building.

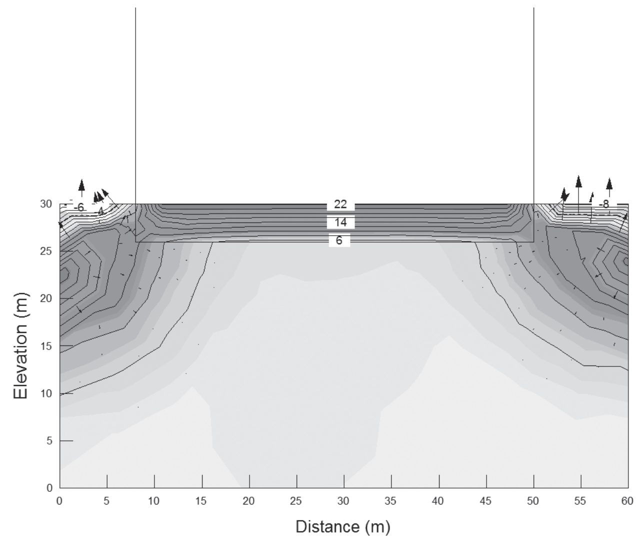

Figure 5. Thermal FE modeling results of the Atwood Building.

The Temp/W Module of Geo Studio 2004, Finite Element modeling software, was used to examine the thaw bulb of each building to compare thaw bulbs as a result of the foundation configuration. The average temperature of the interior of both buildings was assumed to be 22.2°C, and the average outside air temperature during the freezing period was found to be -8.2°C, from the temperature data obtained from a nearby airport described earlier. Soil properties such as thermal conductivity and heat capacity were inputted into the program, and the thaw bulb for each building was generated as shown in Figures 4 and 5.

The thermal contour lines are labeled with their appropriate temperature while the 0°C line (signifying the freezing front) is delineated with a bold dashed line. The arrows in the diagrams represent heat flow vectors. The direction of the arrow represents the direction of heat flow, and the size of the arrow determines the magnitude. Regional shading also relates to the thermal gradient. These two models could be refined to produce more accurate results (e.g., freezing front) by including details of the wall and openings in the basement. However, they are good enough to show that (1) sufficient heat migration was allowed from the building into the foundation, thus preventing frozen ground to develop in the Frontier Building; (2) the unheated parking garage/basement in the Atwood Building acts as a thick insulating layer preventing heat from infiltrating the surrounding soil, thus allowing frozen ground to develop.

Conclusions

After comparing the thermal analysis of the two buildings, the following conclusions were determined:

- Decreasing ambient air temperature did not impact the dynamic properties of the Frontier Building. This was due to the fact that the building's foundation design allowed for a large enough thaw bulb to prevent significant frost penetration.
- The Atwood Building's dynamic properties were impacted by seasonal frost due to its foundation design creating enough of an insulating layer to inhibit heat migration.
- Foundation design, with respect to heated or unheated, plays a crucial role in whether or not the structure's foundation will be influenced by frozen ground leading to potential impact on dynamic properties.

Acknowledgments

The strong-motion instrumentation was sponsored by the Advanced National Seismic System Program of U.S. Geological Survey. This study is partially supported by Chancellor's Research Funds of the University of Alaska Anchorage. We want to thank the management of the Frontier Building for their support to this project.

Seasonal Thermal Regime of a Mid-Latitude Ventilated Debris Accumulation

Sébastien Morard
Geography Unit, Geosciences Department, University of Fribourg, Switzerland
Reynald Delaloye
Geography Unit, Geosciences Department, University of Fribourg, Switzerland
Jonathan Dorthe
Geography Unit, Geosciences Department, University of Fribourg, Switzerland

Abstract

The internal and reversible mechanism of air circulation throughout a porous debris accumulation-like talus slope, relict rock glacier, and rockfall deposit acts as an efficient advective conveyor of heat, which strongly influences the ground surface thermal regime during the whole year. Combining the detection of visual evidences and ground surface temperature (GST) measurements (continuous logging, winter mapping) has proved to be relevant for identifying areas affected by internal ventilation and for characterizing the spatial pattern of the seasonal ground surface temperature anomalies. Five types of specific annual ground thermal regime can be defined. Vegetation, soil, and micro-fauna appear to be related to these different thermal regimes. The distribution of vegetal associations is closely linked to the ground temperature in summertime.

Keywords: air circulation; ecosystems; seasonal thermal regimes; Swiss Alps and Prealps; talus slopes.

Introduction

The mechanism of deep air circulation (the so-called chimney effect or wind tube) is known to be a process of ground overcooling in the lower and, presumably, deeper parts of porous talus slopes (e.g., Wakonnig 1996, Delaloye et al. 2003, Sawada et al. 2003). It occurs frequently in mid-latitudes, where it can generate and/or preserve extrazonal permafrost conditions up to more than 1000 metres below the regional lower limit of discontinuous mountain permafrost (Gorbunov et al. 2004, Sone 2005, Delaloye & Lambiel 2007). The process plays, moreover, a decisive role in the conservation of specific terrestrial ecosystems (Gude & Molenda 2003).

Detailed investigations on the thermal regime of talus slopes and other porous debris accumulations (relict rock glaciers, rockfall deposits) have been carried out since 1997 in western Switzerland (Jura mountains, Prealps, and Valais Alps) in several sites located between 650 and 2000 m a.s.l. with a corresponding mean annual air temperature (MAAT) ranging from +8 to +2°C, respectively (Fig. 1) (e.g., Delaloye 2004, Lambiel 2006). They demonstrate that internal air circulation is a mechanism common to almost all prospected sites causing a significant annual negative anomaly of the ground surface temperature (GST) (up to more than 7°C below MAAT) at the bottom of the debris accumulation, independent of the slope orientation.

The present paper describes the seasonal spatial pattern of the ground surface thermal regime in porous debris accumulations, which are affected by the air circulation mechanism. It provides some key methods for detecting and assessing both the occurrence of a ventilation mechanism and its spatial influence. It also gives a preliminary overview on the related specific terrestrial ecosystems, in particular on the development and spatial extent of vegetal associations and soils.

Background

Cold airflow blowing out of the ground in summertime in the lower parts of scree slopes was used for centuries in mountainous or volcanic mid-latitude areas as natural refrigerators for the conservation of food (e.g., DeSaussure 1796). Several assumptions have been advanced to explain the origin of ground cooling (Harris & Pedersen 1998). Recent studies (Wakonnig 1996, Delaloye et al. 2003, Sawada et al. 2003) and our analysis of several tens of sites investigated in Switzerland demonstrate that a deep reversible air circulation process (the so-called "chimney effect") acting throughout the whole of an accumulation of blocky material (Delaloye & Lambiel 2007) is likely to be the main factor controlling the ground surface thermal regime on these sites. The cooling effect of air circulation in a porous medium has also been used artificially in embankments to preserve permafrost conditions under highway and railway infrastructure in high-latitude or high altitude (e.g., Goering & Kumar 1996, Niu & Cheng 2005).

The reversible air circulation

Variations of both the direction and the velocity of the air circulation throughout an accumulation of loose sediments are primarily controlled by the thermal contrast between the outside and inside (ground) air causing a gradient of driving pressure (Delaloye et al. 2003). The flow direction reverses seasonally. During winter, an ascent of relatively warm light air tends to occur in the upper part of the debris accumulation. It leads to a dynamic low (a depression) in the lower part, causing a forced aspiration of cold external air deep inside the ground even through a thick—but porous—snowpack. A gravity discharge of relatively cold dense air occurs during summer in the lowermost part of the debris accumulation, preventing the GST to rise significantly above 0°C in this

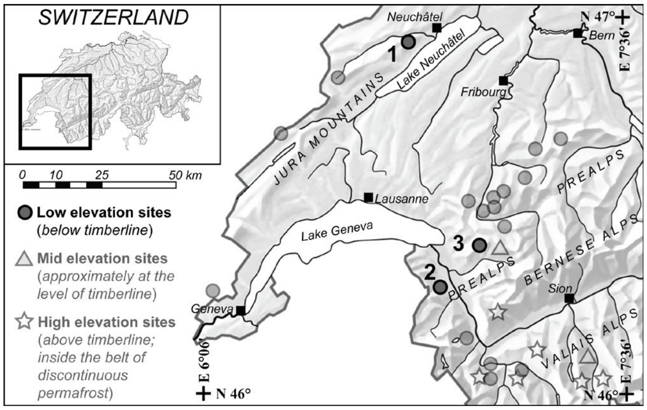

Figure 1. Location map of investigated areas with ventilated terrain in western Switzerland (after Delaloye 2004, Lambiel 2006, Dorthe & Morard 2007). Main sites: 1: Creux-du-Van; 2: Dreveneuse; 3: Bois des Arlettes.

section. As a consequence, a diffuse aspiration of external warm air occurs in the upper part of the slope.

An internal "cold reservoir" is built up during winter by the advection of external air (Sone 2005). The efficiency of the process depends on the intensity and duration of cold weather periods. The "frigories" are supposed to be "stored" by groundwater freezing (latent heat) and by conduction in the rocky materials and/or in the underlying finer ground (Delaloye & Lambiel 2007). The thermal conditions observed at the ground surface and in the shallow sub-surface in summertime are mainly influenced by the intensity of winter cooling and the recharge of the cold reservoir.

Specific ecosystems

The lower parts of ventilated talus slopes usually shelter specific ecosystems, whose typical distribution areas are located at higher latitude and/or higher elevation (e.g., Rist et al. 2003, Gude & Molenda 2003). Besides the occurrence of boreo-alpine species, significant differences in phenological development (like dwarfing of trees, early yellowing, or shorter developmental staging of vegetation) have also been highlighted between flora growing in the cold ventilated areas and those located outside (Ruzicka 1999, Körner & Hoch 2006).

Sites Characteristics

Data from the three main sites of investigation in western Switzerland (Creux-du-Van, Dreveneuse-du-Milieu, Bois des Arlettes) are used in this paper. The sites are located between 500 and 1200 metres below the estimated elevation of the regional lower limit of discontinuous mountain permafrost (about 2200–2400 m a.s.l. on northern slopes) (Fig. 1, Table 1).

Sites description

The Creux-du-Van (Cr) north-facing talus slope consists of limestone pebbles in the uppermost part transiting gradually to metric boulders downwards. The lower part of the slope is covered by an organic soil, and several patches of dwarf red spruces (*Tofieldio-Picetum* association) are occurring. The thickness of the blocky layer was estimated by geophysics to be about 20 m with the possible existence of a frozen body (Marescot et al. 2003). The site has been intensively studied since 1997 (Delaloye et al. 2003, Delaloye 2004).

Table 1. Topo-climatic characteristics of the investigated sites.

N°	Sites	Elevation	MAAT	Orientation
1	Creux-du-Van	1170-1290	+ 5.4°C*	N
2	Dreveneuse	1600-1800	+ 3.8°C**	E
3	Bois des Arlettes	1650-1900	+ 3.9°C***	NW

Locations are displayed on Figure 1. MAAT (Oct. 2004 to Sept. 2005) measured at: *1210 m a.s.l.; **1700 m a.s.l. (derived from Moléson, 2000 m a.s.l.); ***1740 m a.s.l.

The Dreveneuse-du-Milieu (Dr) east-facing talus slope consists of limestone pebbles and angular decimetric blocks. It is connected to a 200 m long relict rock glacier extending downward in a forested area. A few dwarf red spruces are found in the lower part of the slope as well as locally on the relict rock glacier. The thickness of the blocky layer was estimated by geophysics to be about 20 m for the talus slope and about 15 m for the relict rock glacier.

The large Bois des Arlettes (Arl) talus slopes face to the northwest and also consist of limestone debris. They dominate several sizeable relict rock glaciers. The thickness of the blocky layer was estimated to be about 25 m for the talus slope and 15–20 m for the relict rock glacier. Vegetation is almost lacking on the talus slope. The relict rock glaciers are conversely covered by a thin organic soil and a mixed forest, including some patches of azonal vegetation (*Salicetum Retuso-Reticulatae*) with alpine species such as *Pritzelago alpina* or *Dryas octopetalia*.

Meteorological conditions of the year 2004–2005

Data presented in the paper date from the hydrological year 2004–2005 (Fig. 2).

Relatively warm conditions occurred from October to mid-January in comparison to the climatic norm 1961–1990, interspersed with a cold phase by mid-November. Two successive persistent cold periods were then recorded until mid-March, separated by a short spell of milder weather in the first days of February. Afterwards, air temperatures remained warmer than the norm, except for August.

Winter 2004–2005 was also characterized by relatively late snowfalls, the snow cover remaining thin (less than about 50 cm) until mid-February. The snow cover reached its maximal thickness (1.5 m at Creux-du-Van and probably as much on the two other sites) by mid-March.

Methods

According to Delaloye (2004) and Morard et al. (2008), the observation of visual evidences (like "snowmelt windows" in the upper part of a slope in winter or ground-ice occurrences in early summer in the lower part) was used to point out the activity of a ventilation mechanism through a debris accumulation (Figs. 4, 5). In addition, ground temperature measurements were carried out to assess the spatio-temporal variability of the ventilation system.

Several single-channel dataloggers (UTL-1) were installed

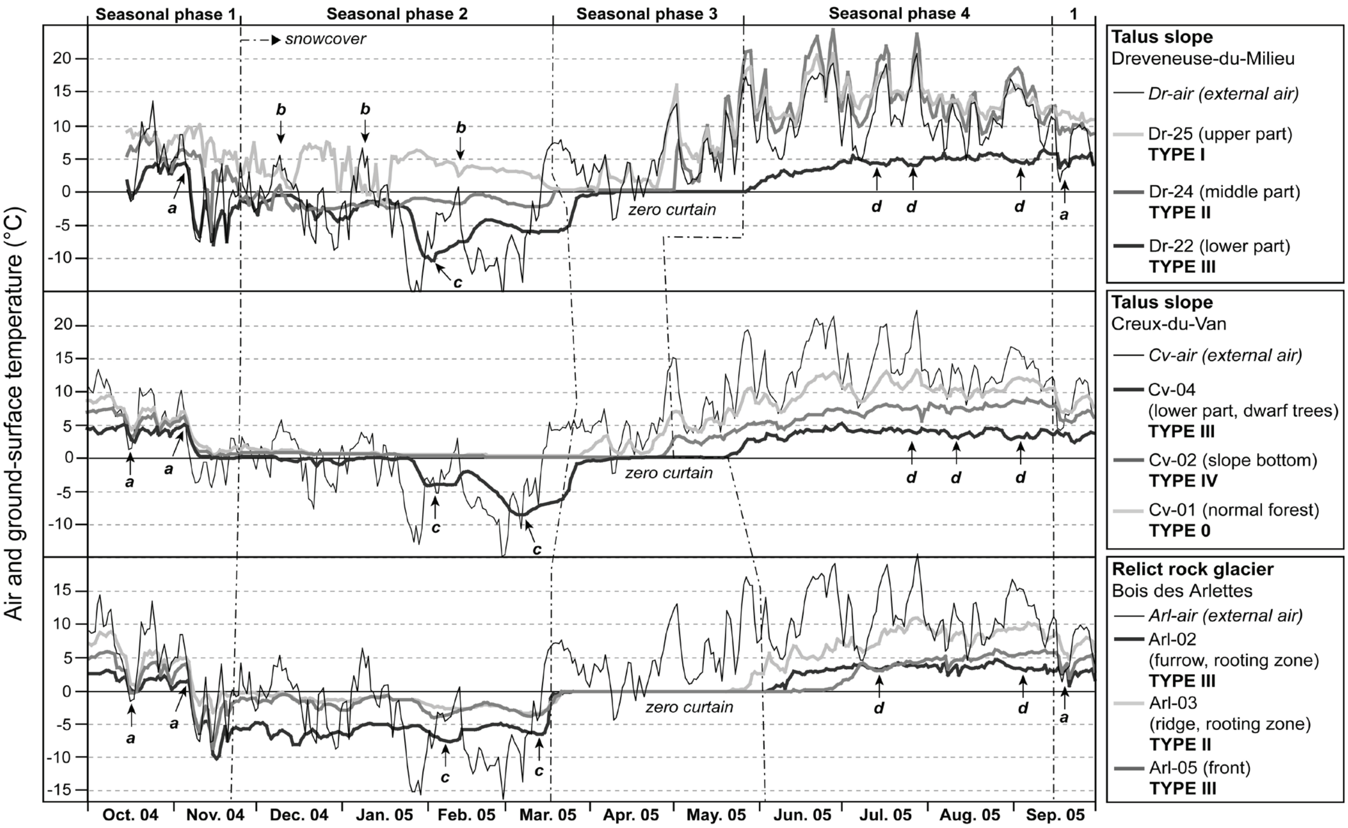

Figure 2. Thermal behaviors of the different parts of a ventilated talus slope–relict rock glacier complex. Data are daily air and ground-surface temperature. Locations of the dataloggers are shown in Figures 4 and 5. Arrows: a) inversion of the air flow direction; b) mild weather events; c) colder ground-surface temperature in January-–March 2005; d) coldest ground temperature in summertime.

on the different sites, mostly along a longitudinal profile crossing the whole debris accumulation. They recorded the ground surface temperature at a depth of about 10–20 cm every two hours. Atmospheric air temperatures were measured in situ (Creux du Van, Bois des Arlettes), or derived from official meteorological stations of the Federal Office of Meteorology and Climatology network using an altitudinal gradient of -0.58°C/100 m (Dreveneuse).

The comparison between ground and surrounding air temperature provides information about both the direction and intensity of the airflow. A similar relationship corresponds to an aspirating regime, while an inverse relationship indicates an expelling phase reflecting partially the thermal state of the ventilated system at a given moment (Lismonde 2002). A close non-delayed relationship between air and ground temperatures is assumed to be related to a higher intensity of the air flow.

To determine both the efficiency and the spatial pattern of a ventilation system, the winter temperature at the ground/snow interface was also mapped after a long period of cold weather in February 2005 using the BTS (bottom temperature of the snow cover) technique.

Results

Time series reported in Figure 2 and summed up in Table 2 illustrate the annual behavior of the GST for the three main sites of investigation along a slope profile. Four seasonal phases (1–4) can be distinguished for describing the thermal regime of the various parts of a ventilated debris accumulation, paying attention to the thermal anomalies in regard to the outside air temperature.

Seasonal phase 1: Autumn and early winter conditions

The fall–early winter phase until the onset of a thick snow cover is characterized by the frequent reversibility of the ventilation system. The air flows downwards in mild weather, whereas aspiration occurs in the lower parts of the ventilated terrain when the weather becomes colder. Not only the foot of talus slopes suffers an intense cooling of the ground, but also the relict Bois des Arlettes rock glacier (arrows "a" in Fig. 2). In all these places, this seasonal phase 1 is characterized by a negative thermal anomaly.

In November 2004, the GST in the upper part of the Dreveneuse talus slope (Dr-25) remained permanently above the freezing point, with variations inversely related to those of the external air temperature. Snowmelt windows, hoarfrost, wet blocks, basal icing of a thin snow cover, and condensation fog are visual evidences of the outflow of "warm" air during this phase.

During the phase 1, the lower part of the Dreveneuse talus slope (Dr-22) cooled from +4°C to -6.8°C between 6–10 November 2004, whereas the GST in the upper part of the slope remained as high as +8°C. At Bois des Arlettes, a rapid decrease of the GST from +1.5°C to -6.4°C and from +4°C to -6°C was also observed in a furrow in the rooting zone (Arl-02), and on the front (Arl-05) of the relict rock glacier, respectively. Where the soil is thicker and damper as in the Creux-du-Van lower talus slope (dwarf trees area), a zero curtain period can start (Cv-04).

Table 2. Temperature characteristics of the investigated sites.

UTLs	MAGST (°C)	ATA (°C)	GFI (°C)	NFD (day)	ZCD (day)
Dr-air	*3.76**	*0*	*-613*	*105*	*0*

Location on Figures 4 and 5. * Mean annual air temperature (°C). MAGST: mean annual ground surface temperature (°C); ATA: annual thermal anomaly (°C); GFI: ground freezing index (°C); NFD: number of frozen days; ZCD: zero curtain duration (day).

Seasonal phase 2: winter conditions

Winter is often characterized by a thicker (more than 1 m) and continuous snow cover as well as by colder weather conditions. The ascending air circulation regime is prevailing.

According to the elevation, the ground surface or its close subsurface should normally not freeze under the thicker snow cover, as it was recorded at the terminal edge of the Creux du Van talus slope (Cv-02) and in the surrounding area (Cv-01).

In the upper part of a talus slope, as in Dreveneuse (Dr-25), the GST remained warm for the whole winter, but dropped strongly for a short time by mild air temperatures (arrows "b" in Fig. 2). The only temperature below freezing point was registered during the mildest weather period in January 2005. The GST tended however to decrease gradually from about +7°C in the beginning of November to +2°C in March. An inverse relationship to the outside air temperature is also observed. Warm air outflow is easily perceptible as well as associated phenomena like snow funneling with hoarfrost, snowmelt windows, and vaulted spaces at the base of the snowpack.

GST was at or below freezing point during the whole winter in the middle and lower parts of the talus slopes (Dr-24, Dr-25, Cv-04), as well as on the relict rock glacier (Arl-02, Arl-03, Arl-05). The GST mapped in February illustrates the spatial geometry of the colder areas (Fig. 3). The thermal regime is mainly controlled by the evolution of the external air temperature (arrows "c" in Fig. 2) with a time lag of a few days which seems to increase by the end of the winter.

Seasonal phase 3: Snowmelt period

At the onset of the snowmelt phase in March, the GST rose suddenly to 0°C in the lower parts of the ventilated terrains and remained stable for 42 days at Dr-24 to 87 days at Arl-05 (Table 2). In the upper part of a talus slope (Dr-25), the snowmelt phase provoked a temperature drop to about 0°C. This non-constant zero curtain phase lasted for a few days only.

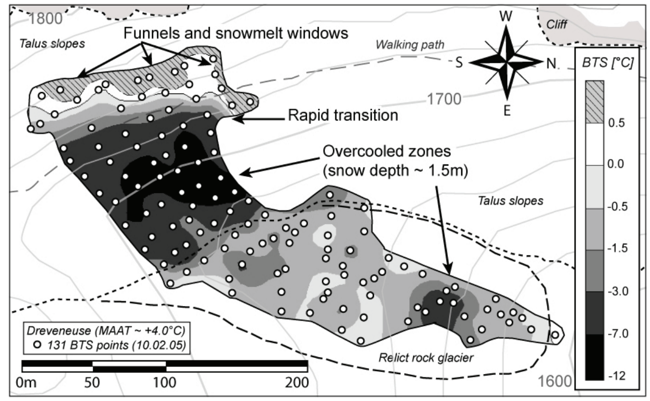

Figure 3. Ground surface winter temperature mapping (Dreveneuse-du-Milieu, 10 February 2005). Note the overcooled zone in the middle/lower part of the talus slope, the cold areas on the relict rock glacier, and the rapid transition in the uppermost zone to warmer ground temperature.

Seasonal phase 4: summer conditions

The gravity discharge of cold dense air prevents the GST to increase above +6°C in the lower parts of the debris accumulations as at Dr-22, Cv-04, Cv-02, Arl-02, and Arl-05. There is a more or less well-established inverse relationship between the airflow temperatures and those of the external air (as indicated by arrows "d" in Fig. 2). At these places, cold air outflow, azonal vegetation, ground ice, or late-lying residual snow patches can be observed.

In the upper and middle parts of talus slope (Dr-25, Dr-24), the GST varies in close correspondence with the evolution of the surrounding air temperature. In the marginal ridges of the relict rock glacier (Arl-03) and in the areas outside the porous debris accumulations (Cv-01), this GST regime can be considered as normal: the fluctuations are smooth and depend directly on the air temperature.

Synthesis and Discussion

Annual thermal regime of a ventilated system

Air circulation throughout a porous debris accumulation produces major differences in the thermal regime of areas only a few (tens of) meters from each other. Temperature anomalies occur and vary seasonally, depending both on the location on the landform and the meteorological factors (external air temperature and snow cover). Indeed, five types of annual thermal regime can be defined on the basis of the four seasonal phases described above:

- Type I: positive anomaly in autumn, winter, and summer. This behavior concerns the upper part of a ventilated system, where in particular the GST remains significantly higher than 0°C during winter due to the expelling of internal warm air. A positive annual thermal anomaly will result in such places (+4.18°C at Dr-25). A spell of mild weather in winter may cause the weakening or the end of the ascending airflow and consequently an episodic decrease of the GST.
- Type II: slight negative anomaly possible in winter, positive anomaly in summer. This kind of thermal regime affects the section located immediately above the coldest

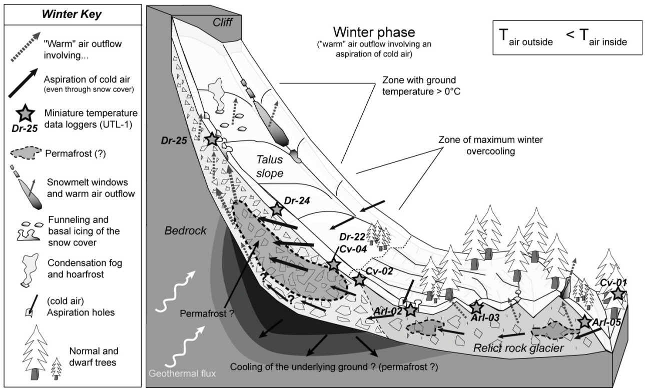

Figure 4. Model of winter ascending air circulation (in talus slope relict rock glacier system). The stars indicate the general position of the dataloggers presented in Figure 2.

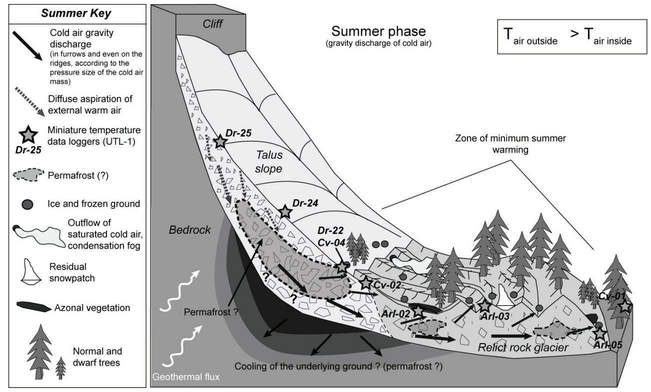

Figure 5. Model of summer descending air circulation (in talus slope/relict rock glacier system). The stars indicate the general position of the dataloggers presented in Figure 2.

area. Air aspiration occurs in late fall and winter but there is no influence of the summer gravity discharge. The annual thermal anomaly is slightly positive (Dr-24) or slightly negative (Arl-03), probably due to different ground surface properties (blocky material directly exposed to solar radiation in summer at Dr-24, thick soil and shady forest at Arl-03).

- Type III: negative anomaly in fall, winter, and summer, late lying of snow. This annual type is associated to the coldest part of the system, permanently frozen during winter due to the aspiration of external air (even through the snow cover) and remaining cool in summer because of the gravity discharge of internal cold air. Such areas are located in the lower part of the talus slope as well as locally on the connected relict rock glacier–if existing. The annual thermal anomaly reached -3.28°C to -4.91°C at Dr-22, Cv-04, Arl-02 and Arl-05 (Table 2).
- Type IV: slight negative anomaly possible in winter, negative anomaly in summer less pronounced than in type III, late-lying snow. This area is located under the coldest zone at the bottom of a talus slope and is partially affected by the summer gravity discharge. The annual thermal anomaly is slightly negative (CV-02).
- Type 0: no seasonal anomaly. During winter and in the presence of snow, the ground temperature does not drop below 0°C. This behavior concerns mainly sectors which are not affected by the air circulation and, where the heat fluxes are only conductive. The mean annual temperature is close to MAAT (CV-01).

Dissymmetry of seasonal overcooled zones

A spatial shift can be identified between the zones of maximum winter overcooling and those of minimum summer warming (Figs. 4, 5). The seasonal contrast between types II and IV shows that in a talus slope, the area affected by the winter aspiration of cold air, is shifted upwards compared to the cold summer area, the seasonal gravity discharge concentrating in the lowermost parts of the slope. Such a shift has not so far been observed on the downward relict rock glaciers. However, the occurrence of thermal regimes of type III and the lack of warm areas on these landforms indicate that internal ventilation is occurring as far as the front of a relict rock glacier and should be connected to those of the upper talus slope. Figures 4 and 5 illustrate the resulting concept of air circulation throughout a talus slope–relict rock glacier complex and the possible location of permafrost within the system.

Spatial implication on related terrestrial ecosystems

Temperature is one of the key factors (with moisture) controlling the distribution of organisms and primary production (such as pedological processes) in ecosystems. The spatial distribution of vegetation and soils on a ventilated system often indicates different GST conditions.

The seasonal asymmetrical position of cold zones plays an important role on the vegetal distribution. The thermal regime of type II is not associated with azonal vegetation. At Arl-03, for instance, the presence of *Rhododendro-Vaccinetum Juniperetosum* Ass. indicates normal ground thermal conditions during the vegetation period in summer. Conversely, a cold summer ground surface thermal regime of types III and IV is associated with alpine species like *Pritzelago alpina* and *Dryas octopetalia* (for instance at Arl-02) and limits the growth of tree roots (Körner et al. 2006) (Dr-22, Cv-04). The phenological development is strongly conditioned by the summer ground temperature.

Soils found in overcooled sectors evolve differently from the general pedoclimatic trend (Gobat et al. 2003). Furthermore, cold summer temperature directly influences the development of humus. Spatial variations in pH, organic texture, and kind of macrorests is clearly dependent on the location of ventilated systems (Rossel et al. 2004) and the GST regime.

A strong thermal stability is observed in summertime, but also from year to year (Delaloye 2004), where the cold air outflows occur. It would also provide possible favorable long-term abiotic conditions for azonal and less-competitive species. Genetic DNA-analyses carried out on different separated populations of wingless beetles found in cold scree slopes have shown on the one hand an own genetic evolutionary way (island-like character of this biotope), and on the other hand the existence of true faunal relicts from glacial periods (Gude et al. 2003).

Conclusion

The main conclusion of our study is that thermal anomalies induced by advective heat fluxes ("chimney effect") are observed in many porous debris accumulations located below the regional lower limit of discontinuous permafrost in the Swiss mountains. An interconnection in the airflow between a talus slope and a relict rock glacier located immediately downstream has also been identified.

The combination of visual and thermal measurements has proved to be a relevant method for detecting and characterizing heterogeneous ground surface thermal regimes of a ventilated debris accumulation.

A succession of negative seasonal anomalies is typical in the lower part of a ventilated area, while in the upper part the GST regime presents usually a positive anomaly during the whole year. Other differentiated types of seasonal thermal regimes occur in the upper and lower margins of the coldest places of a debris accumulation. Moreover, the occurence, development, and spatial pattern of distribution of specific "cold" terrestrial ecosystems are directly influenced by the internal circulation of air.

Abstract

This study provides a detailed inventory of lakes in the Lena Delta, northern Siberia. The inventory is based on Landsat-7 ETM+ image data and spatial analysis in a Geographical Information System (GIS). Several morphometric lake attributes were determined from the resulting dataset and statistically analyzed with respect to the lakes' association with one of the three geomorphological main terraces of the Lena Delta. Significant differences in the morphometric lake characteristics allowed the distinction of a mean lake type for each main terrace. The lake types reflect the special lithological and cryolithological conditions and geomorphological processes prevailing on each terrace. Special focus was laid on the investigation of lake orientation and the discussion of possible mechanisms for the evolution of the second terrace's oriented lakes.

Keywords: GIS; lake morphometry; Lena Delta; oriented lakes; remote sensing; thermokarst lakes.

Introduction

Numerous lakes occur as characteristic landforms throughout the Lena Delta. They are of importance to the contemporary ecology and geomorphology in this sensitive Arctic environment as well as for the reconstruction of the delta's environmental history. So far, only general descriptions of the lake population were available (e.g., Grigoriev 1993). They suggest that several lake types of different genesis can be distinguished and that the western delta is characterized by oriented lakes. However, a detailed inventory of the Lena Delta lakes did not exist. Such an inventory potentially provides a base dataset essential to a variety of research conducted in this region. This study was aimed to create a lake dataset of the Lena Delta including morphometric and spatial characteristics using remote sensing and GIS techniques to analyze the dataset regarding a morphometric lake classification, and to investigate possible hypotheses of the morphogenesis of the lakes in this periglacial delta environment.

Regional Setting

The Lena Delta in northern Siberia is the largest Arctic river delta (Walker 1998). It is situated in the zone of continuous permafrost and is widely affected by thermokarst. It is characterized not only by alluvial sediments and active fluvial processes, but also by large non-deltaic units. Three main terraces can be distinguished by their geomorphology (e.g., Are & Reimnitz 2000, Schwamborn et al. 2002) (Fig. 1). The first main terrace, which represents the modern active delta, is comprised of the lower and upper floodplains and the first terrace above the floodplain. It forms most of the eastern Lena Delta and is characterized by alluvial Holocene sands with silts and peat. The second terrace captures broad parts of the western Lena Delta. It consists of Late Pleistocene to Early Holocene sands of fluvial genesis, but is hardly influenced by modern fluvial processes. The third main terrace is the relic of a Late Pleistocene accumulation plain with fine-grained and ice-rich deposits.

Materials and Methods

Remote sensing

A mosaic of three Landsat-7 ETM+ scenes taken in the summers 2000 and 2001 covering 98 % of the Lena delta (Schneider et al., in prep.) was used as a basis for lake extraction using the software ENVI™ 4.1. First, we conducted a gray-level thresholding on the mid-IR band 5 to separate open water from land, as water bodies are strong absorbers in these wavelengths and easily distinguishable from other land cover classes. Second, the water class was subjected to a segmentation algorithm to differentiate standing water from rivers and the sea. This method creates separate classes for coherent pixels with the same value. As rivers and estuaries are connected with the sea, they form one single class and were deleted. Some lakes along the coastline that have broad (in the range of several pixels) connections to the sea were thereby also removed from the dataset. They experience a strong marine influence; for example, during storm floods, which can lead to major changes in lake morphometry and lagoon formation. Thus, these lakes were not considered for morphometric and further analysis.

GIS and morphometric analysis

The resulting raster dataset of all remaining lakes was imported into ArcGIS™ 9.0 and converted into vector format

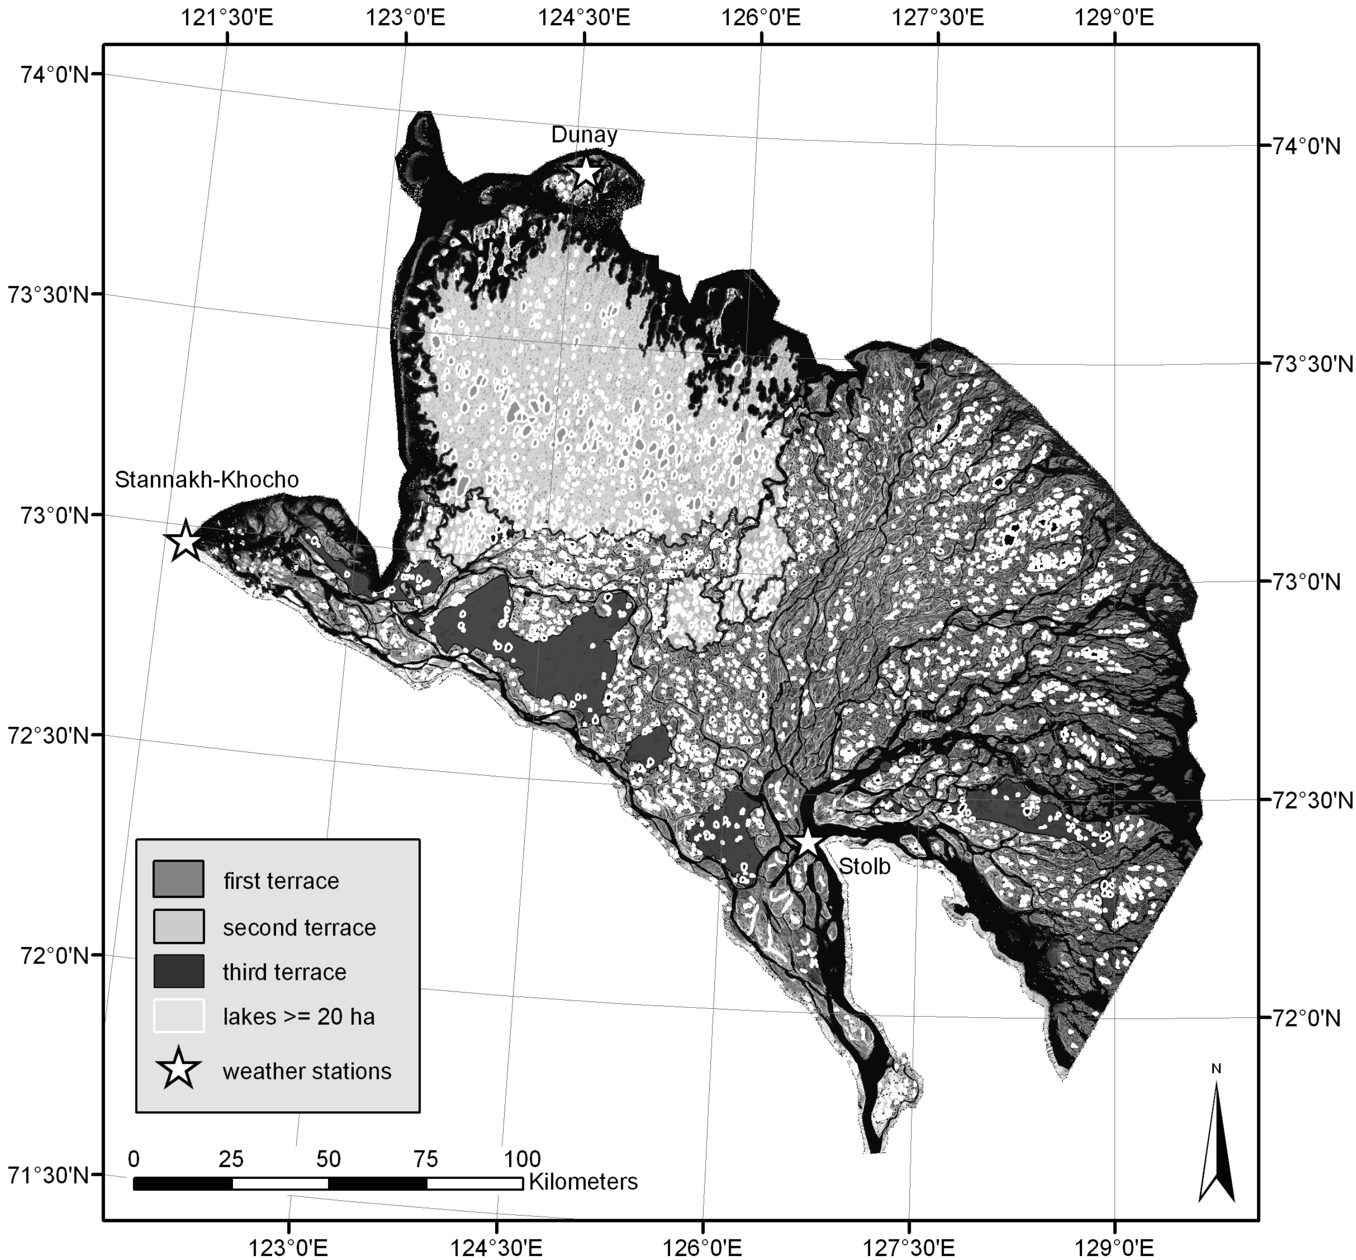

Figure 1. Landsat-7 ETM+ mosaic of the Lena Delta (Band 2) with analyzed lakes and main terraces, and meteorological stations.

where each lake is represented by a polygon. Shape metrics like *area*, *perimeter*, *circularity index* ($4\times\pi\times area/perimeter^2$), *elongation index* (main axis/minor axis), *orientation of main axis* (reference axis is E-W, value range is [0.1;180]°), and *degree of deviation from mean orientation* were calculated. The *circularity index* (values between 0 and 1, with 1 being a perfect circle) is not simply a counterpart to the *elongation index*, but also reflects the smoothness of the shoreline.

As the spatial resolution of the Landsat imagery is 30 m, minimum lake size for analyses was set to 20 ha to ensure reasonable results for reckoning the shapes of the lakes. The lake dataset was manually checked for errors due to misclassification caused by light cloud cover in some places.

On the second terrace in the western Lena Delta, several coalesced lakes occur, which is obvious in the red spectrum from deep basins divided by flat underwater ridges, some of them cut by deeper channels beneath the present lake water level. As our analyses were aimed on lake genesis, we manually divided the coalesced lakes (n=51) along the middle line of the ridges into their single basins and treated each basin as an individual lake (n=120 of which n=17 < 20 ha were excluded from further analysis). The final lake dataset contained 2669 lakes.

Another vector layer was created for the second and third geomorphological main terraces of the Lena Delta by manually digitizing their boundaries based on the Landsat image data, where they are visually easily distinguished. At places of uncertainty, results of field observations were used to determine terrace affiliation. The lake dataset was then divided into three subgroups according to the lakes' association with one of the geomorphological main terraces. The subgroup for the first terrace lakes was created by subtraction of the second and third terrace lakes from the whole lake population.

The variables described above were statistically analyzed for these subgroups using the software SPSS™ 12.0. Several statistics were calculated for the variables within an explorative data analysis (EDA). Variables were tested for normal distribution using the *Kolmogorov-Smirnov test* and for homogeneity of variance using the *Levene test*. In case of non-normal distribution skewness was minimized by data transformation and subsequent tests were performed with the transformed data. To test significant differences in the means of the variables between the three terraces analysis of variance (ANOVA) was performed. Non-parametric *Median test* and *Kruskal-Wallis test* (rank-based) were used with the non-transformed data for validation. Furthermore, multiple comparative tests (*Games-Howell*) were applied to identify terraces between which significant differences in the mean values occur at the 5% level. Bivariate correlations were calculated for the variables *area*, *circularity*, *elongation*, and *degree of deviation from mean orientation* using the rank-based *Spearman's Rho* correlation coefficient.

Results

The total area of lakes ≥ 20 ha is 1861.8 km², which corresponds to 6.4 % of the delta area, as the delta area within the extent of the mosaic was calculated to be 29,000 km² (Schneider et al., in prep.). Table 1 shows the area calculations for the three geomorphological main terraces. The results show great differences in lake occurrence, density, and area. The first terrace shows the highest number of lakes in total, but lake density and the ratio of lake area to the area of the corresponding terrace are highest on the second terrace. For the third terrace, all calculated values are the lowest.

Major results of the EDA are the following (see also table 2). Means, medians and percentiles for *area* show that comparatively larger lakes occur on the second terrace and rather smaller lakes on the first. The frequency distributions are strongly skewed towards lower values on all terraces, so smaller lakes are in general much more abundant than larger ones. Maximum values for the *circularity index* are well below 1 (< 0.7), i. e. throughout the delta no nearly circular lakes occur. Lakes with values of nearly 1 for the *elongation index* (which means almost equal major and minor axes) therefore have complex shorelines at the image resolution. Values for *circularity index* and *elongation index* show generally the largest deviation from perfect circularity for the first terrace and the smallest for the third terrace. Mean *orientation* of all lakes is 90.0°, the median is 80.2°. Means (medians) are 94.9° (95.9°) on the first main terrace, 78.6° (75.9°) on the second terrace, and 90.7° (82.0°) on the third terrace, respectively. Figure 2 shows the frequency distributions of *orientation*. The percentage of lakes with a deviation from the *orientation* mean (median) of ≤ 10° of the according terrace are 9.6 % (9.5 %) for the first terrace, 63.0 % (66.2 %) for the second, and 24.7 % (35.8 %) for the third terrace, respectively. Also the means and medians of *degree of deviation from mean orientation* show that lakes on the second terrace deviate the least and lakes on the first terrace the most from the according mean orientation.

The results of the ANOVA as well as of the non-parametric tests show significant differences in the parameter values between the three main terraces for all variables. Multiple comparative tests revealed the following results at the 5% level. The lakes of the first terrace significantly differ from the second terrace lakes in all variables. No significant differences were found between the first and the third terraces regarding *orientation*, and between the second and the third regarding *orientation* and *area*. On the first terrace, lakes are smaller on average than on the second and third terraces. Nearly circular lakes are more abundant on the third than on the other terraces.

In the context of our analyses we defined oriented lakes as lakes with little deviation from mean orientation and with a deviation from circularity. Deviation from mean orientation is significantly smaller on the second terrace than on the other two terraces, it is highest on the first terrace. Thus, lakes on the second terrace can be statistically characterized as oriented lakes with their main axes tending in NNE-SSW directions.

Of the 18 tests for correlations ten were significant at the 5% level. These include medium negative correlations (r = -.444 to -.465) between *circularity* and *elongation* on all terraces as expected from the design of the variables. All other significant correlations are very small ($|r| \leq .186$) except for the correlation between *area* and *degree of deviation from mean orientation* on the third terrace (r = -.415, p = .01).

Discussion

For all analyzed morphometric lake variables we found significant differences between the three geomorphological main terraces of the Lena Delta. From these differences we deduce one mean lake type for each terrace:

1. Lakes on the first terrace are on average small and elongated, with irregular shapes and strong deviations from mean orientation.
2. On the second main terrace, large elongated lakes with a NNE-SSW orientation of their major axes prevail. Lake density is highest here.
3. The third terrace lakes are mainly characterized by regular shorelines and little deviation from circularity.

These results imply that the forming of a lake's shape towards one of these mean lake types is linked to the according delta main terrace, i. e. lake morphometry is influenced differently on the different main terraces. Different lake morphometries can be caused primarily by diverse lake genesis or by secondary processes subsequently altering the lake's primary shape. The different conditions and processes prevailing on each terrace of the Lena Delta are used to explain the development of the mean lake types found.

The first main terrace is the only one with widespread recent and Holocene fluvial and deltaic activity. The genetic lake type

Table 1. Area calculations for the three geomorphological main terraces of the Lena Delta.

		First terrace	Second terrace	Third terrace
Terraces	Area in km²	15,840.1	6098.6	1711.6
	Percentage of delta area	54.6	21.0	5.9
Lakes ≥ 20 ha	Number	1796	792	81
	Number per 1000 km²	113.4	129.9	47.3
	Percentage of total lake number	67.3	29.7	3.0
	Total area in km²	997.0	808.1	56.7
	Percentage of terrace area	6.3	13.3	3.3
	Percentage of delta area	3.4	2.8	0.2

* Differences from 29,000 km² and 100% total delta area arise from the percentage of sea and river area, respectively, in the mosaic.

	Interquartile range	48.1	45.3	11.7	33.5

typical for such environments is abandoned lakes. Walker (1983) differentiates between abandoned-channel lakes resulting from channel braiding and abandoned meanders or oxbow lakes resulting from meandering. They are predominantly small, often elongated and/or crescent-shaped because they occupy former river branches or meanders, and do not show any particular orientation as the fluvial system shows no clear directional pattern itself at a small scale. Thus, the morphometric characteristics for these lakes are consistent with the mean lake type deduced for the first terrace of the Lena Delta. Further lake types described for the first terrace are polygon ponds and small circular thermokarst lakes (e.g., Grigoriev 1993). Polygon ponds were generally not considered in this study because of their small size. As for the circular thermokarst lakes no area range is reported in the literature, but we assume that they mostly have areas below 20 ha and were therefore not treated in our analyses. Their characteristics, such as smooth shorelines and approximate circularity, are not reflected in the mean lake type of the first terrace.

The morphometry of the lakes on the second terrace and their formation will be discussed in the following section on lake orientation.

Characteristics of the lake shapes on the third main terrace are typical for thermokarst lakes in ice-rich permafrost. The results are therefore consistent with landscape descriptions given in the literature (e.g., Grigoriev 1993). The shape of the lakes is controlled by their thermokarst genesis and is not significantly changed by other factors during further evolution.

In comparing morphometric lake characteristics in the Lena Delta with other arctic deltas like the Colville or the Mackenzie River deltas, only the first geomorphological main terrace should be considered, as it represents an actual deltaic environment. Lake types described for the Colville Delta are abandoned lakes, point-bar lakes, and thermokarst lakes (e.g., Fürbringer 1977, Walker 1983). In the Colville Delta, remnants of oriented lakes also occur, but these were not a part of the delta originally until a river branch cut through an area with oriented lakes (Walker 1983). For the Mackenzie Delta, typical lakes are described as irregular in outline with indented shorelines, and genetic lake types are primarily abandoned channel lakes, point-bar lakes,

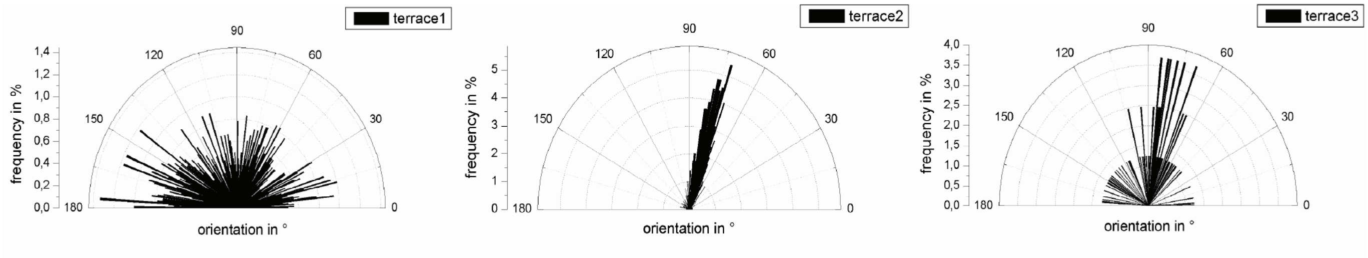

Figure 2. Frequency distribution of *orientation* of the Lena Delta lakes (intervals = 1°).

floodplain lakes, and thermokarst lakes (Mackay 1963). Lake types described for these deltas are thus comparable to the first terrace lakes of the Lena Delta.

Lake orientation

The character of lake orientation as expressed by the variables *degree of deviation from mean orientation* and *circularity* differs significantly between the three main terraces as described above. The process of lake orientation is long term and requires stability of exogenous orienting factors. Active fluvial processes prevailing on the first terrace may overlay tendencies of lake orientation there. Existing discrepancies between the second and the third terraces, however, must be discussed in detail.

Thermokarst lake evolution on both terraces reaches back at least to the early Holocene warming period (Schirrmeister et al. 2003, Schwamborn et al. 2002). Exogenous factors that have been discussed as causing or influencing lake orientation; for example, prevailing wind directions, solar radiation, etc. (e.g., Livingstone 1954, Mackay 1956, Carson & Hussey 1959), therefore, have affected both terraces in the same way for several thousand years. The different character of lake orientation implies a dependence of further endogenous; i.e., terrace-specific factors.

Lithology and cryolithology of the second and third main terraces differ considerably. Sediments on the second main terrace are Late Pleistocene fluvial sediments that consist of homogeneous fine- and medium-grained sands with massive cryogene structures. Large ice wedges are absent, and the ground ice content is generally rather low (15–25 wt%) (Schirrmeister et al. 2007). The sediments are comparable to those in the North American Arctic Coastal Plain where oriented lakes occur. The homogeneity of the sands allows for a uniform distribution of forces driving orientation processes. If these forces operate directionally, orientation can clearly develop. Sediments on the third main terrace, however, are mainly composed of the Yedoma Suite, with peat, sands, and silts with high ground-ice content (30–80 wt%) and inhomogeneous ice distribution (huge ice wedges and intrapolygonal sediments with segregated ground ice in the form of ice bands and small ice lenses) (Schirrmeister et al. 2003). This heterogeneity prevents a continuous distribution of external effects because of the different physical characteristics of the sediments; for example, bulk density or thermal conductivity. Orienting factors, therefore, cannot operate uniformly, and the development of a clear orientation is strongly impeded. The negative correlation between the lake *area* and the *degree of deviation from mean orientation* of

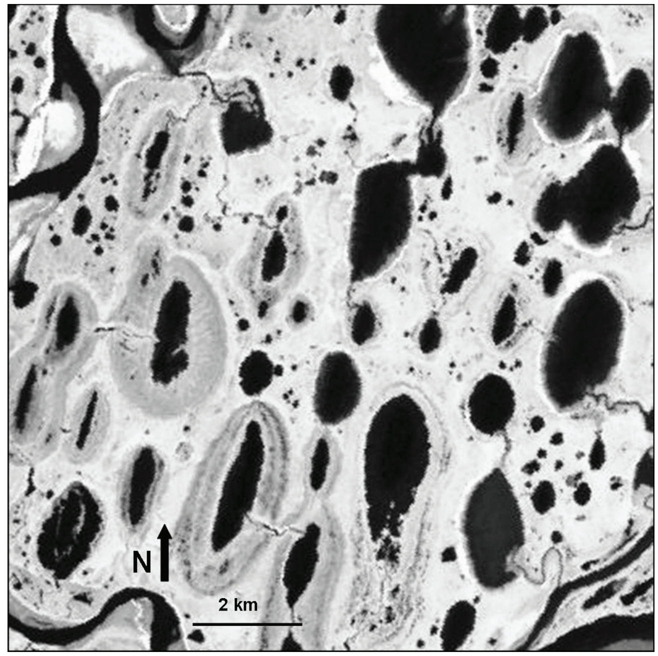

Figure 3. Section of oriented lakes in the western Lena Delta (subset of the Landsat-7 ETM+ mosaic).

the third terrace lakes may still implicate a tendency towards lake orientation in the course of lake growth. The mean NNE-SSW orientation of the poorly elongated third terrace lakes is consistent with that of the second terrace.

As for the cause of lake orientation in the Arctic Coastal Plain, several hypotheses have been discussed. The theory supported by most authors supposes preferential erosion of the lake shores at right angles to prevailing summer wind directions due to wind-driven currents and wave activity (e.g., Livingstone 1954, Mackay 1956, Côté & Burn 2002, Hinkel et al. 2005). The literature reports northern to northeastern main wind directions for the entire Lena Delta in the summer, and southern to southwestern in the winter (e.g., Grigoriev 1993, Gukov 2001). However, wind data of several meteorological stations scattered throughout the delta area show great differences in prevailing directions. Unfortunately, there is no station in the western Lena Delta close to the oriented lakes. Of the three stations closest to the western Lena Delta lakes (Fig. 1), two are situated directly at the Laptev Sea coast. On Dunay Island (73.9°E 124.6°N, data from 1955–1994), wind blows mainly from eastern directions; the Stannakh-Khocho station (73.0°E 121.7°N, data from 1981–1994) registered prevailing winds from southern directions with a minor peak from eastern directions for the whole time span, and from eastern directions at times of positive air temperatures, respectively. The third station is located in the central southern delta on Stolb Island (72.4°E 126.5°N, data from 1955–1991) and shows pronounced southern wind directions. All three stations may not reflect the actual wind situation of the second main terrace, as climate on Stannakh-Khocho and Stolb Island is supposedly influenced by the mountain ranges flanking the Lena Delta in the south. On the Island Dunay, which is a few kilometers off from the mainland of the second terrace, the marine influence has an impact on weather conditions. It can be suggested though, that, because of the flat relief of the second terrace, major wind directions in the inner part of the terrace do not differ much from the situation at its margins; thus wind data from Dunay Island might be the most suitable for assessing the situation on the second terrace. Assuming that the eastern prevailing wind direction measured over the forty-year time span was consistent throughout the lake orientation process, the wind hypotheses proposed for North American oriented lakes might also be applicable for the oriented lakes of the Lena Delta. However, little is known about the detailed conditions and factors that might be involved in lake-orientation processes in the Lena Delta or the stability of wind regimes over Holocene time scales. Further research is necessary to prove or reject any particular orientation theory for this unique Arctic environment.

Conclusions

The three main terraces of the Lena Delta vary largely in the occurrence of morphometric lake characteristics. This led to the deduction of one mean lake type for each terrace. The first main terrace, which represents the modern active delta, is characterized by small lakes of irregular shape, like abandoned lakes. Large oriented lakes with their major axes tending in NNE directions dominate on the second terrace, which consists of Late Pleistocene to Early Holocene homogeneous sands. On the third terrace, which is represented by relics of a Late Pleistocene accumulation plain with heterogeneous fine-grained and ice-rich deposits, typical thermokarst lakes with regular, circular shorelines prevail. Mean morphometric lake characteristics are consistent with the lithological and cryolithological conditions and geomorphological processes prevailing on each terrace. Wind hypotheses proposed for North American oriented lakes might also explain the orientation of lakes on the second terrace of the Lena Delta, but the detailed conditions and mechanisms of the evolution of the oriented lakes in the Lena Delta remain to be investigated.

Acknowledgments

We thank Thomas Kumke for helpful assistance with statistical analyses, Mikhail N. Grigoriev, Georg Schwamborn, and Hartmut Asche for fruitful discussions and Pier Paul Overduin for grammar and spell check. We are grateful to Alexander Brenning and another anonymous reviewer for constructive comments on the manuscript.

Vegetation and Permafrost Changes in the Northern Taiga of West Siberia

Nataliya Moskalenko
Earth Cryosphere Institute SB RAS, Moscow, Russia

Abstract

The goal of this ongoing study is to examine the impact and indicators of climate change and disturbance from natural gas pipeline construction on vegetation and permafrost conditions in various northern bioclimatic zones. The results of 37 years of observations (1970–2006) from one site near Nadym, an area of sporadic permafrost, are reported. Field methods include landscape and vegetation mapping, and permanent fixed transects across natural complexes and at plots established both in natural and disturbed conditions. Transect and plot measurements were focused on labile components of vegetation and permafrost such as species composition, active layer thickness, and ground temperature. Impacts and interactions were assessed through regression and autocorrelation of frequency of plant species and active layer thickness. Undisturbed plots show an increase of woody plants, presumably due to climate warming, and disturbed sites showed thermokarst and changed soil moisture regime and, during recovery, an increase in the frequency of succession species.

Keywords: climate change; human-induced disturbances; landscape; permafrost; vegetation.

Introduction

Vegetation and permafrost changes in natural northern environments have been studied by Koloskov (1925), Gorodkov (1932), Sumgin (1937), Tyrtikov (1969, 1979, 1980). They demonstrated that freezing and thawing conditions change in response to vegetation dynamics. Increases in moss and lichen cover thickness result in the reduction of seasonal thaw depths and decreases in soil and ground temperatures.

The work reported here is part of a large, long-term, ongoing program on vegetation and environment interactions at seven sites in the Yamal-Gydan region of northern West Siberia. The sites span the gamut of bioclimatic zones, permafrost conditions, and intensity of human disturbances. The program also includes a Circumpolar Active Layer Monitoring (CALM) program site established in 1997 (see Brown et al. 2003). The results from the Nadym site are reported.

Description of the Observation Site

The site is located near the town of Nadym and the natural gas pipeline Nadym-Punga (Burgess et al. 1993). It is in the northern taiga with sporadic permafrost (Melnikov 1983) on the III fluvial-lacustrine plain with altitude ranging from 25–30 m above sea level. The plain is composed of sandy deposits interbedded with clays, with an occasional covering of peat (Melnikov et al. 2004). Patches of permafrost are closely associated with peatlands, tundras, mires, and frost mounds.

At Nadym, records have been made since 1972. Annual geobotanical censuses are made on 28 permanent fixed plots (10 x 10 m) in natural and disturbed conditions. The structure, average height, phenological and vital condition, frequency, and coverage of plant species on 50 registered 0.1 m^2 plots were recorded. In addition, soil descriptions, microclimatic supervisions, and measurements of ground temperature in boreholes at depths up to 10 m (Dubrovin et al. 1996), and seasonal thaw depths were kept.

Table 1. Thawing depths (h_{th}) on two peatland types.

Vegetation	h_{th} in cm	*K
Rubus chamaemorus-Ledum palustre-Cladina rangiferina	67.1±17.1	-0.71 (0.5-0.8)
Carex rotundata-Sphagnum lindbergii	173.7±28.2	0.58 (0.5-0.7)

*K - Coefficient of correlation (confidence level).

Analysis of Results

The measurements of the active layer thickness plots show that the smallest values of seasonal thaw depth are observed under *Rubus chamaemorus-Ledum palustre-Sphagnum-Cladina rangiferina* cover on flat peatland (Table 1). This type of peatland serves as an indicator of depths of seasonal thaw. Areas with deepest thaw are confined to large sedge-moss pools within peatlands and to bogs.

There has been marked an increase in air temperature at Nadym. Figure 1A shows the trend from 1970–2006 that amounts to 0.04°C per year. The air and soil temperature increase on the peatland is the likely cause for the appearance of tree species (*Betula tortuosa*, *Pinus sibirica*) and the rise in frequency of shrubs (*Ledum palustre, Betula nana*). For the investigated period the ground temperature on undisturbed palsa peatland has increased from -1.8 up to -0.5°C (Fig. 1B(1)). On a flat peatland the rise in ground temperature was less (Fig. 1B(2)). The active layer thickness on palsa peatland has increased by 35% for the 37-year period (Fig. 1C).

In the first years following vegetation removal in 1972 cotton grass/cloudberry groupings covering only 20% of

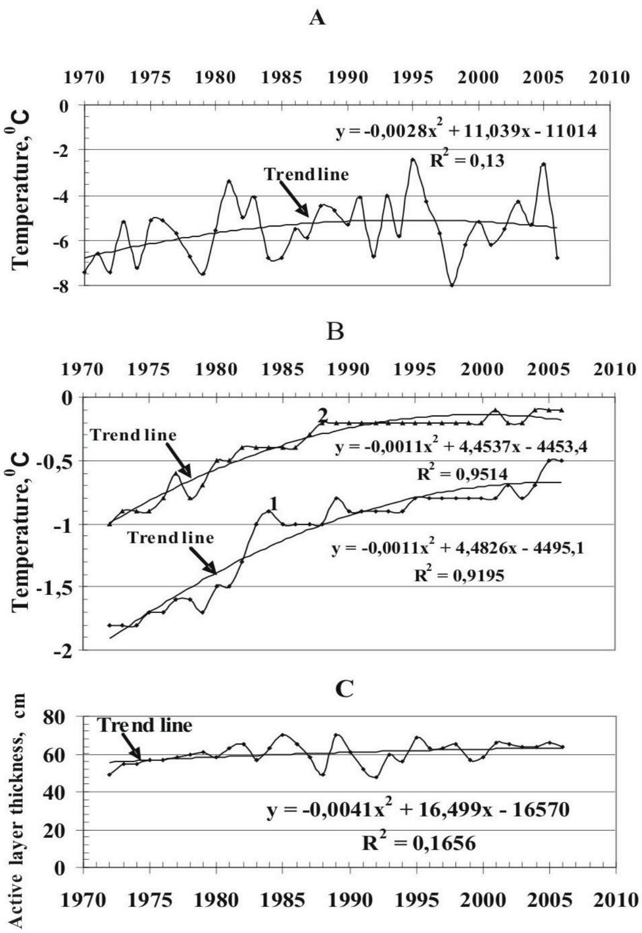

Figure 1. Mean-annual temperature (A), ground temperature at the depth 10 m (B) on palsa peatland (1) and flat peatland (2) and active layer thickness (C) on palsa peatland.

the surface had formed on the disturbed peatland plots. In four years these were replaced by cotton grass/cloudberry/*Polytrichum* groupings. The coverage of the surface by sedge and mosses in 7 years had increased up to 40%, and in 10 years up to 60%. At this time the amount of cloudberry (*Rubus chamaemorus*) had decreased, the role of cotton grass (*Eriophorum scheuchzeri, E. vaginatum*) had increased, and occasional shrubs and lichens appeared on rare moss hummocks, although the latter made no appreciable contribution to the vegetation cover. Also significant moss cover developed with *Polytrichum* species and peat mosses. In 15 years the disturbed plots had a continuous cloudberry/cotton grass/*Polytrichum*/*Sphagnum* cover. In 30 years the surface and the permafrost table had lowered with the development of thermokarst and bogs, and it was covered with cotton grass/peat moss.

The resulting fragment of cotton grass/peat moss bog continues 33 years after disturbance, although this bog community radically differs from the initial tundra (Table 2) community in appearance, structure, frequency, coverage of dominant species, and ecological condition. The undisturbed tundra has also changed; for example, the frequency of *Ledum palustre* on a natural plot has clearly increased. This is most likely in response to a rise in air temperature (Fig. 2).

The ITEX (International Tundra Experiment) program has reported similar increases of shrub forms from plot warming experiments (see Hollister et al. 2005, Walker et al. 2006).

On the disturbed plots the frequency response of *Ledum palustre* is different. First it increased in dry years, and then after 1990 it decreased in connection with the increase in precipitation and the development of bogging; but during all periods of observation its frequency is less than on undisturbed plots. The *Rubus chamaemorus* frequency on undisturbed plots shows no clear trend (Fig. 3A) compared to the increase of *Ledum palustre*. However on the disturbed plots *Rubus chamaemorus* frequency decreases and mirrors the changes seen for of *Ledum palustre.* The frequency of *Rubus chamaemorus* has decreased considerably in recent years in connection with increased precipitation and development of bogging. However in the first years after disturbance, in contrast to *Ledum palustre,* the frequency of

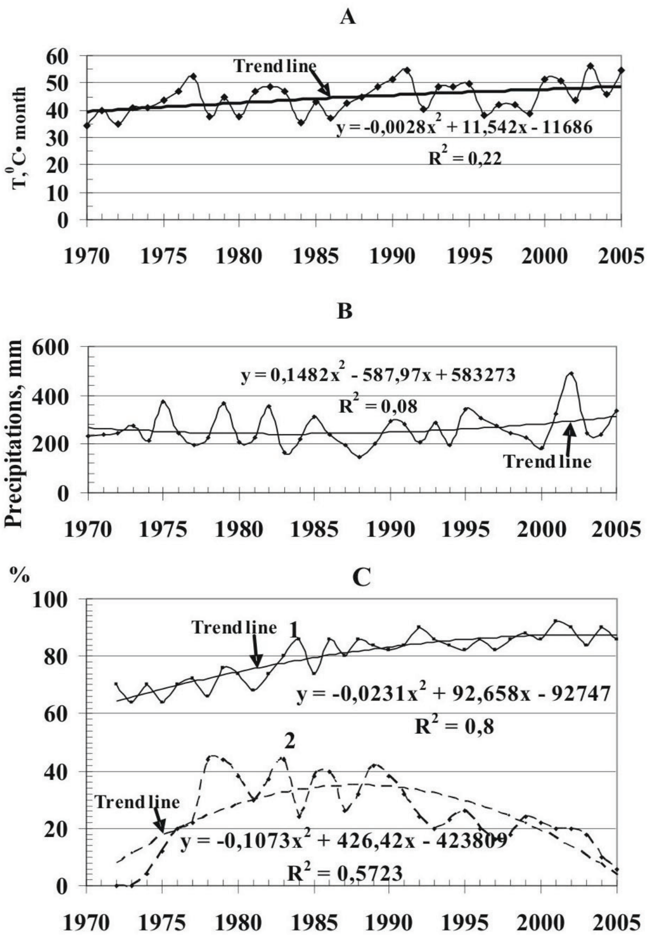

Figure 2. Thawing index of air temperature (the sum monthly mean air temperatures above 0°C) (A), summer precipitation (B) and frequency of *Ledum palustre* (C) in natural (1) and disturbed (2) conditions.

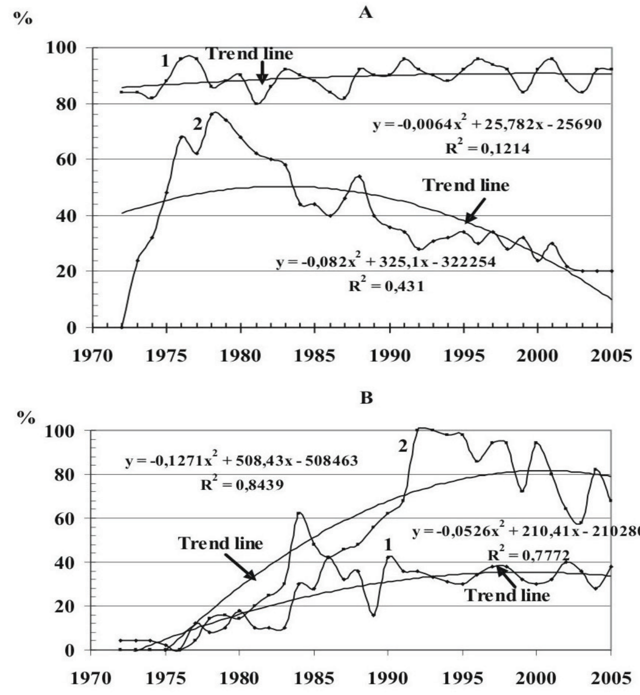

Figure 3. Frequency of *Rubus chamaemorus* (A) and *Eriophorum vaginatum* (B) in natural (1) and disturbed (2) conditions.

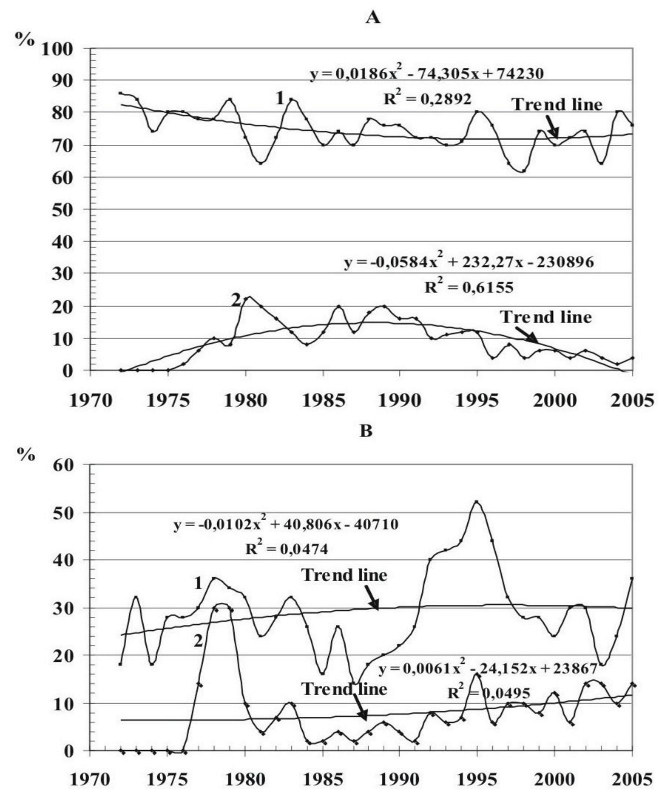

Figure 4. Frequency of *Cladina stellaris* (A) and *Sphagnum fuscum* (B) in natural (1) and disturbed (2) conditions.

Rubus chamaemorus increases while under little competition from other species, and has almost returned to its initial condition. The frequency of *Eriophorum vaginatum* in natural sites increased and this is correlated with increased precipitation. In disturbed sites the *Eriophorum* was twice that of undisturbed sites and is the result of development of wetter soil conditions and bogginess (Fig. 3B).

The frequency of *Cladina stellaris* in natural conditions has a weak negative downward trend (Fig. 4A) while on disturbed sites the negative trend is more pronounced and similar to the trend for *Ledum palustre*, namely an increase till 1990, and then, in connection with activation of increased precipitation and bogging, it began to decrease to 40 times less than in the natural condition.

The frequency of *Sphagnum fuscum,* both in natural and in the disturbed condition shows a small positive trend with the maximum on both plots falling in the same years which were warm and had adequate summer precipitation (Fig. 4B).

Thus, the fragment of cotton grass/peat moss bog, formed in 33 years after removal of *Rubus chamaemorus-Ledum palustre-Sphagnum-Cladina* plant community, differs from initial tundra community in appearance, structure, frequency, and coverage of dominant species.

These long-term records of species frequency on disturbed and undisturbed permanent plots were processed using a method of autocorrelation (Vasilevich 1970). As a result, all species were divided in three groups based on various

Table 3. Coefficients of autocorrelation between interannual values of frequency of plant species for flat peatland in natural (above a line) and disturbed (under the line) conditions, according to descriptions for 1972–2002 using "Statgraph."

Key to first column see in Table 2.

characteristics of interannual frequency changes: (1) the group with succession frequency changes (autocorrelation coefficient, K decreases with time throughout entire period of observations); (2) the group with cyclic frequency changes (K decreases and increases with certain periodicity); (3) the group with irregularly cyclic frequency changes (observed, different periodicity in changes of K values).

This analysis has shown (Table 3) that species with succession changes of frequency play a greater role in vegetation cover formed after disturbance, while participation of species with cyclic and irregular cyclic changes in frequency decreases.

In *Rubus chamaemorus-Ledum palustre-Sphagnum-Cladina* vegetation, species with cyclic behaviour form the most cover (48%). Nine species from this group are chamaephytes (low shrub-*Andromeda polifolia, Chamaedaphne calyculata, Vaccinium vitis-idaea*; lichens-*Cladina rangiferina, C. stellaris, Cladonia amaurocraea* and mosses-*Dicranum congestum, Pleurozium schreberi, Polytrichum commune*).

A smaller number of species (39% cover) have irregular cycles of frequency. This group of species contains 5 chamaephytes (3 species of lichens-*Cetraria cucullata, C. islandica, Cladonia coccifera;* 2 species of mosses-*Sphagnum fuscum, Tomenthypnum nitens)*; 2 phanerophytes (*Pinus sibirica, Betula nana*); and 2 cryptophytes *(Carex rotundata, Eriophorum scheuchzeri*). Only three species (2 chamaephytes-*Ledum palustre, Sphagnum angustifolium,* and 1 hemicryptophyte-*Eriophorum vaginatum*) show succession changes of frequency. Correlation coefficients over the sampling period permanently decrease for these species.

The frequency of these species has increased in undisturbed sites. For example, *Eriophorum vaginatum* has increased from 4% up to 42%, *Ledum palustre* from 64% up to 90%, and at *Sphagnum angustifoliu*m from 2% up to 24%. Probably the increase in frequency of these species is typical of the *Rubus chamaemorus-Ledum palustre-Sphagnum-Cladina* stage of flat peatland as it develops toward the final *Eriophorum-Ledum-Dicranum-Cladina* stage.

The analysis of developmental stages of vegetation on flat peatland following disturbance shows, as one would expect, a greater number (52%) of characteristic succession species. Of these 12 species, 8 are chamaephytes (low shrub-*Andromeda polifolia and Vaccinium vitis-idaea*; lichens-*Cladina stellaris, Cladonia coccifera* and mosses-*Polytrichum commune, Sphagnum angustifo1lium, S. lindbergii);* 3 species-hemicryptophytes (*Eriophorum vaginatum, Rubus chamaemorus* and *Oxyccocus microcarpus*) and 1 species-cryptophyte (*Eriophorum scheuchzeri*).

Species associated with mature surfaces have both cyclic and irregularly cyclic frequencies and contribute only half as much to the cover in disturbed plots compared to succession species. All species with irregularly cyclic frequency changes are chamaephytes (low shrub-*Vaccinium uliginosum;* lichens-*Cetraria islandica, Cladina rangiferina;* and mosses-*Sphagnum fuscum* and *Sphagnum lindbergii)*. *Cetraria cucullata, C. islandica,* and *Sphagnum fuscum* have the same character of frequency changes both in disturbed and natural conditions.

The group with cyclic frequency changes on disturbed sites includes chamaephytes (shrub-*Ledum palustre, Chamaedaphne calyculata*; lichen-*Cladonia amaurocraea*; moss-*Pleurozium schreberi*); and phanerophyte (*Betula nana*).

Conclusion

This research has determined the impact of climatic changes and human-induced disturbances on vegetation and permafrost conditions in West Siberia North. It has demonstrated the interactions between permafrost and vegetation and has identified plant communities that can be used as indicators of seasonal thaw depths.

The stages of vegetation recovery after the termination of human-induced disturbances were revealed at the sites with removed vegetation, located in different landscape conditions.

Changes in the frequency of plant species in undisturbed sites are correlated with the thaw index of air temperature and amount of precipitation.

During the study the appearance of tree species (*Betula tortuosa*, *Pinus sibirica*) and rise in frequency of shrubs (*Ledum palustre, Betula nana*) are related to a warming trend.

Natural plant communities are dominated by species with cyclic and irregular cyclic changes of frequency over the study period. For plant communities in disturbed and unstable conditions, considerable participation by species with succession changes of frequency is observed.

Abstract

New data about thermal properties of volcanic deposits is presented together with a short review of permafrost conditions in the study area. This data is necessary for estimation of primary permafrost characteristics (thickness, active layer depth), yet pyroclastic volcanic deposits have not been sufficiently studied. Measurements were made across a wide range of densities and humidity, in the frozen and thawed state. These deposits have a low ability to transfer heat and can act as efficient insulators. According to our results, dry (*W*=0%) cinder and ash (both frozen and unfrozen) have a similar thermal conductivity of about 0.15-0.18 $Wm^{-1}K^{-1}$. At *W*=35%, the thermal conductivity is about 1 $Wm^{-1}K^{-1}$.

Keywords: cinder; permafrost; thermal properties; volcanic ash.

Introduction

The main goal of our work was to study the thermal properties of pyroclastic volcanic deposits in the frozen and thawed states. This data is necessary for the estimation of primary geocryological characteristics (thickness, active layer depth), but pyroclastic volcanic deposits have been inadequately studied to date. Furthermore, these deposits can play an important role in permafrost aggradation during eruptions (Kellerer-Pirklbauer et al. 2007) and in the prevention of permafrost thaw beneath lava flows.

Study Area

The Klyuchevskaya volcano group (Fig. 1) is situated in the Central Kamchatka Depression (55-56°N, 160-161°E) and consists of the active volcanoes Klyuchevsky (~4800 m a.s.l.), Bezymianny (2900 m a.s.l.), Ushkovsky (3900 m a.s.l.), and Plosky Tolbachik (3100 m a.s.l.), as well as ten others that are not active today and numerous small forms like cinder cones and extrusive domes (Braitseva et al. 1995). Here, the Large Fissure Tolbachik Eruption (LFTE) took place in 1975 and 1976, during which about 500 km² were covered by scoria and ash, and three new cinder cones and lava fields were formed (Fedotov & Markhinin 1983).

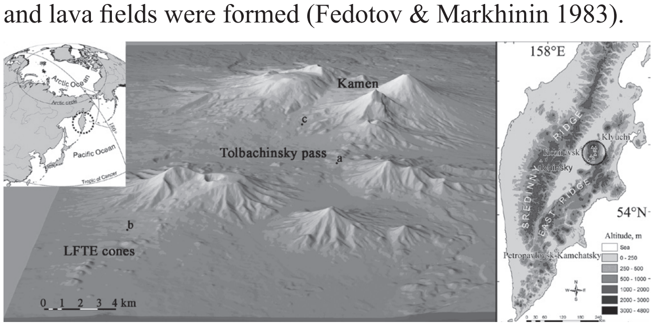

Figure 1. Study area.

Vegetation zones are largely controlled by altitude and eruptions; foliage forest occurs up to 200 m a.s.l., fir forest to 400 m a.s.l., stone birch forest to 800 m a.s.l., shrubs and elfin woods to 1200 m a.s.l., mountain tundra to 2000 m a.s.l., and isolated patches of grass and lichen are found up to 2500 m a.s.l. Around cinder cones of LFTE there are dead forest areas where vegetation has been damaged during the eruptions.

Geocryological Conditions

Permafrost and periglacial processes are widespread in the study area; permafrost covers about 2000 km². The lower boundary of permafrost in the study area is 750-900 m a.s.l. for north-facing slopes and 650-800 m a.s.l. for south facing slopes without forest vegetation, according to our data. The measured MAGTs vary from -2.8°C at 1330 m a.s.l. to -7°C at 2500 m a.s.l. Numerous solifluction lobes, clay cryoturbation spots, polygonal structures, and areas of sorted ground occur between 1000 and 1700 m a.s.l.

Glaciers occupy about 240 km² in the study area, and many of them are covered by debris and pyroclastic deposits, especially the terminus region. This can preserve ice from summer ablation. The equilibrium line altitude (ELA) is situated between 2000 and 2700 m a.s.l. The mean ice thickness is about 30-60 m for valley glaciers, and 100-250 m for glaciers in calderas. Large fields of dead ice exist near Klyuchevsky volcano (Muravyev 1999).

The thickness of the active layer decreases with altitude. Measurements of active layer depth have been conducted at several places (at elevations 800-2700 m a.s.l.) by wire probe (5 mm in diameter) or in pits. The maximal seasonal thaw depth is up to 2.5 m at 900 m a.s.l. and 50 cm at 2500 m a.s.l. Below the lower boundary of permafrost, in forested zone, the seasonal freezing is up to 2-2.5 m thick.

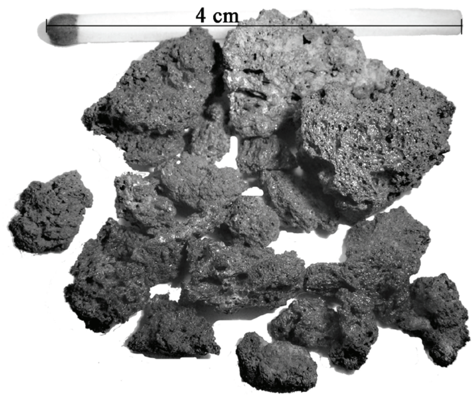

Figure 2. Volcanic cinder particles.

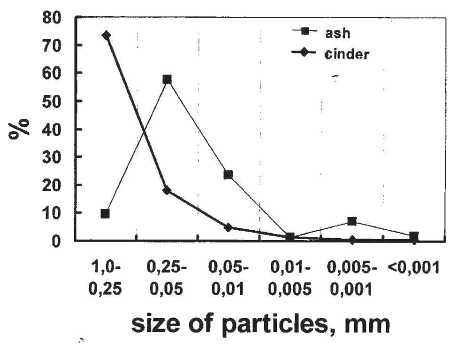

Figure 3. Granulometric composition of volcanic cinder and ash.

We studied the dynamics of the active layer on 100 m x 100 m grids in the framework of the CALM program (point a and b on Figure 1); measurements were made at the end of the warm season. The sites are situated at altitudes of 1330 m and 1630 m asl. The surface is composed of volcanic cinder with no vegetation. Active layer depth at CALM sites did not show significant changes in the last five years.

Physical Properties of Samples

Samples for this study were collected near Tolbachik and Kamen volcanoes (Fig. 1). Volcanic ashes from different sites were investigated at natural humidities (only sample 2 was studied for a range of humidities) (Table 1). Volcanic cinder (Fig. 2) was collected near LFTE cones only, and investigated at several humidities for unsorted particles (size <1 cm) and those sifted through 1 mm and 2 mm sieves. Mean granulometric composition for ash and cinder are shown on Figure 3. These deposits are ultra pure, their pH is neutral (6-8), and total organic carbon content (TOC) is very low (0%-2%). The freezing temperature of these coarse grained deposits is about 0°C.

Methods

Field data about thermal conductivity for thawed deposits was collected using a needle probe with constant power. The accuracy of the measurements is about 12%. These data are available only for volcanic ashes. Deposits at these locations have been sampled for density and humidity, and for laboratory investigations.

Table 1. Volcanic ash samples list. [a]-collected near Tolbachinsky pass, [b]-collected near LFTE cones, [c]-collected near Kamen volcano.

Sample	Depth, m	Age, years	ρ, gr/cm^3	ρ_d, gr/cm^3	Humidity W, %
1[a]	0.2	1475±50	1.50	1.07	38
2[b]	0.2	30	1.40	1.20	30
3[a]	0.55	1475±50	1.44	0.88	64
4[c]	0.15	-	1.60	1.32	21
5[a]	0.75	1475±50	1.67	1.26	33
6[c]	0.4	-	1.47	1.47	13

In the laboratory we use the I-type regular mode method (α-calorimeter) (Ershov 2004). Thermal diffusivity (a) was detected by heating and cooling the ground in an environment with constant temperature (outside of area with intensive phase changes). The temperature range was 0ºC to +20ºC and -22ºC to -12ºC. All measurements were made two times. The accuracy of measurements is about 10%.

Specific heat capacity (C) is calculated as the sum of ground components (rock matrix, water, ice). Thermal capacity was set to 4200 Jkg^{-1}K^{-1} for water and set to 2100 Jkg^{-1}K^{-1} for ice. Thermal capacities for the rock matrix were measured on an ITC-400 by monotonous heating. The accuracy of measurements is about 10% (Platunov 1972).

Thermal conductivity (λ) was calculated as: $\lambda = C\rho\, a$.

The analysis of chemical and granulometric composition, pH, and TOC (total organic carbon) were made in the laboratories of the Institute of Physicochemical and Biological Problems of Soil Science, using standard techniques.

The preparation and processing of the material for radiocarbon dating was carried out by the ^{14}C laboratory of the Department of Geography at the University of Zurich (GIUZ). The dating itself was done by AMS (accelerator mass spectrometry) with a tandem accelerator at the Institute of Particle Physics at the Swiss Federal Institute of Technology Zurich (ETH).

Results and Discussion

Results on thermal conductivity are presented in Figures 4 and 5.

Figure 4 shows data for volcanic ashes. Sample 2 was investigated at two rock matrix densities and several humidities. At ρ_d=1.2 gr/cm^3, λ increased with an increase in humidity (from 0% to 38%) from 0.17 to 0.67 Wm^{-1}K^{-1} in the thawed state and to 0.78 Wm^{-1}K^{-1} in the frozen state. At ρ_d=1.0 gr/cm^3, the increase was smaller (up to 0.53 and 0.63 Wm^{-1}K^{-1}, respectively). All other ash samples were investigated at natural humidities and densities. For dry samples, λ was set

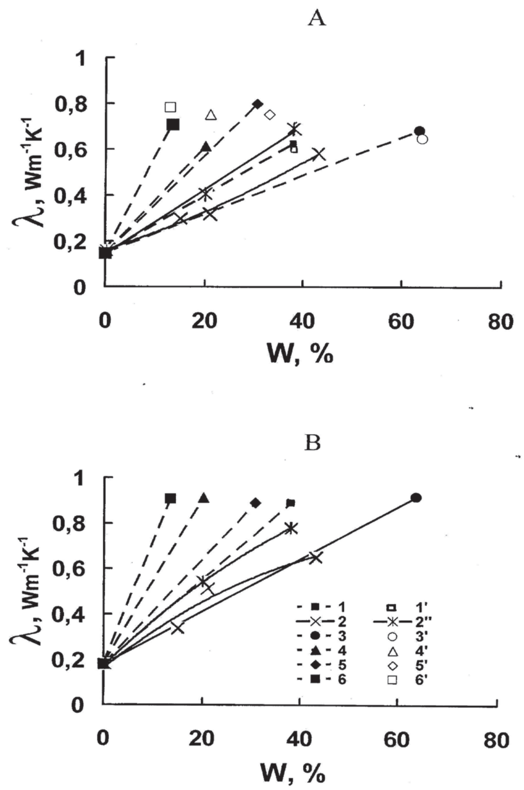

Figure 4. Correlation between thermal conductivity (λ) and humidity (W) for thawed (A) and frozen (B) volcanic ash at different densities (ρ_d): 1 – 1.1 gr/cm³, 2 – 1 gr/cm³, 2″ – 1.2 gr/cm³, 3 – 0.88 gr/cm³, 4 – 1.32 gr/cm³, 5 – 1.33 gr/cm³, 6 – 1.47 gr/cm³; 1′, 3′, 4′, 5′, 6′ – field data (ρ_d are the same).

to 0.17 Wm⁻¹K⁻¹ as in sample 2. The dotted lines on Figure 4 show the estimated correlation of λ to humidity. The lower the density, the lower the λ, but the relation is clearer with samples from one site. We believe that this is due to different age and mineral composition. Field data is presented only for thawed ash samples (1', 3', 4', 5', 6'); the divergence with laboratory data is about 12%.

According to our results, the thermal conductivity of dry (W=0%) ash and cinder (both frozen and thawed) is similar at about 0.15-0.18 Wm⁻¹K⁻¹. The dependence of λ on density and humidity is similar for volcanic cinders to that in ashes. Unsorted cinder is non-homogeneous and does not fit the method requirements, so that data for cinder sample 3 is only an estimate. This cinder is very porous, resulting in a lower λ value.

The dependence of thermal diffusivity (a) on humidity and density is similar to that for λ. For volcanic cinders with W = 0%–35%, a = 0.17 to 0.30–0.54×10⁻⁶m²s⁻¹ in the frozen state, and up to 0.21–0.33×10⁻⁶m²s⁻¹ in the thawed state. For volcanic ashes at natural humidities and densities, a = 0.20×10⁻⁶m²s⁻¹ (sample 3) – 0.36×10⁻⁶m²s⁻¹ (sample 6) for frozen material, and 0.392×10⁻⁶m²s⁻¹ – 0.580×10⁻⁶m²s⁻¹ for thawed material.

The C from the ITC-400 for volcanic cinder is 750 Jkg⁻¹K⁻¹ and for volcanic ash is 750–800 Jkg⁻¹K⁻¹. Only for ash sample 3 is it 1000 Jkg⁻¹K⁻¹.

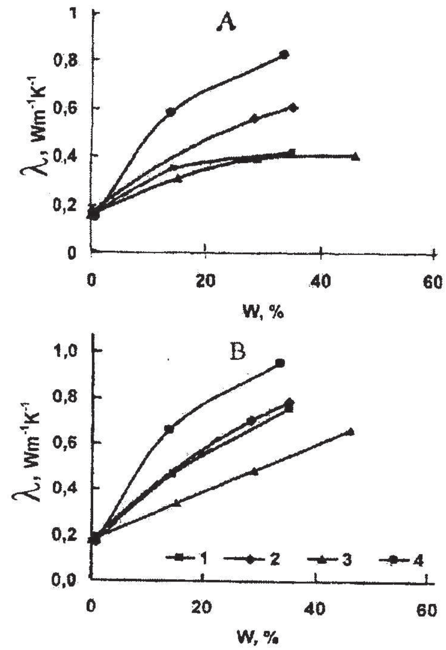

Figure 5. Correlation between thermal conductivity (λ) and humidity (W) for thawed (A) and frozen (B) volcanic cinder at different densities (ρ_d): 1 – 1.1…1.2 gr/cm³) (≤1 mm), 2 – 1.1 gr/cm³ (≤2 mm)), 3 – 0.9 – 1.0 gr/cm³ (≤1 cm), 4 – 1.3 - 1.4 gr/cm³) (<1 mm).

Conclusions

New thermal conductivity data were collected for pyroclastic deposits in both the thawed and frozen states. Results show that thermal conductivity is very low under dry conditions and increases as the humidity and density of the deposit increases. The thermal conductivity of dry cinder and ash, according to our measurements, is about 0.15-0.18 Wm⁻¹K⁻¹. The maximum thermal conductivity is about 1 Wm⁻¹K⁻¹ with an ice content 35%-40%. Field measurements for thawed ashes compare well with laboratory data.

The low heat transfer rate in these deposits can play an important role in the formation and preservation of permafrost. The formation of permafrost during eruptions is in relation to active layer thickness and thickness of deposited volcanic deposits. Pyroclastic volcanic deposits can preserve underlying permafrost layers from thawing due to its effective insulation properties and thermal offset effects. In the case of large explosive eruptions, permafrost can aggrade in surrounding terrain, especially during a winter eruption when the falling cinder has subzero temperatures and buries large quantities of snow and ice.

Abstract

Vegetation succession on different age glacial surfaces may provide clues to how tundra regions will respond to future climate and land-use changes. In the Toolik Lake region, of Alaska, three major glacial advances occurred during the middle to Late Pleistocene. Here we use a new group of maps of the upper Kuparuk River region to examine the interrelationships between glacial history, surficial geomorphology, vegetation, and spectral properties. Older surfaces in the region have greater amounts of shrub- and moss-rich vegetation and higher values of the Normalized Difference Vegetation Index (NDVI), an index of vegetation greenness. Younger surfaces have a higher proportion of disturbance-related features such as non-sorted circles and areas with warmer soils. Landscape responses to climate change are likely to be heterogeneous and may be most easily detected in areas where there are already high amounts of shrubs or areas with high disturbance regimes.

Keywords: climate change; ecosystems; GIS; glacial history; NDVI; patterned ground; vegetation.

Introduction

The Toolik Lake region is situated in close proximity to several major Late Cenozoic glacial surfaces (Hamilton 1986). In this cold region, landscape evolution proceeds more slowly than in temperate regions, so that differences in geomorphology and vegetation are evident on surfaces spanning hundreds of thousands of years. These surfaces have not been altered by agriculture or other anthropogenic influences, so the region is an excellent laboratory to examine the effects of geological processes on ecosystem function. Such studies can help us understand how arctic systems change over long periods of time and provide insights regarding how they might change in the future in response to climate change. This paper focuses on the linkage between glacial geology, surficial geomorphology, and vegetation in the upper Kuparuk River region, where the glacial history has been shown to be a defining characteristic for a wide variety of terrestrial and aquatic ecosystems characteristics (Jorgenson 1984a, Walker & Walker 1996, Oswald et al. 2003). We use mapped information that is part of a hierarchical geographic information system (HGIS), which has been assembled for the University of Alaska's Toolik Lake Field Station and an Arctic Geobotanical Atlas (Walker et al. 2008 this volume)

Glacial geology

The complex topography of the Toolik Lake region results from glacial deposits that flowed into the region during three major glacial advances. Glacial deposits within the Toolik Lake region are assigned to Sagavanirktok (middle Pleistocene), Itkillik I, and Itkillik II (Late Pleistocene) glaciations of the central Brooks Range glacial succession (Detterman et al. 1958, Porter 1964, Hamilton & Porter 1975, Hamilton 1986, Hamilton 2003) (Fig. 1a). A simplified version of Thomas Hamilton's glacial geology map of the upper Kuparuk River region (Hamilton 2003) was used for this analysis.

The Sagavanirktok glaciation consisted of several separate glacial events dating broadly from middle Quaternary time (about 780,000 to 125,000 yr B.P.). During the initial (maximum) advances, large valley glaciers flowed north along the Itkillik River, Sagavanirktok River, and Kuparuk River drainages. Most of the upper Kuparuk River watershed, including the Imnavait Creek watershed, is on drift of older Sagavanirktok-age deposits. The surfaces of the Sagavanirktok River glaciation have massive gently sloping moraines that rise about 100 m from the valley bottoms to the crests trending SSE to NNW (Hamilton 1986). These moraines are well represented in the Imnavait Creek watershed. The hills formed by these moraines are rounded by gelifluction and heavy loess cover and are topped with 20 cm to 40 cm of peat. Occasional glacial erratics protrude up to 1 m above the tundra surface.

Itkillik I glaciers abutted divides (west, east, and south of the upper Kuparuk drainage) but overflowed those divides only locally. The subsequent Itkillik II glaciers advanced between about 25 and 11.5 kya ^{14}C and formed extensive ice-stagnation features around Toolik Lake. Glacial flow patterns during the Itkillik II advance were generally similar to those of the present-day river drainages. Other features on the glacial geology map include bedrock, river deposits, lacustrine deposits, fan deposits, colluvial deposits, and shales and siltstones of the Chandler Formation (along the north boundary of the map), Toruk Formation (middle-eastern portion of the map), and Fortress Mountain Formation (north side of the Atigun River).

Surficial geomorphology

The landscapes in the Toolik Lake region have been

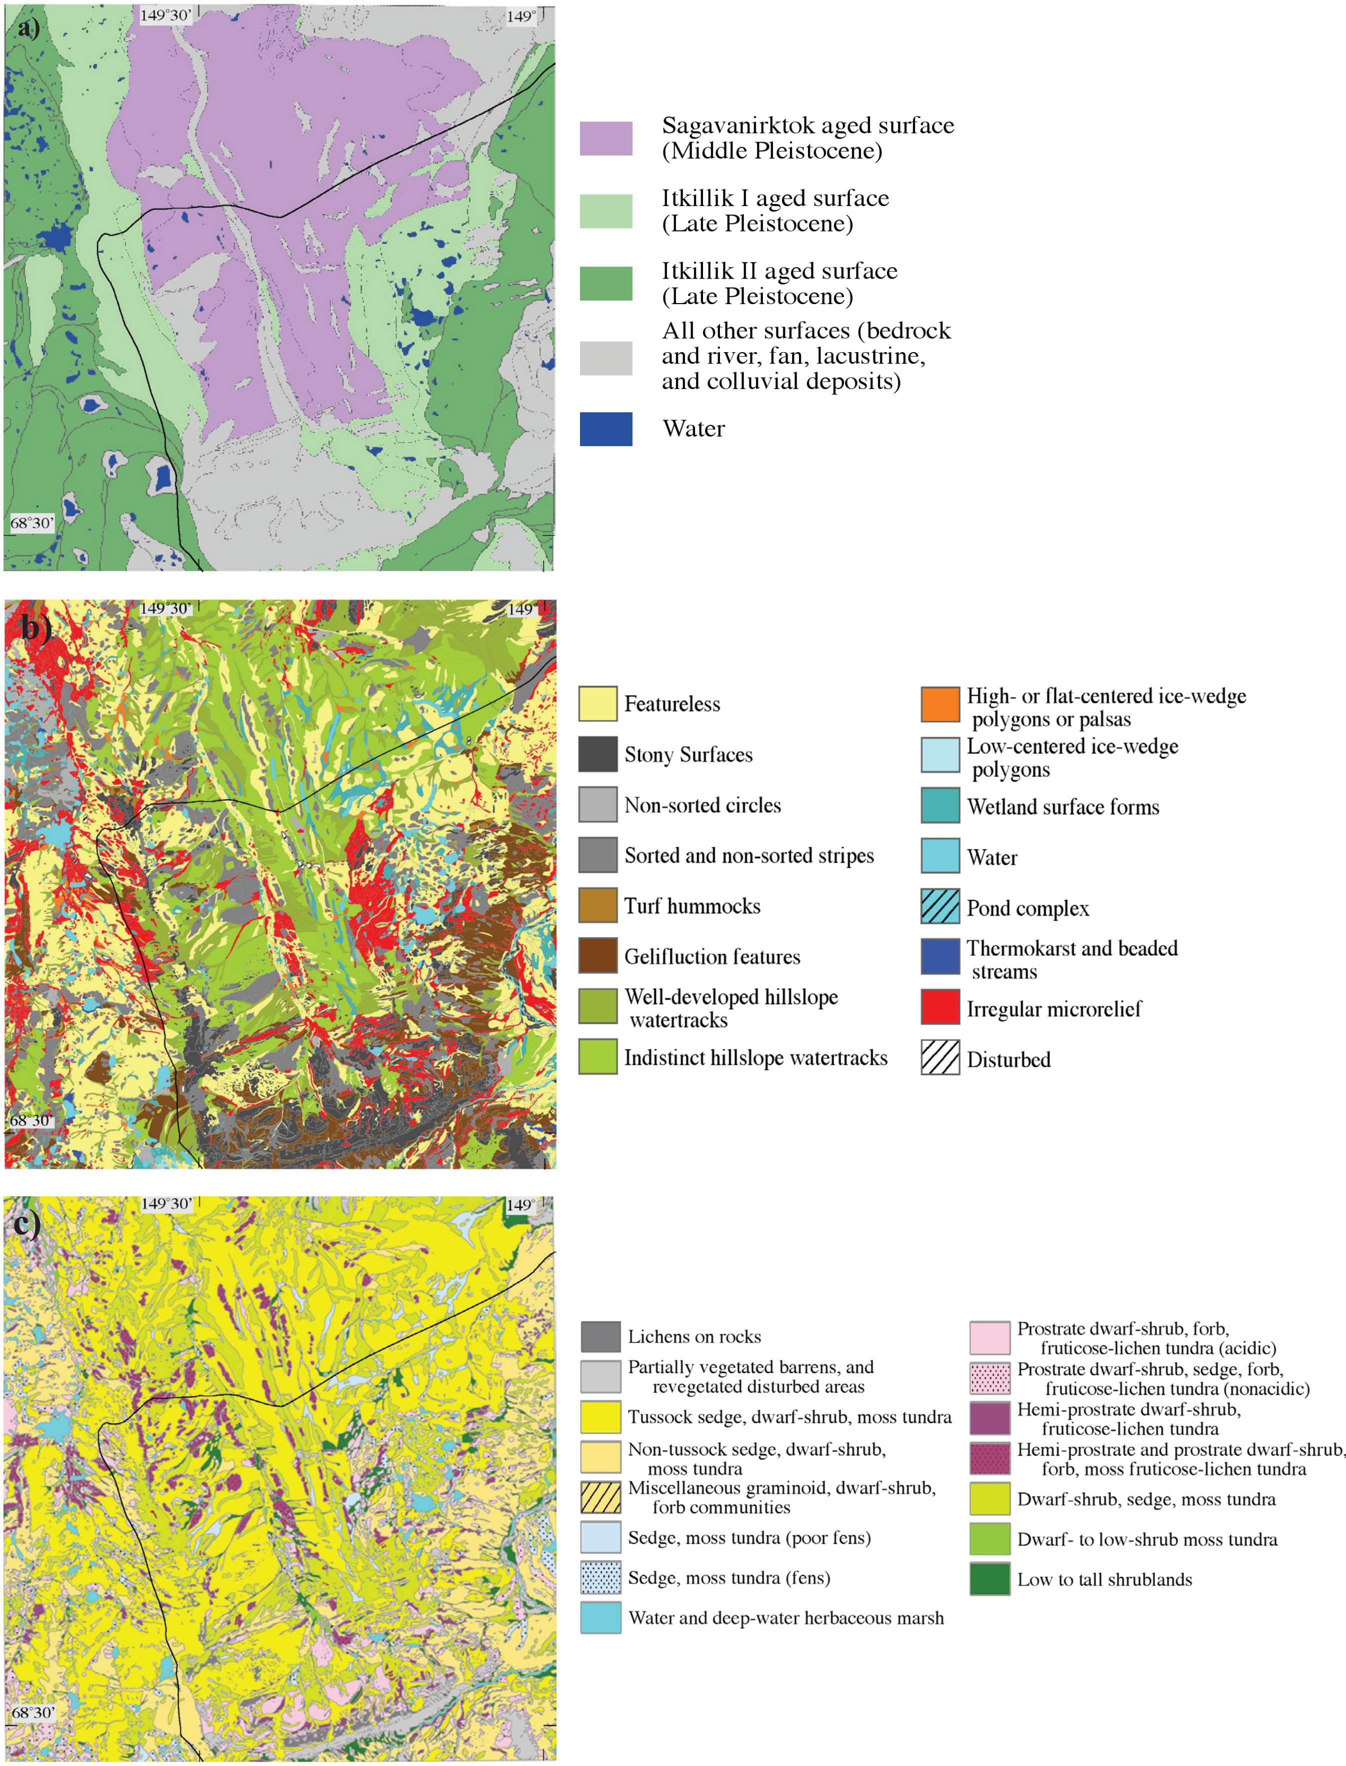

Figure 1. a) Glacial geology, b) surficial geomorphology, and c) vegetation of the Toolik Lake region.

modified by a variety of geomorphological processes including alluviation, colluviation, and periglacial processes (Fig. 1b). Common surficial geomorphological map units described for the Imnavait Creek region (Walker & Walker 1996) include sorted and nonsorted circles (frost boils), turf hummocks, gelifluction lobes and terraces, water tracks, high- and low-centered ice-wedge polygons, wetland features (strangmoor, aligned hummocks, palsas), and thermokarst features.

Vegetation

The vegetation of the region (Fig 1c) was studied and mapped as part of the Arctic Long-Term Ecological Research (LTER) project at Toolik Lake (Walker et al. 1994, Walker & Walker 1996), and the Department of Energy R4D (Response, Resistance, Resilience and Recovery of vegetation from Disturbance) project at Imnavait Creek (Walker & Walker 1996). Fifty plant communities and land-cover types were recognized during the mapping of the upper Kuparuk River region, and they are designated by numeric codes in the GIS database. These were grouped into the 14 physiognomic map units shown on Fig. 1c. (For more details on the vegetation mapping, see Walker et al. 2008)

NDVI

The Normalized Difference Vegetation Index (NDVI) is an index of vegetation greenness that can be linked to plant biomass and other biophysical properties of the vegetation (Shippert 1995). The NDVI = (NIR – R)/(NIR + R), where NIR is the spectral reflectance in the Landsat Thematic Mapper in the near-infrared channel (0.76–0.9 µm) and R is the reflectance in the red channel (0.63–0.69 µm). Four images were used in the analysis (3 Aug 1985, 8 Aug 1995, 4 Aug 1999, and 21 Jul 2001). The NDVI was calculated for each 30-m pixel in each image, and a composite average NDVI was calculated for each pixel using the mean value for the four years. To examine how plant production varies with glacial history, we examined the distribution of the Normalized Difference Vegetation Index (NDVI) on the three glacial surfaces.

Analysis of the Maps

The surficial geomorphology, vegetation, and NDVI maps were stratified according to the glacial units in Figure 1a. Results of the analysis are shown in Figures 2 and 3.

Effects of glacial history on surficial geomorphology

Terrain evolution associated with the glacial history of the region was noted by Hamilton (Hamilton & Trexler Jr. 1979). Our analysis extends Hamilton's earlier observations to surface forms that are superimposed on the larger landforms of the regions (Fig. 2). The broad hill-slope deposits of the Sagavanirktok-age surfaces are dominated by indistinct and well-developed water-track patterns (55% on Sagavanirktok surfaces, 13% on Itkillik-I, and 9% on Itkillik-II surfaces). The older Sagavanirktok surfaces also have more peaty wetlands (3% on Sagavanirktok surfaces and 2% on Itkillik-I

and Itkillik-II surfaces). Stripes and nonsorted circles are more abundant on the younger surfaces, especially the Itkillik II surfaces. Stripes cover 12% of Sagavanirktok surfaces, 13% of Itkillik-I, and 16% of Itkillik-II surfaces. Non-sorted circles cover 1% on Sagavanirktok surfaces, 1% on Itkillik-I, and 3% of Itkillik-II surfaces. Lakes are also more abundant on the younger surfaces (less than 1% on Sagavanirktok surfaces, 2% on Itkillik-I, and 5% on Itkillik-II surfaces).

Effects of glacial history on vegetation and plant production

The Sagavanirktok age surfaces have a dominance of acidic tussock tundra (61% tussock-sedge, dwarf-shrub, moss tundra cover, compared to 38% on Itkillik I, and 24% on Itkillik II surfaces) and relatively high percentages of

8. Prostrate dwarf-shrub, forb, fruticose-lichen tundra (acidic)
9. Prostrate dwarf-shrub, sedge, forb, fruticose lichen tundra (nonacidic)
10. Hemi-prostrate dwarf-shrub, fruticose-lichen tundra
11. Hemi-prostrate and prostrate dwarf-shrub, forb, moss fruticose-lichen tundra
12. Dwarf-shrub, sedge, moss tundra
13. Dwarf- to low-shrub moss tundra
14. Low to tall shrublands

Figure 3. Proportion of vegetation types on a) Sagavanirktok aged, b) Itkillik I aged, and c) Itkillik II aged glacial surfaces.

erect-dwarf shrub tundra types (21% on Sagavanirktok-age surfaces, 20% on Itkillik-I, and 13% on Itkillik-II surfaces) and poor-fen wetlands (4% on Sagavanirktok surfaces, 1% on Itkillik-I surfaces, and 0% on Itkillik-II surfaces) (Fig. 3). In contrast, the much younger Itkillik II surfaces have a dominance of nonacidic tundra (nontussock-sedge, dwarf-shrub, moss tundra, 2% on Sagavanirktok surfaces, 17% on Itkillik-I surfaces, and 39% on Itkillik-II surfaces) and are more vegetatively diverse with relatively high percentages of snowbed vegetation (hemi-prostrate-dwarf-shrub vegetation types, less than 1% on Sagavanirktok surfaces, 3% on Itkillik-I, and 5% on Itkillik-II surfaces), rich fens (0% on Sagavanirktok surfaces and 2% on Itkillik-I and Itkillik-II surfaces), and dry nonacidic tundra (prostrate dwarf shrub, sedge, forb, lichen tundra, 0% on Sagavanirktok surfaces, 1% on Itkillik-I and 3% on Itkillik-II surfaces.

Landscape age at Toolik Lake is also linked to biomass and the Normalized Difference Vegetation Index (NDVI) (Fig. 4). Older landscapes have higher NDVI and greater amounts of standing biomass (Shippert et al. 1995). The higher NDVI values of the older landscapes are due in part to relative proportions of dry, moist, and wet vegetation types on different aged surfaces. Generally, drier vegetation with lower NDVI is dominant on younger surfaces, as shown in the area analysis of vegetation on the different age glacial surfaces (Fig.3). Of greater regional significance is the difference in biomass and NDVI of vegetation growing on moist upland surfaces. The biomass of the *Sphagno-Eriophoretum vaginati* tussock tundra, which grows on the older acidic surfaces, is about 25% greater than its nonacidic counterpart *Dryado integrifoliae-Caricetum bigelowii* (512 g m^{-2} vs. 403 g m^{-2}). These types also have different key ecosystem properties, including active layer depths (Nelson et al. 1997) (Walker et al. 2003 submitted), trace gas fluxes (Oechel et al. 2000), species composition (Gough et al. 2000), abundance of frost boils (Bockheim et al. 1998), and soil carbon (Bockheim et al. 1996).

Implications with Respect to Land-Cover Change

The difference in shrub cover on the different glacial surfaces is of particular interest because of relevance to the issue of shrub expansion associated with climate warming (e.g., Sturm et al. 2001). While the older surfaces have overall greater cover of erect dwarf-shrub tundra types, as noted above, the younger surfaces have greater cover of taller riparian shrubs (4% on Sagavanirktok surfaces, 9% on Itkillik-I, and 7% on Itkillik-II surfaces). This is possibly due to the greater abundance of rocky and gravelly stream channels on the younger surfaces and steep south facing slopes with relatively warm, nutrient-rich soils.

Area analysis of the vegetation units occurring on the different age glacial surfaces shows that the older landscapes have more acidic tundra, less dry nonacidic tundra, fewer snowbeds, more dwarf-shrub tundra, much less moist nonacidic tundra, fewer rich riparian shrublands, fewer rich fens, more poor fens, and fewer lakes. Torre Jorgenson noted differences in the abundance of plant communities on the different glacial surfaces (Jorgenson 1984b), and soil heat flux was higher on the younger surfaces (Jorgenson

1984a). Others have linked Hamilton's glacial units to a hypothesis of vegetation succession, whereby peat formation (paludification) and ice aggradation on older surfaces lead to restricted drainage, a general acidification of the soils, and the introduction of *Sphagnum* mosses to wet hill slopes. Thicker moss carpets change the soil chemistry, hydrology, and soil thermal properties, resulting in peat formation and acidic mires in colluvial basins, extensive water-track development, and tussock tundra on gentle hill slopes (Jorgenson 1984a, Walker et al. 1989, Walker & Walker 1996, Mann et al. 2002).

Variation in the degree of paludification is a primary factor controlling the distribution of acidic tussock tundra, *Sphagno-Eriophoretum vaginati* and its non-acidic counterpart *Dryado integrifoliae-Caricetum bigelowii* (Walker et al. 1994). The plant association *Dryado integrifoliae-Caricetum bigelowii* is included within the "non-tussock sedge, dwarf-shrub, moss tundra" unit on the vegetation map (Fig. 1c) and occurs most abundantly on younger surfaces, often with high disturbance regimes, including Itkillik-age glacial surfaces, loess deposits, solifluction features, frost-boil complexes, and alluvial terraces; whereas well-developed tussock tundra (included in the "tussock-sedge, dwarf shrub, moss tundra" unit) forms under conditions of long-term site stability. The *Dryado integrifoliae-Caricetum bigelowii* and related associations found on younger landscapes are also floristically much more diverse than tussock tundra, and important with respect to regional biodiversity. These associations have the highest species diversity of any of the communities sampled in the region (Walker et al. 1994). Several authors have noted the affect of soil pH on tundra plant diversity (Walker 1985, Gough et al. 2000); however, the effects of landscape age on other aspects of biodiversity such as upon total regional plant community and animal diversity have not been studied in any detail.

Paleoecological studies from lakes on the Itkillik II and Sagavanirktok-age surfaces near Toolik Lake indicate that the onset of moist conditions between the early and middle Holocene triggered processes of plant succession leading up to the current conditions (Oswald et al. 2003). Soil moisture appears to have been better retained by fine-textured soils and more gently sloped landforms on the Sagavanirktok surfaces, promoting greater plant cover, thicker organic soil horizons, shallower active layers, aggradation of permafrost, and acidic soils; whereas the better-drained Itkillik surfaces continued to support relatively xeric, sparse, non-acidic vegetation.

Our study found the older Sagavanirktok-age surfaces have a greater abundance of shrubby vegetation types than the younger surfaces. These were dominated by communities with dwarf-shrubs and large areas of shrubby watertracks. We also found that the best developed (tall) shrub communities were most common on the younger Itkillik-age surfaces, suggesting that the higher disturbance regimes, warmer soils, and higher nutrient regimes in certain microsites promoted the development of well-developed shrub communities. Future changes of the regional vegetation will be in response to both

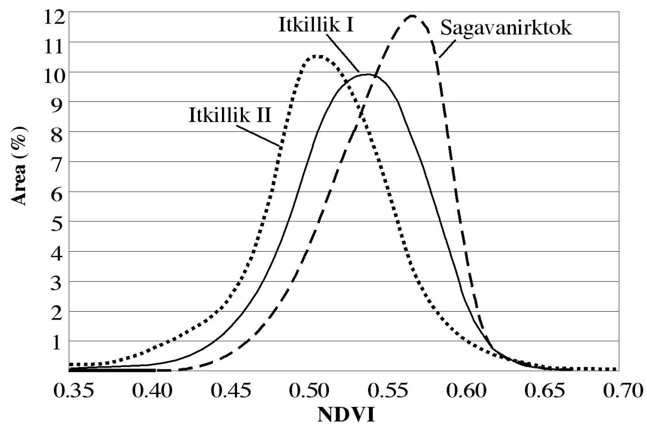

Figure 4. Distribution of NDVI on different aged glacial surfaces.

altered climate and changes in natural and anthropogenic disturbance regimes. We are currently conducting a more detailed study of the greening response of these surfaces during the period of Landsat satellite-observations (1981 to present) (Munger 2007), which will yield further insights regarding the past and future land-cover changes in these landscapes.

Choosing Geotechnical Parameters for Slope Stability Assessments in Alpine Permafrost Soils

Abstract

The shear strength of alpine permafrost soils can be expressed in terms of internal friction ϕ' and cohesion *c* utilizing a Mohr-Coulomb failure criterion as for many other soils. The challenges lie in the correct parameterization, in other words the assignment of realistic values for the chosen parameters ϕ' and *c*. Because the strength of frozen soils depends on the temperature, a correlation of the effective angle of internal friction ϕ' and cohesion *c* with temperature-dependent parameters, such as the volumetric ice content w_i, is proposed. The correlations are based on laboratory tests carried out on undisturbed samples of alpine permafrost soils. Utilizing an example calculation, this paper provides guidance in dealing with limit equilibrium slope stability analysis and assistance in selecting appropriate soil parameters.

Keywords: alpine permafrost soil; failure; limit equilibrium analysis; shear strength parameters.

Introduction

When assessing the stability of permafrost slopes, engineers are often faced with the challenge of selecting appropriate soil parameters and model. Only a limited number of laboratory test results are available from which such parameters could be extracted. Based on published data and interpretation of laboratory tests on undisturbed samples of alpine permafrost soils presented by Arenson et al. (2004) and Arenson and Springman (2005a, 2005b), reassessing the strength of those soils for the use in limit equilibrium analysis was carried out. The chosen strength model for describing the shear resistance is a Mohr-Coulomb failure criterion with a frictional and a cohesive component. The idea is based on presentations by Ting et al. (1983) and Goughnour and Andersland (1968) which suggest different mechanisms for different ice contents. The parameters to select are the effective angle of friction ϕ', representing the structural hindrance of the mass of the soil particles, and the cohesion *c,* representing the bonding effect of the ice between the soil particles. The Mohr-Coulomb criterion will be adapted to frozen soils found in warm alpine permafrost. Water in the soil pores changes phase as temperature reaches the freezing point. Four different states can therefore be distinguished (Fig. 1):

(1) In a frozen state, single soil grains may have no contact with other grains in the ice matrix. The soil fraction does not add frictional contribution to the resistance so that only the cohesive component is active. The cohesive component can be described with the variable *c*, which depends on temperature and strain rate.

(2) In a transient process with increasing temperature, the volume of the ice phase decreases allowing for soil grain contacts. This effect causes the formation of a frictional component with a simultaneous decrease of the cohesional bonding effect. No liquid water is present.

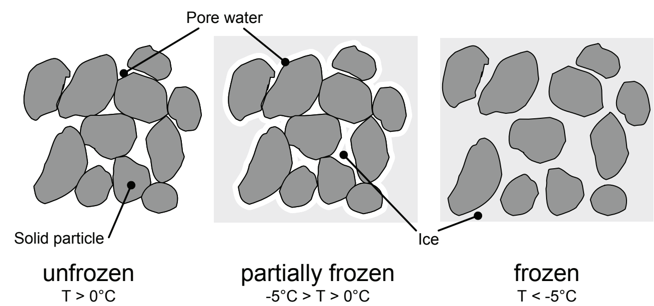

Figure 1. Different states that may be encountered in an alpine permafrost soil.

(3) In a different state, both frozen and unfrozen water are present in parallel in the voids between the particles and on the particle edges. The bonding effect of the ice present in some voids provides a cohesive component *c* to the soil strength, and at the same time the full granular friction can be mobilized.

(4) In the unfrozen state, all pore water is in the liquid phase. The soil behaves as any unfrozen soil. Taking into account the drained long-term behavior of soil, the cohesive component is set to zero; *c* = 0 kPa. Most soils in alpine environments have only little fines, and therefore the assumption of drained conditions is realistic.

The concept will be followed that the drained loading of a completely dry or fully saturated soil will lead to a state where no cohesion appears (*c* = 0 kPa). Unsaturated conditions where significant apparent cohesion can be observed will not be discussed here but are not in contradiction to the described model. It is not the aim to show a material description based on physically manifest relations but to show the potential of the approach.

Literature Review

A brief literature review was performed to complement test results of Arenson et al. (2004) and Arenson and Springman (2005a, 2005b) and to enlarge the database of known shear strength parameters of frozen soils in order to increase confidence in the proposed interpretation of the Mohr-Coulomb model. They conducted a series of triaxial compression tests on undisturbed permafrost soil samples, including controlled temperature and volumetric ice content ,together with an interpretation of the test results towards a definition of an effective angle of internal friction ϕ' and cohesion *c*. From the test series it can be observed that the effective angle of internal friction decreases with the volumetric ice content, whereas the cohesion increases (Fig. 2).

One of the key parameters for describing a warm permafrost soil in order to assess the shear strength is the unfrozen water content, hence the volumetric ice content w_i. These relationships are unique for each individual soil and control the attribution of the effective angle of internal friction ϕ' and cohesion *c*. The effective angle of internal friction ϕ' at a temperature $T > 0°C$ defines the initial conditions for the decrease.

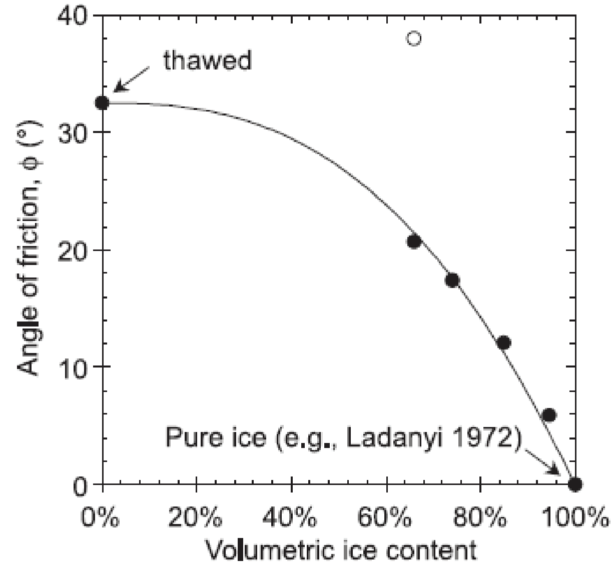
In addition, the strength of the ice is temperature dependent. Therefore it is important to quantify the effective angle of internal friction, the cohesion at a given volumetric ice content in function of the temperature or vice versa for each frozen soil individually. This can be done with temperature controlled triaxial or simple shear tests. However, due to practical difficulties, such tests are rarely carried out in practice, and only limited data are available for comparison.

As for temperature colder than about -5°C, results of unconfined compression tests on frozen soil and ice samples are presented in the literature, from which the uniaxial strength and therefore cohesion can be derived. However no information about the effective angle of internal friction ϕ' can be derived. At the given temperatures it can be assumed that all the water is frozen for all sandy and silty soils. The samples are mostly not tested at temperatures above 0°C, therefore no information about the effective angle of internal friction ϕ' is available.

Some tests on sand (e.g., Tsytovich 1975) can be interpreted to define both effective angle of internal friction and cohesion with defined temperature, whereas the volumetric ice content is not shown explicitly. The calculated cohesion *c* of the samples tested at temperatures above 0°C indicates an unsaturated state, but information about saturation is not available.

Ladanyi (1990) shows tests with a measured unfrozen angle of effective friction of ϕ' = 35°. The frozen sand samples were tested at temperatures below and equal to -5°C. At these temperatures all the pore water is basically frozen. The effective angle of friction is assumed to be negligible at this stage.

Goughnour and Andersland (1968), Sego et al. (1982), as well as Sego and Chernenko (1984) present additional values for triaxial compression strength of frozen sands at low



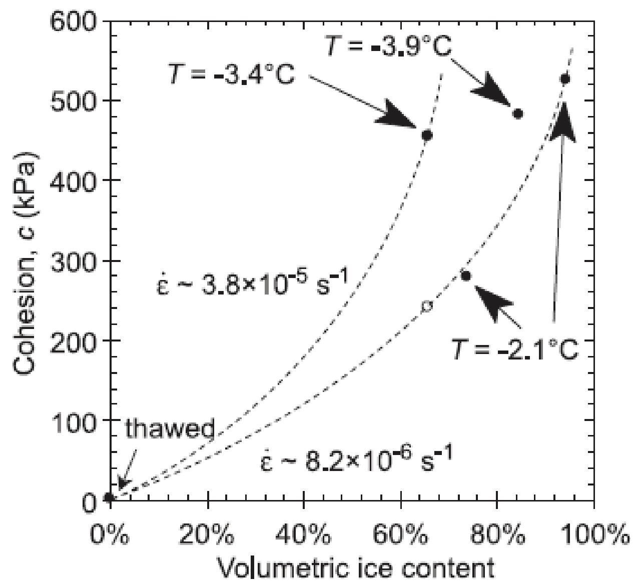


Figure 2. Effective angle of internal friction ϕ' and cohesion *c* as function of the volumetric ice content (Arenson & Springman 2005b).

temperatures. Hivon and Sego (1995), Sego and Chernenko (1984), Sego et al. (1982) and Stuckert and Mahar (1984) take into account the impact of salinity on the strength parameters of frozen soils. However, for comparison, tests were carried out on non-saline samples.

Yuanlin and Carbee (1984) have conducted unconfined compression tests with a constant strain rate and a variation of temperature on frozen silts. The effective angle of internal friction at temperatures above 0°C is not known and assumed to be in the order of ϕ'_{cv} =,32°, which is reasonable for a silty soils. No information about the volumetric ice content is provided. It was assumed that the samples are completely frozen at T = -5°C. The same is true for the results published by Stuckert and Mahar (1984).

In summary, the number of available test data from triaxial compression testing on frozen soils compared to

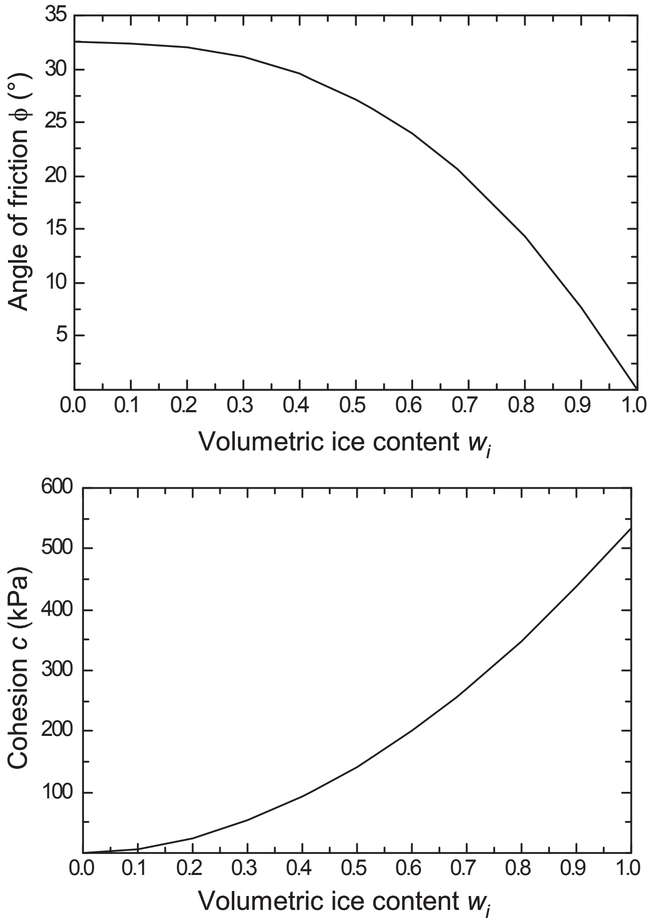

Figure 3. Effective angle of internal friction ϕ' and cohesion c as a function of the volumetric ice content w_i for $\phi'_{initial}$=32°. ϕ' and c are calculated according Equations 1 and 3, respectively.

the number of unconfined compression tests is very limited. In consequence the aim of adding test results to the data produced by Arenson (2005a) was not successful. This reduces the statistical base for the proposed interpretation of the Mohr-Coulomb failure criterion, but nevertheless the concept is worth being followed.

Model

Because of the limited test data available, the approach presented is mainly based and fitted to the data of Arenson and Springman (2005a). The test results have been reevaluated in respect of the two main components of shear strength, i.e. the effective angle of internal friction ϕ' and the cohesion c, as well as for the volumetric ice content w_i and the temperature T. With the given database it was appropriate to normalize the results for a specific temperature and then give a correlation for alternative temperatures. All the relations are curve fits with power law.

As a first input variable the effective angle of internal friction ϕ' of the dry or saturated unfrozen material is needed. For design purposes it is suggested to neglect the dilatancy effects (ψ=0). Unfortunately it is not explicitly stated if a critical, constant volume angle of internal friction, ϕ'_{cv}, or a peak value, ϕ'_{peak}, is presented for most publications where an unfrozen effective angle of internal friction is available.

With increasing volumetric ice content the effective angle of internal friction ϕ' decreases from ϕ'= $\phi'_{initial}$ to ϕ'=0. Arenson and Springman (2005b) suggest the following relationship:

$$\phi' = \phi'_{initial} - \phi'_{initial} \bullet w_i^{2.6} \tag{1}$$

with

ϕ' (°)	effective angle of internal friction,
$\phi'_{initial}$ (°)	initial effective angle of internal friction,
w_i (-)	volumetric ice content.

It is important to note that the angle of internal friction is unaffected by the temperature.

The second input variable is the cohesion c (here not defined as effective or total cohesion). In contrast to the effective angle of internal friction ϕ', the value of cohesion rises with the volumetric ice content w_i. The cohesive strength of the ice matrix is dependent on the temperature represented by two steps of calculation. Firstly the cohesive strength will be calculated for a reference temperature (e.g. -2.1°C) to relate the calculated values to Arenson and Springman (2005b). Secondly cohesion is adapted to any given temperature with a linear correlation. The formulas are given with:

$$c_{(T=-2.1°C)} = 534.93kPa \bullet w_i^{1.91} \tag{2}$$

$$c = -\frac{c_{(T=-2.1°C)}}{2.1} \bullet T \tag{3}$$

with

c (T = -2.1°C) (kPa)	cohesion at reference temperature,
c (kPa)	cohesion,
T (°C)	temperature.

Using these two formulae (Fig. 3) it is possible to set individual strength profiles to a soil stratum for any given temperature profile according to the initial effective angle of internal friction ϕ' and the volumetric ice content w_i of the material. It is now obvious that with the variation of the soil temperature profile provoked by seasonal change of the surface temperature, a redistribution of the strength parameters occurs with time. With higher soil temperatures the frictional component of the shear strength gains importance and vice versa.

The correlations were counterchecked with the few test results described in the literature review section. Effects of the variation of the strain rate are not discussed within this contribution. The significance of the strain rate rises with the volumetric ice content of the sample, whereas the aim of the parameterization is the description of the behavior of temperate alpine permafrost soils; that is, close to zero centigrade. Where not explicitly described, the volumetric ice content w_i was calculated using a power law function neglecting exact knowledge of the soil composition and volumetric water content. The function was chosen as

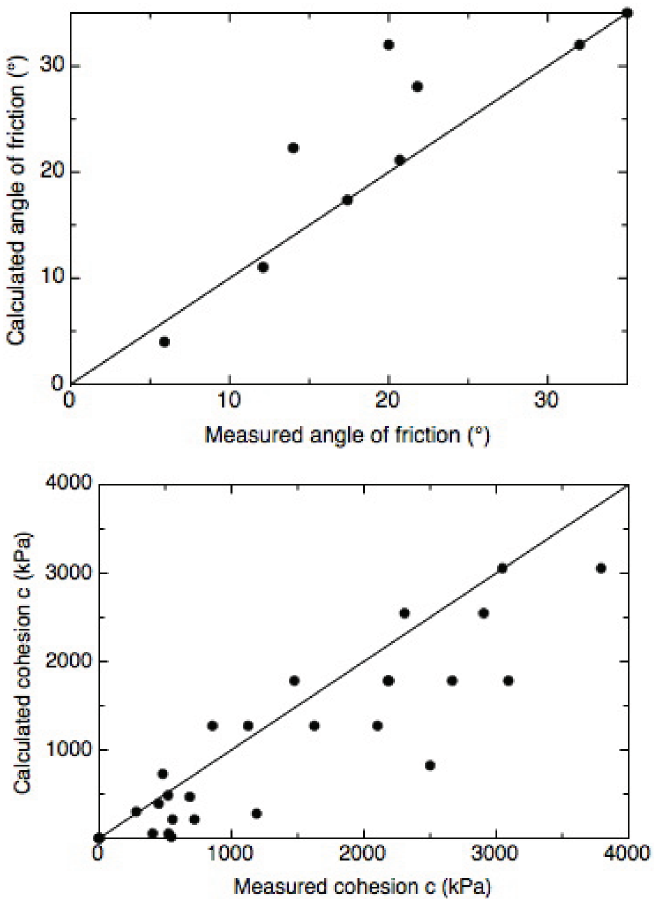

Figure 4. Calculated versus measured angle of friction ϕ' and calculated versus measured values for cohesion *c*.

$$w_i = \left(-\frac{1}{5} \bullet T\right)^{\frac{1}{2}} \quad (4)$$

Equation 4 is based on test results available and has similar form to the unfrozen water content function suggested by Tice et al. (1976). It further inherits the assumption that all soils are completely frozen at T = -5°C. This seems low but includes the variability in the permafrost soil composition even concerning certain clay size particle contents. Such an assumption is on the conservative side.

Figure 4 shows the measured against the calculated values obtained with the proposed strength model. In these figures all the evaluated data is shown, even though some of the tests were conducted at temperatures below to T = -5°C. The inserted diagonal line represents the ideal case of *calculated=measured* values.

The linear correlation with an inclination of 1.1, instead of the drawn ideal line of 1.0 (R^2=0.77) for the effective angle of internal friction ϕ' (Fig. 4), indicates an overestimation of the calculated values, whereas an inclination of 0.8 (R^2=0.80) stands for a more conservative prediction for the cohesion. Some of the scatter can be explained with the variation of the strain rates that have not been considered in the analysis presented.

Table 1 shows the evaluated data for the tests and calculations on material with a temperature T above -5°C.

Example Application

To get a brief overview on the impact of a temperature dependent parameterization of an alpine permafrost soil, a profile from the Muragl rock glacier in Switzerland was chosen for a limit equilibrium analysis using the numerical program Slope/W (GeoStudio2004). Even though rock glacier materials represent special and unique conditions, the concept can be applied to any other frozen soil, assuming soil properties are available. Details and an overview of the Muragl rock glacier can be found in Arenson (2002). The modeled slope has a length of approximately 500 m and a height of approximately 235 m, which results in an overall inclination of about 25°. Bedrock can be found at an average depth of 33 m.

Two measured temperature profiles were applied on the section with a temperature resolution of ΔT = 1.0°C and a geometrical resolution of Δy = 0.5 m. The profiles represent typical conditions with the first temperature profile representing the summer maximum surface air temperature of 12.2°C and the second, the winter minimum surface air temperature of -6.0°C from a one year measurement cycle (Fig. 5). The two states do not implicitly represent coldest or warmest conditions for the interpretation of a global safety factor.

The geotechnical parameters have been set on the basis described above with a resolution according to the temperature profile. The initial effective angle of internal friction was set to ϕ' = 33°, and bedrock was assumed to be impenetrable by a failure mechanism. The limit equilibrium approach follows the Morgenstern-Price method. Neither water flow nor possible unsaturated strength in the unfrozen active layer has been accounted for during the analysis.

19.6	-0.1	-0.1

Table 3 shows the parameters for each temperature layer. The correlations follow the rules presented above.

Figures 6 and 7 show the results of the limit equilibrium calculations on the Muragl rock glacier cross sections.

The global factor of safety varies between 1.22 and 1.48 from summer to winter, which is a change of 21%. The calculated critical mechanisms show significant differences in size and depth. This is due to the difference in the contribution of friction and cohesion to the global shear resistance. An increase in the frictional component of the shear resistance causes the failure mechanism to shift towards the surface, whereas an increase in cohesion results in a deeper lying failure surface.

These preliminary analyses show minimum safety factors relatively close to a critical value of 1. However, such a result is expected for slopes that form under natural conditions. Nevertheless, the results allow for the possibility of large deformations. It is interesting to note that the failure planes for the winter conditions (Fig. 7) are located approximately at similar depths than the shear zone observed in the active Muragl rock glacier (Arenson et al. 2002). These deformations may therefore be interpreted as the main deformation mechanism observed in active rock glaciers

referred to as creep. Creep is not considered directly during the stability analysis presented. The parameters included in the analysis were chosen as large strain parameters, i.e. large creep deformations are included to a certain extent.

Conclusions

Engineers often struggle with assessing slope stability for temperate frozen slopes. By selecting the appropriate shear strength parameters it is possible to give realistic temperature dependent assessment of the stability of alpine permafrost slopes. A simple approach is presented to incorporate seasonal temperature changes, allowing calculation of slope stabilities in an environment of temperature increase due to global warming. In such a case the model proposes an increasing contribution of the friction component and a decreasing amount of cohesion in the mobilization of shear strength. This leads towards shallower failure surfaces with a lower probability of failure, due to the fact that the angle of effective friction is far less subjected to variability than the cohesive portion of the general shear resistance. In a transient process alpine permafrost slopes with inclinations higher than the sum of the effective angle of friction ϕ'_{cv} and the angle of dilatancy ψ will be subjected to local failures due to the decrease of the bonding effect of the ice matrix. After reaching a new long-term equilibrium the former alpine permafrost slopes will reach a state as observed for the majority of natural slopes with an inclination at about the effective angle of friction.

The major problem with using the presented approach for warm frozen slopes is the lack of test data. Even though results from triaxial compression are standard in geotechnical engineering, only a few data are available for temperate coarse-grained permafrost soils. In addition, it is recommended that interaction between thermal modeling and slope stability calculations utilizing temperature dependent strength parameters should be employed in slope stability analysis. As such numerical tools become available it is still crucial to carry out proper geotechnical laboratory tests for an accurate soil characterization.

Abstract

Barrow, Alaska, has a long heritage of permafrost research. The area's initial permafrost temperature measurements were made during the First International Polar Year (1882-83). In the mid 1940s, the U.S. Geological Survey initiated a program of geothermal measurements. In the early 1960s the U.S. Army's Cold Regions Research and Engineering Laboratory established a series of plots for active layer measurements. In the 1990s, National Science Foundation projects expanded the active layer measurement program as part of the emerging Circumpolar Active Layer Monitoring network. A program of borehole temperature measurements was initiated in 2000, when two deep boreholes were drilled and equipped with thermistor cables and data loggers. These sites, located within and adjacent to the Barrow Environmental Observatory, and several other long-term projects on erosion and plant phenology, contribute to this permanent, protected permafrost observatory. Long-term permafrost monitoring programs at Barrow have contributed substantially to development of geocryological theory.

Keywords: active layer; Alaska; Barrow; borehole monitoring; permafrost; thermal regime.

Introduction

The Barrow, Alaska, area has a long history of permafrost observation and research. The initial permafrost temperature observations at Barrow were made during the First International Polar Year (1882–83) in a meat cellar with an average February temperature of -11°C at a depth of 11 m. Beginning in the mid 1940s and continuing into the 1950s, the U.S. Geological Survey (USGS) conducted a wide range of permafrost investigations, including geothermal measurements in many boreholes and shallow measurements in association with construction and exploration activities (Brewer 1958, Lachenbruch & Marshall 1986). In the early 1960s the U.S. Army's Cold Regions Research and Engineering Laboratory (CRREL) established twenty 10×10 m grids on which active layer measurements were made seasonally throughout most of that decade (Brown & Johnson 1965, Brown 1969). Many of these investigations were made in cooperation with, or supported by, the former Naval Arctic Research Laboratory (NARL) in Barrow. Beginning in the early 1990s, a series of National Science Foundation (NSF) projects expanded the active layer measurement program to a 1×1 km grid under what was to become a site within the Circumpolar Active Layer Monitoring (CALM) network. Active layer measurements have been made annually on the CRREL and CALM grids since 1992 (Brown et al. 2000). A program of borehole temperature measurements on the same USGS boreholes was initiated in 2000 and in April 2001. Under this program, two new 50 m deep boreholes were drilled and equipped with thermistor cables, a micrometeorological station, and data loggers (Yoshikawa et al. 2004).

The CALM grids and the deep permafrost observatory boreholes are located within the Barrow Environmental Observatory (BEO), 7500 acres of privately owned land that has been designated for research and long-term observations by the Ukpeagvik Iñupiat Corporation (UIC) landowners and the regional North Slope Borough government (Fig. 1). Several other long-term observational projects are located within the BEO, including the Arctic Coastal Dynamics key sites along Elson Lagoon (Aquirre et al. 2008), and the International Tundra Experiment located within the CALM grid (Hollister et al. 2006, 2008).

The initiatives mentioned above are approved projects of the present International Polar Year (2007–2009). The International Permafrost Association's legacy for the IPY is to establish a permanent network of permafrost observatories on protected lands. The Barrow permafrost observatory is an excellent example of a long-term monitoring site. It is also part of the Global Terrestrial Network for Permafrost (GTN-P) (Brown et al. 2000). As a follow-up to the First International Polar Year measurements, temperatures are being monitored with miniature data loggers in several active meat cellars in the Barrow communities.

Earlier papers by the present authors have reported on previous results for these active layer and permafrost temperature sites (Nelson et al. 1998, Romanovsky et al.

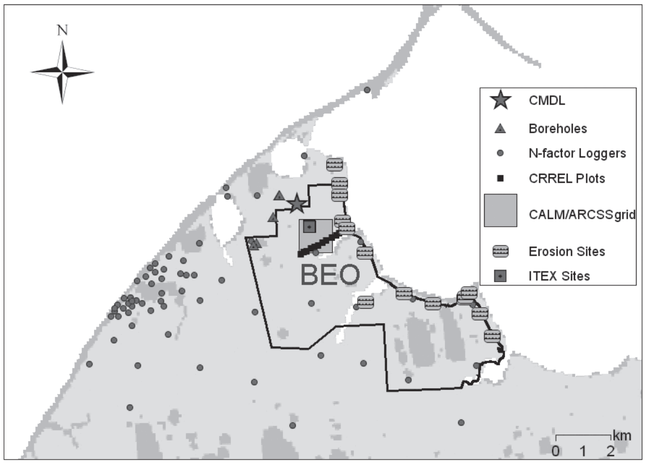

Figure 1. Map of the Barrow Environmental Observatory, showing main research sites mentioned in the text.

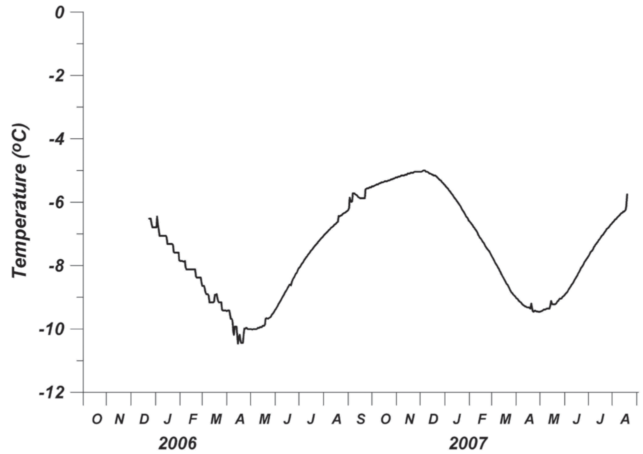

Figure 2. Temperature (hourly readings) in the meat cellar of a Barrow resident (Richard Glenn), from late 2005 through summer 2007. Instrumentation was changed in March 2006.

2002, Hinkel & Nelson 2003, Yoshikawa et al. 2004). This paper updates the earlier results from continuing projects, adds to their interpretations, and documents the existence of this permafrost observatory. A complete history of permafrost research at Barrow remains to be written.

Local Environment

Barrow, Alaska (71.3°N, 156.5°W, population 4600) is situated at the confluence of the Beaufort and Chuckchi Seas. Although Barrow's climate is influenced by its proximity to the Arctic Ocean, mean annual temperature in the village is -12°C, and the annual range of mean monthly temperature is about 31°C. Precipitation averages 106 mm yr^{-1}, with about 63% falling as rain during the brief summer. Topography is dominantly level, the area's primary relief being produced by the juxtaposition of drained thaw lakes and intervening "upland" tundra (Hinkel et al. 2005). Soils, developed on the unconsolidated Gubik Formation of Late Pleistocene age (Black 1964), show considerable variation (Bockheim et al. 2001). Permafrost underlies the entire area and reaches depths of more than 400 m. The upper permafrost contains abundant excess ice, with combined pore and lens ice averaging 50-75% in the upper 2 m (Sellmann et al. 1975). Ice-wedge networks are ubiquitous in the Barrow area.

Data Collection

The Circumpolar Active Layer Monitoring (CALM) program has operated in Barrow since 1991. Initially developed under the auspices of the International Tundra Experiment (ITEX), CALM acquired its own funding base from the U.S. National Science Foundation in 1998. The CALM protocol is well documented in published papers and on the CALM web site (Brown et al. 2000, Nelson et al. 2004a, 2004b; <http://www.udel.edu/ Geography/calm/>). At Barrow, thaw depth is measured at each of the 121 grid nodes on the CALM/ARCSS 1 km^2 grid; nodes are spaced 100 m apart. Using a graduated steel probe, thaw depth measurements are typically made in mid-August, when the active layer is at its maximum thickness. Active-layer thickness data continue to be collected annually on the 10×10 m "CRREL Plots" established in the early 1960s (Brown & Johnson 1965, Brown 1969).

Soil temperatures have been monitored hourly since 1993 at two sites near the CRREL study area. Measurements are recorded to depths of 1.2 m using Campbell data loggers reading Measurement Research Corporation (MRC) thermistor probes, and yield data comparable to those obtained during CRREL's programs at Barrow in the early 1960s. Several other shallow (0.0 to 1.2 m) ground temperature installations are maintained in cooperation with the U.S. Department of Agriculture's Natural Resources Conservation Service and the National Oceanic and Atmospheric Administration.

High-precision frost heave and thaw settlement measurements are made on the BEO using differential global positioning system (DGPS) technology (Little et al. 2003). Several of the former CRREL sites are monitored via DGPS, as is a series of nearby geomorphic forms, primarily frost boils. These observations continue a series of measurements first implemented at Barrow in the early 1960s (Lewellen 1972).

As part of the International Polar Year 2007–2008 initiative, the program of thermal measurements in Barrow meat cellars, first instituted in 1882-83 (Ray 1885), has been resumed. Data are recorded in the meat cellars of several Barrow residents at 1 hr intervals, using miniature two-channel data loggers (Fig. 2). Peak annual temperature lags several months after its July peak in the Barrow air-temperature record. Temperature is recorded at a depth of approximately 7 m in the cellar.

Snow surveys are conducted each spring by measuring snow depth at the 121 grid nodes on the 1 km^2 CALM/ ARCSS grid. Typically, two measurements are made at each grid node using a graduated steel probe. Snow depth measurements are made in April or May.

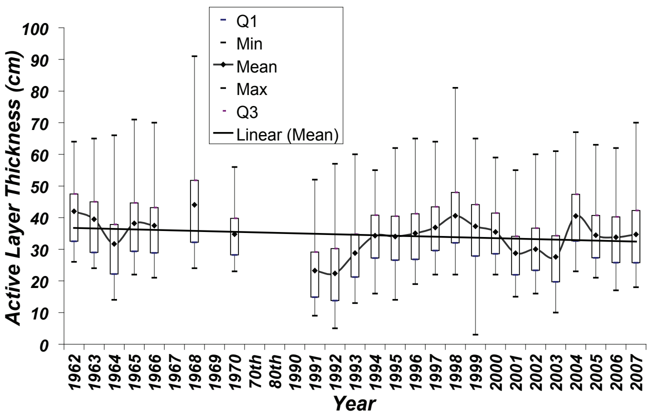

Figure 3. Box plots (Tukey 1977) of active-layer thickness on the CRREL plots at Barrow for the period 1962–2007. Maximum, minimum, and mean values are indicated, as are quartile (Q) locations and a linear fit to annual mean values.

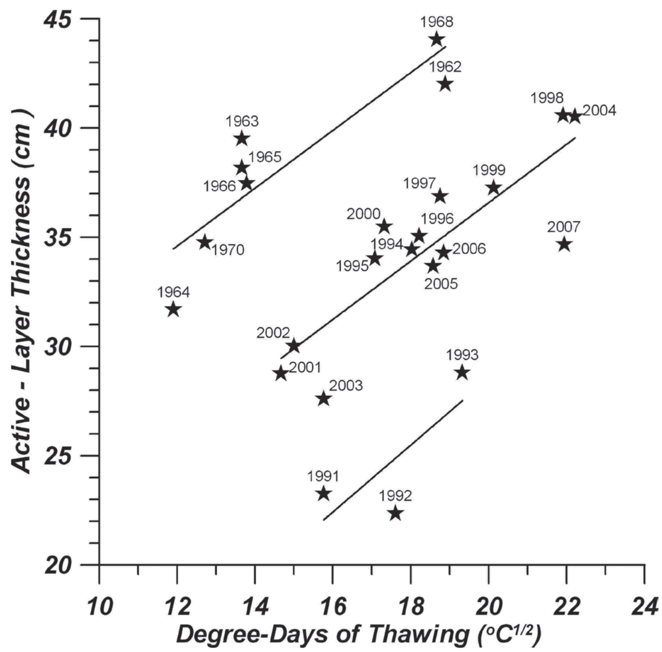

Figure 4. Active-layer thickness vs. thawing index at Barrow, Alaska, 1962–2007.

Four boreholes are being monitored under the Thermal State of Permafrost (TSP) program (Romanovsky et al. 2002), using Campbell data loggers. Two boreholes are the original USGS holes (Lachenbruch & Marshall 1986), with new cables and the two new ones were drilled in 2001. New thermistor cables were installed in several of the 1950s USGS boreholes to depths of 9, 14, and 24 m.

Long-term air-temperature measurements began at the National Weather Service site in Barrow in 1922, and data from this ongoing program are available through the archives of the U. S. National Climate Data Center (<http://www.ncdc.noaa.gov/oa/ncdc.html>). A geographic-ally extensive data set was also collected at hourly intervals between 2001 and 2005 within a 150 km^2 area surrounding Barrow, including sites within the BEO, using a network of approximately 70 data loggers recording air and near-surface soil temperature, as part of the Barrow Urban Heat Island Study (Hinkel et al. 2003; Hinkel & Nelson 2007).

Data from NSF-supported sites are reported annually to the University Consortium for Atmospheric Research, and are ultimately deposited in the National Snow and Ice Data Center's Frozen Ground Data Center (<http://nsidc.org/fgdc/>). Data sets are made available periodically on CDs issued by the Global Geocryological Data system (Parsons et al. 2008). CALM data are also available through the CALM program's web site at the University of Delaware.

Results

Active layer

For the last decade (1998–2007), CALM active-layer thickness (ALT) data, averaged over the grid, have remained close to the range of values from the 1960s (Fig. 3). ALT values in the early 1990s were substantially less than in the 1960s and early 2000s. Maximum values were recorded in 1998 and 2004 (42 cm); these values coincide with the warmest summers. The 2003 minimum (29 cm) was similar to 1993 but deeper than the shallowest thaws of 1991 and 1993 (24 cm).

Based on statistical analysis of ALT values from the Barrow CRREL plots, Nelson et al. (1998) argued that the active layer in ice-rich terrain displays "Markovian behavior," i.e., it tends to remain within a tightly constrained range of depths until a climatic, anthropogenic, or other perturbation causes it to shift to a new datum, where it remains until another perturbation causes it to become "set" at another new level (Fig. 4).

Average active-layer thickness from the Barrow CRREL plots is plotted against the square root of the thawing index (annual thawing degree days) for all years of record in Figure 4. The additional data collected over the past decade appear to confirm the hypothesis advanced by Nelson et al. (1998). Three distinct curves have emerged, each consisting of a series of sequential years.

Nelson et al. (1998) advanced a series of hypotheses to explain the apparently sudden changes in ALT, concluding that they most likely result from penetration of thaw into the ice-rich layer in the upper permafrost. Subsequently, Shur et al. (2005) provided a theoretical explanation for such behavior, involving the "transient layer," an intermediate layer of ground that cycles between permafrost and non-permafrost status at decadal to millennial time scales. Bockheim & Hinkel (2005) found abundant cryostratigraphic evidence for fluctuations in the transient layer ("transition zone") in the Barrow area.

Thaw settlement

The transient layer concept advanced by Shur et al. (2005) also helps to explain why data from mechanical probing of the active layer may not show long-term correspondence with climatic warming. Penetration of thaw into or through the transient layer can result in pronounced differential settlement at the surface. Besides jeopardizing structures at the surface, this phenomenon may obscure the record of climate-induced changes in ice-rich permafrost environments (Streletskiy et al. 2008).

The Barrow site was used to evaluate long-term trends in terrain first surveyed in the early 1960s (Lewellen 1972). DGPS and ALT measurements were performed in June and August of every year for the period 2001–2006. All sites were equipped with temperature loggers measuring air and ground surface temperature at hourly intervals. Winter heave (Hw) was assumed as the difference in elevation of the ground surface between June of a specified year and August of the previous year. Summer subsidence (Hs) was estimated as the difference in ground surface elevation between August and June of the same year.

On average, winter heave did not compensate for summer ground subsidence at most of the North Slope landscapes investigated during the 2001–2006 observation period (Streletskiy et al. 2008). Comparison of our data at Barrow with the historical record there (Lewellen 1972) shows that significant changes in the elevation of the ground surface have occurred over the past four decades. The survey of 1964 was made in July, while our measurements were made in June and August. Comparison of elevation data from August of 2006 with those from July of 1964 shows that total elevation change (Ht) for three sites is -21.4 to -23.6 cm, while one site shows Ht = 30.6 cm. This produces an average value of -8.9 cm in 42 years, or -0.2 cm/year. Comparison of the July 1964 data with those from June of 2006 yields an average for the four sites of -6.2 cm or -0.15 cm/year. Average Hs over the last four years at the four sites is -2.2 cm, while Hw is 1.4 cm, The average elevation change at the four sites between June of 2006 and June 2003 is 1.1 cm, while the difference between August elevations for the same period is -7 cm. Long term subsidence and frost heave almost compensate for each other, while over the short term the amplitude of both Hs and Hw varied greatly. Long-term ground elevation change is less than that over the short term. The amplitude of surface elevation changes may, however, have increased during the last 40 years.

Interpolation/validation procedures

Owing to logistical constraints, "end-of-season" active-layer thickness is measured on a different date virtually every year. Variations in year-to-year weather dictate that the active layer may not have reached its maximum extent in late August in some years, while in other years upfreezing from the base of the active layer may have begun by this time. In both situations an underestimate of maximum ALT is obtained. Figure 5 shows results from a form of interpolation, used to describe the dynamics of thaw penetration at Barrow by comparing data derived from two techniques for measuring ALT: direct measurements using a metal probe at the CRREL plots and those interpolated from MRC temperature probes. Only summers in which ALT was measured more than three times were used (1963, 1964, 1966, 1994, and 2004). The polynomial fit is based on 42 sets of measurements from

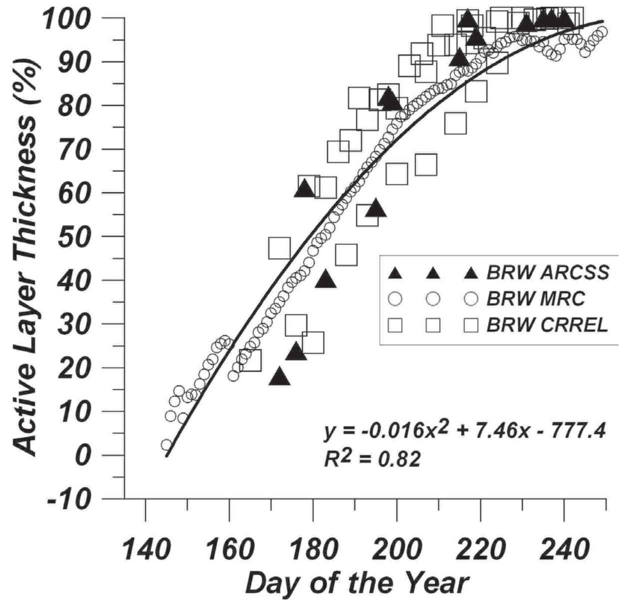

Figure 5. Active-layer depth measurements from the CALM grid, CRREL plots, and nearby Campbell/MRC installation. Statistical relation in the figure were obtained by fitting a polynomial to the probed data. The solid line was produced by fitting a polynomial equation to the MRC data, yielding an R^2 value of 0.96.

these years, where maximum thaw depth was assumed to have been reached. An independent data set, measured at the neighboring 1 km^2 CALM grid (BRW ARCSS), was included (years 1995, 1996, 2001, and 2006); these were also believed to show maximum thaw. Finally, daily interpolated values of ALT from the MRC probes for 1993-2001 period (BRW MRC) were plotted. Despite differences in measurement techniques, sampling design and date of observation, the points fall very close to the fit produced from the Barrow CRREL plots (BRW CRREL). This procedure accounts for about 80% of the variation in thaw depth at the Barrow sites. This technique, based on Pavlov's (1984) methodology, can be used to estimate percent of thaw penetration on a particular day of the year or to adjust a measured thaw depth to maximum ALT (Streletskiy et al. 2008).

Permafrost temperature

Figure 6 shows permafrost temperatures from the several newly instrumented boreholes. The upper graph shows the first year's results for the new 50 m borehole. The lower graph compares the 1950 annual profile with current measurements. These initial results, for this specific site at the 14 m depth, indicate warming of about 1.2°C. This small increase over such a long period is consistent with a previous analysis of long-term permafrost temperature variations at Barrow for the period 1924–1997 (Romanovsky et al. 2002).

Those results implied that the observed 1.2°C difference at 14 meters in permafrost temperatures between 1950 and current temperatures is due to very recent warming during the late 1990s. Much colder permafrost temperatures at the permafrost table (up to 2 to 3°C colder) were typical for Barrow during the 1970s.

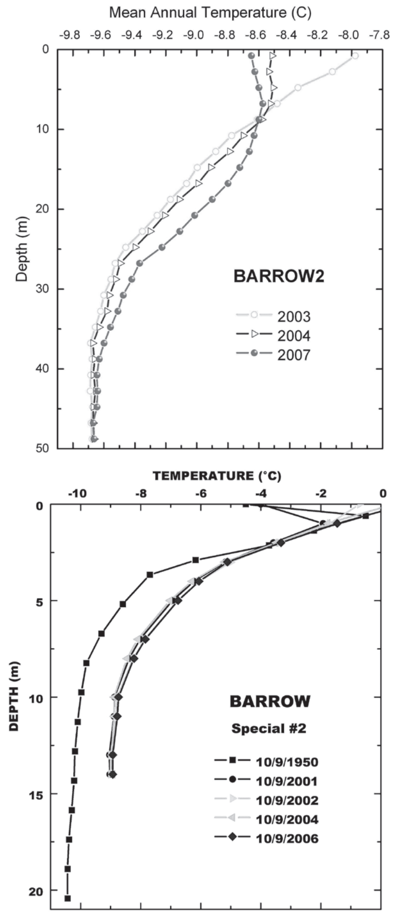

Figure 6. Upper: Annual permafrost temperatures at the new North Meadow Lake permafrost observatory, Barrow, Alaska. Lower: Comparison of 1950 and 2000s permafrost temperatures at the nearby Special 2 site.

Conclusions

Barrow has served as a permafrost observatory for more than a century, and the geocryological data record produced in the Barrow vicinity is unrivaled in Alaska in terms of length, diversity, and depth. The Barrow area played host to many pioneering studies on the roles that permafrost plays in global-change science, and the BEO continues to provide data important to those efforts. Because the Barrow Environmental Observatory is adjacent to an urbanized area there is abundant opportunity for local applications of the information obtained within BEO confines. The village of Barrow generates a significant urban heat-island effect (Hinkel et al. 2003, Hinkel & Nelson 2007), and the BEO is therefore an excellent location to attempt discernment between the geocryological impacts of anthropogenic factors and climatic variations (Nelson, 2003).

Barrow's geocryological data records illustrate the importance and effectiveness of sustained, well-organized monitoring efforts supported by adequate logistical arrangements. Sustained monitoring programs contribute much to the often subtle interplay between theory, application, and observation. Monitoring programs can reveal relationships that become apparent only decades after measurement programs are begun.

Acknowledgments

The permafrost investigations described in this paper were carried out within the Barrow Environmental Observatory, private land designated for research and long-term observation by the Ukpeagvik Iñupiat Corporation (UIC). The Barrow Arctic Science Consortium (BASC), a not-for-profit organization dedicated to scientist/community collaboration, was designated by UIC to manage the BEO with support from the U.S. National Science Foundation. We are grateful to both UIC and BASC for the opportunity to establish and maintain these observatories. Individual projects are supported by NSF grants in support of CALM (OPP-9732051 to the University of Cincinnati and OPP-0352958 to the University of Delaware) and TSP (ARC-0632400 and ARC-0520578 to the University of Alaska Fairbanks). Opinions, findings, conclusions, and recommendations expressed in this paper are those of the authors, and do not necessarily reflect the views of the National Science Foundation. We are grateful to four anonymous reviewers for criticism and suggestions that led to significant improvements in this paper. This paper is a contribution to both the present International Polar Year, and to the Permafrost Young Researchers Network (PYRN) through the efforts of the junior author (DAS).

Abstract

The Circumpolar Active Layer Monitoring (CALM) program was established in the early 1990s to observe temporal and spatial variability of active layer thickness, active layer dynamics, near-surface permafrost parameters, and the response of these factors to changes and variations in climatic conditions. The CALM network involves 15 participating countries and is comprised of 168 sites distributed throughout the Arctic, parts of Antarctica, and several mountain ranges of the mid-latitudes. Groups of sites are used to create regional maps of active layer thickness. Data obtained from the network are used to validate permafrost, hydrological, ecological, and climatic models at a variety of geographic scales. Several sites have records of frost heave and thaw subsidence that are contributing to a reconceptualization of the role of the active layer in global-change studies.

Keywords: active layer; climate change; mapping; monitoring; permafrost; thaw subsidence.

Introduction

Although formal monitoring programs incorporating measurements of depth to permafrost were in existence in the nineteenth century (Richardson 1839, Yachevskyi & Vannari 1912, Shiklomanov 2005) they generally lasted only a few years. Until the early 1990s, the majority of data describing and measuring the thickness, variability, and thermal regime of the active layer were collected in support of specific ecological, geomorphic, or engineering investigations and programs. The limited duration of most field measurement programs yielded only short data records, providing an inadequate basis for analyzing long-term trends. Sampling designs and data-collection procedures were not standardized, making inter-site and inter-regional comparisons problematic. The prospects for using information about the active layer in larger geographic and systems contexts were limited further by the lack of a suitable archive for such information.

Increasing recognition of the active layer's importance in the context of global climate change (e.g., Kane et al. 1991) provided much of the impetus for creating a long-term monitoring program focusing on the active layer and shallow permafrost. This paper provides a sketch of the CALM program's history, including a review of its benchmark objectives and achievements. As the CALM II program nears the end of its second five-year term of financial support, it is appropriate to take stock of accomplishments and to project future directions.

Early History of CALM

Following discussions at an international symposium held in West Siberia in 1989 (Melnikov 1990), the concept of the Circumpolar Active Layer Monitoring (CALM) program was developed to observe the long-term response of the active layer and near-surface permafrost to changes in climatic parameters. Initial foci of the program included "data rescue" activities and creation of a data archive (Barry 1988, Barry et al. 1995), building an alliance of field scientists willing to share data (Brown et al. 2000), execution of critical field experiments (Mueller 1996, Nelson et al. 1998a), and development of a data-collection protocol (Nelson et al. 1996). By the middle of the decade, many of these tasks had been implemented (Brown et al. 1995, 1997) and most of the components necessary to implement a comprehensive international network of CALM stations were in place.

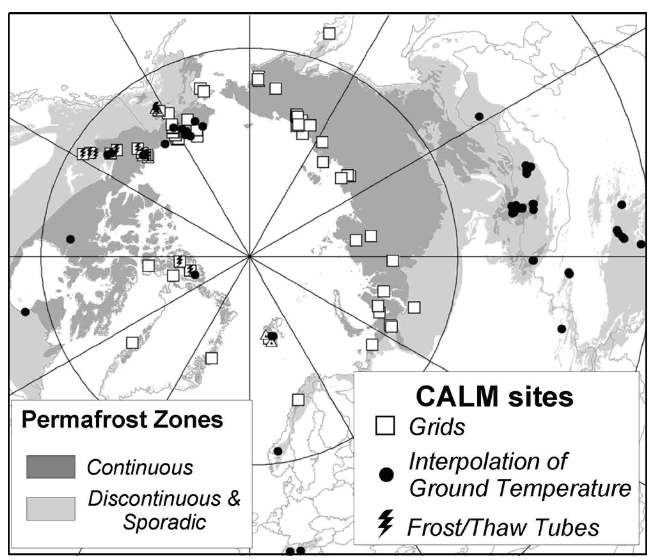

Figure 1. Permafrost distribution and location of CALM sites in the Northern Hemisphere as of 2008. Sites are grouped according to active layer monitoring methods. After Shiklomanov et al. (2008).

During this early period, considerable emphasis was placed on developing monitoring and sampling methodologies. In association with the Arctic Flux Program in northern Alaska (Weller et al. 1995), a grid-based sampling framework was developed and tested extensively (Fagan 1995) for obtaining data with manual probes. Experiments were also conducted with frost/thaw tubes (Nixon & Taylor 1998, Nixon et al. 2003) and monitoring of the shallow thermal regime (Paetzold et al. 2000, Hinkel et al. 2001). Results indicated that the various techniques were complementary and that no single data-collection strategy could achieve adequate results at all sites. Accordingly, CALM has maintained a variety of measurement techniques to the present time (Fig. 1).Until 1998, no formal funding mechanism for CALM was in place, and the initial CALM protocol was published as part of a manual (Molau & Molgaard 1996) developed for the International Tundra Experiment (ITEX) program, which formed an organizational umbrella for CALM during the early and mid-1990s.

CALM I

To implement CALM as a quasi-independent global-change monitoring program, the U.S. National Science Foundation's (NSF) Office of Polar Programs provided a five-year grant (1998–2002) to the University of Cincinnati. The proposal addressed the clear and pressing need to integrate Russian monitoring sites into the CALM network. An organizational meeting at the Seventh International Conference on Permafrost, held in Yellowknife NWT in July 1998, provided a forum for implementing CALM's goals, field instrumentation, sampling designs, and data-handling procedures.

Under the NSF-sponsored *Arctic Transitions in the Land-Atmosphere System* (ATLAS) program, the CALM network expanded by developing additional Alaskan sites. Existing or newly developed sites in Canada, China, Greenland, Kazakhstan, Mongolia, Norway (Svalbard), Sweden, Switzerland, and Antarctica were brought into the program, mostly on a voluntary basis, making it both bipolar and circumpolar. The CALM I project provided a variety of field instruments, data loggers, and standardized protocols for active layer measurements. A web site was established and metadata and data were maintained at this location, with periodic transfer to the Joint Office of Scientific Studies (JOSS) and the National Snow and Ice Data Center (NSIDC) in Boulder, Colorado. CALM data became an integral part of the CDs produced by NSIDC for the 7th and 8th International Conferences on Permafrost (Parsons & Zhang 2003).

Measurements conducted under CALM I represented a distillation of knowledge about the active layer and its behavior as understood at the time the NSF proposal was written in 1997. The proposal focused on five interrelated hypotheses that guided field and analytic work from 1998 to 2003. Several of these hypotheses have been confirmed by subsequent work, while others were in need of refinement from both theoretical and observational standpoints. Brief statements of these hypotheses are summarized in the following paragraphs.

(1) One of CALM I's central hypotheses specified that "the thickness of the active layer will increase in concert with climatic warming," noting that this concept is one of the basic tenets of global-change science in cold regions. Intervening years of monitoring and analytic activities under CALM have confirmed that refinement of this straightforward hypothesis is in order. Although sites in tundra environments show strong correlation between cumulative summer warmth (thawing degree days) and ALT, this relation is much weaker at boreal sites (Brown et al. 2000). Ecological changes, (e.g., non-acidic to acidic tundra (Walker et al. 1998) or development of shrubs (Sturm et al. 2001) may create sufficient insulation at the surface to offset or even counteract a simple temperature-ALT relation. Subsequent work under CALM II has shown that consolidation accompanying penetration of thaw into an ice-rich stratum at the base of the active layer can result in subsidence of the surface but little or no apparent thickening of the active layer, as traditionally defined.

(2) A complementary but very general hypothesis held that nonlinearities in the ALT-temperature relation are introduced by the multiplicity of variables involved. This hypothesis has been confirmed by subsequent work, and both modeling (e.g., Oelke & Zhang 2004, Anisimov et al. 2007, Shiklomanov et al. 2007) and field experiments (e.g., Hinkel & Nelson 2003) continue to address the issue.

(3) Work on the 1 km^2 ACRSS/CALM grids in northern Alaska in the mid 1990s indicated that ALT would show significant spatial and temporal autocorrelation. Subsequent work, which included formal sampling designs and statistical evaluation (Nelson et al. 1998a, 1999, Gomersall & Hinkel 2001, Shiklomanov & Nelson 2002, Hinkel & Nelson 2003, Shiklomanov & Nelson 2003), has confirmed this hypothesis. The strength of the autocorrelation function shows extreme variation in different localities; where the wavelength of important influences is large (e.g., in terrain containing abundant drained thaw lakes) ALT exhibits a large degree of spatial structure. Conversely, where local influences show considerable variation (e.g., in tussock terrain) ALT exhibits little discernable spatial structure, except over very small areas (Mueller 1996). Progress was also achieved under CALM I in the temporal domain. Several studies (Nelson et al. 1998b, Shiklomanov & Nelson 2002, Hinkel & Nelson 2003, Walker et al. 2003) found that, when stratified by vegetation/soil association ("landcover units"), ALT clearly shows a response to variation in summer climatic parameters, particularly temperature, in a predictable fashion. As a result, spatial patterns of ALT remain relatively constant, independent of thaw magnitude (i.e., whether it is a "hot" or "cold" summer). The implications of these findings are large, both for scaling to larger regions and for purposes of prediction via climate scenarios.

(4) A fourth, very general, hypothesis suggested that increased ALT and associated hydrological disruptions will lead to adverse societal effects, particularly damage to infrastructure. Considerable evidence exists in support

of this hypothesis, but the issue is awash with nuance and requires a substantial amount of further investigation. Thaw of ice-rich permafrost in many northern locations is causing substantial environmental change and problems for human occupants (Nelson 2003, U. S. Arctic Research Commission 2003, Hinzman et al. 2005). At issue, however, is whether increased ALT, *sensu stricto*, is behind these issues. Again, consolidation accompanying penetration of thaw into underlying ice-rich materials may or may not be reflected by ALT as it is traditionally measured.

(5) The fifth of the 1997 hypotheses represented a "geographic integration" of the first three: *ALT varies regionally in concert with climatic trends*. This hypothesis was verified forcefully in north-central Alaska using CALM data over a period of more than a decade. As elaborated under (3) above, stratification by vegetative/edaphic landcover units facilitates both empirical and predictive mapping of ALT and can yield highly accurate representations of average thaw depth. This hypothesis has been verified through work involving (a) compositionally diverse landcover associations in 1 ha units, distributed over an extensive region (Nelson et al. 1997); (b) integrated 1 km^2 landscape units distributed over the region (Nelson et al. 1998a, Hinkel & Nelson 2003); and (c) regional maps at high spatial resolution over a 13-year time series (Shiklomanov & Nelson 2002). The latter study included validation using a large data set collected on a week-long helicopter survey (Muller et al. 1998).

The CALM workshop

At the close of CALM I field activities, an NSF-funded international CALM workshop was held in November 2002 at the University of Delaware's campus in Lewes, Delaware. The workshop provided an opportunity for CALM scientists to present data and site histories, review methodologies, discuss progress and problems in the network, implement unified data-analytic procedures, and plan future activities. Discussions and collaborations arising from the Lewes workshop resulted in a series of regional papers and poster abstracts addressing the spatial and temporal variation of active layer thickness at a large number of Eurasian and North American and other sites (Nelson 2004a, 2004b). A series of posters, published as extended abstracts, were presented in Zurich, Switzerland, in July 2003 at the 8th International Conference on Permafrost (Haeberli W. & Brandová 2003), where almost all CALM sites were represented.

After the conclusion of funded CALM I field activities in 2002, limited support for fieldwork at Alaskan and Eurasian sites was made possible in 2003 through a one-time contribution from the University of Delaware's Center for International Studies.

CALM II

The achievements of CALM I provided impetus for continuing the network on a long-term basis, and set the stage for a more comprehensive and integrated system of observations. The proposal to NSF for a second five-year support period focused on several objectives based, in turn, on a series of interrelated themes and hypotheses. CALM II's initial objectives, discussed in detail by Nelson et al. (2004b), were: (1) to maintain and expand programs of long-term, active layer observations in existing regional networks; (2) to **c**ontinue to develop CALM's web-accessible database and provide data management and archiving support; (3) to develop standardized active layer data sets for use in validating hydrologic, ecosystem, permafrost, and climate models; and (4) to integrate active layer and thaw settlement observations over seasonal, inter-annual, and decadal time scales and across a range of geographic scales. These topics are addressed at length in other papers in these proceedings (and publications cited therein), and only brief summary statements with key references are given here.

Accompanying the launch of the CALM II program was a revised and expanded data-collection protocol (Nelson & Hinkel 2003).

Observation network

CALM's network of observation sites continues to expand, having grown from 125 at the close of the CALM I program to 168 at the beginning of 2008. One of the most significant developments in this regard was the creation of a formal program of CALM observations on the Antarctic continent and in the maritime sub-Antarctic islands (Bockheim 2005, Boelhouwers et al. 2003, Vieira et al. 2006, Ramos 2007, 2008). The Antarctic Permafrost and Soils (ANTPAS) program (Parsons et al. 2008) incorporates several sites, known collectively as the CALM-South (CALM-S) network. Ground temperatures are monitored at several sites in South Victoria Land on Livingston Island/South Shetland Islands (Hauck et al. 2007). The CALM-S program is being developed to investigate conditions across environmental gradients from the Andes to the sub-Antarctic islands and through the Antarctic Peninsula and Transantarctic Mountains to the McMurdo Dry Valleys.

Detailed descriptions of ongoing research at many other CALM sites are provided elsewhere in these proceedings (Christiansen & Humlum 2008, Fyodorov 2008, Hollister et al. 2008, Nelson et al. 2008, Riseborough 2008, Smith et al. 2008, Streletskiy et al. 2008, Vasiliev 2008, Viereck 2008, Zamolodchikov 2008). Regional summaries are contained in Shiklomanov et al. (2008). Some concerns about the existing geographic distribution of sites were discussed by Anisimov et al. (2007), and this topic is under investigation (Streletskiy, in progress).

CALM database

The CALM II program is administered through the University of Delaware (UD). Analysis, archiving, and distribution of CALM's long-term observations are integral components of the project. Field data are provided by participants on an annual basis to the CALM office at UD, where they are incorporated into several databases. The data are distributed through the CALM web site (www.udel.edu/Geography/calm), which has been revised extensively and expanded under CALM II. CALM data products are also produced and distributed by the Frozen Ground Data Center at the University of Colorado. Further information is provided elsewhere in this volume by Shiklomanov et al. (2008).

Model validation

Active layer observations and auxiliary information from the CALM network provide a circumpolar database, which has been used extensively to validate process-based geocryological (e.g., Oelke & Zhang, 2004, Shiklomanov et al. 2007) and hydrological (Rawlins et al. 2003) models. Further discussion of the use of CALM data for model validation is contained in Shiklomanov et al. (2008).

Because CALM investigators adhere to a standardized, well-documented protocol, data from the program are useful for validating modeling efforts at a variety of geographic scales. CALM was identified as a model program with respect to data harmonization in the recent U.S. National Research Council report *Toward an Integrated Arctic Observing Network* (Committee on Designing, 2006, p. 82),

Integration

Integration of data, spatial interpolation, and creation of regional representations of active layer thickness were of vital concern early in the CALM program. Nelson et al. (1997) created a map of active layer thickness for a 27,000 km^2 area of north-central Alaska, and conducted validation studies by helicopter survey (Muller et al. 1998, Shiklomanov & Nelson 2002). A spatial time series extending over 1.5 decades now exists for this region

A second regional map is the detailed digital landscape and active layer map created at the Earth Cryosphere Institute (Russian Academy of Sciences). This regional compilation embraces a hierarchy of data layers, including landscape units, organic layer thickness, lithology, and landscape-specific characteristic values of active layer thickness in the northern part of West Siberia. At present, the map is being refined and extended.

Several other regions contain large assemblages of sites and are representative of high-latitude climatic/landscape gradients, making them suitable candidates for spatial data integration. These include the Lower Kolyma River, the Barrow Peninsula on Alaska's North Slope, the Mackenzie River region (Canada), and the North Atlantic region. Each of these regions has been the subject of extensive geocryological research and contains enough information to undertake regional-scale mapping.

Toward an integrated theory of the active layer and upper permafrost

Research treating permafrost-climate interactions has traditionally been based on a two-component conceptual model involving a seasonally frozen active layer and underlying perennial frozen materials. Analysis of data obtained from some of the CALM sites indicated, however, that this conceptualization is inadequate to explain the behavior of the active layer/permafrost system, particularly in ice-rich terrain. To an observer measuring active layer thickness using traditional methodology (e.g., mechanical probing) thaw penetration into the ice-rich layer may not be apparent, owing to thaw consolidation and net subsidence of the surface. This phenomenon has contributed to the view that active layer thickness may not follow climatic trends closely (e.g., Hinzman et al. 2005).

The apparent stability of active layer thickness in many Arctic landscapes, suggested by CALM records, indicates the existence of self-regulating mechanisms that contribute a robustness to the upper permafrost with respect to external climatic forcing. In many regions an ice-rich layer exists below the base of the active layer (e.g., Brown 1967, Mackay 1972, Shur 1988a). Owing to latent-heat effects, such ice-rich layers resist thaw and tend to promote interannual stability in the position of the base of the active layer. During unusually warm summers, however, thaw may penetrate well into this ice-rich layer. Conversely, following colder summers ice may be added to the upper permafrost, possibly resulting in a subsequent decrease of ALT. Although the magnitude, frequency, and variability of these processes are not well documented, Nelson et al. (1998b) hypothesized that they may be responsible for abrupt, long-lasting ("Markovian") changes in ALT at Barrow.

Shur (1988a, b) reconceptualized the active layer/permafrost system, accounting for these factors explicitly. Basing his formulation on earlier Russian work, Shur noted the existence of a *transient layer* that alternates in status between seasonally frozen ground and permafrost over multi-decadal periods. This layer serves as a buffer between the active layer and permafrost. Significant ice segregation can occur within this layer during "cold" years, due predominantly to freezing from below during the autumn and winter. During most "warm" years, this ice-rich layer protects underlying permafrost from thawing, although extreme summers may reduce its vertical extent significantly. Its existence explains the fact that wedge ice and other massive ice formations are located frequently *beneath* the transient layer, as observed for example at Barrow (Brown 1969). Incremental segregation or melting of ice within the transient layer can, however, result in substantial heave or subsidence at the surface over decadal time scales. The thickness of the transient layer plays a crucial role in evaluating the potential response of the active layer/permafrost system to climatic change, and for development of thermokarst processes. For well-developed thermokarst terrain to evolve, the long-term maximum thaw depth should be achieved consistently from year to year during the thawing season.

Shur et al. (2005) discussed the characteristics and behavior of a three-tier system containing a transient layer. The primary characteristics of such a system are the different periodicities at which the constituent layers cycle through 0˚C and the relative abundance, morphology, and distribution of ice contained in each. Although the ice-rich character of the transient layer acts to retard its rate of degradation, progressive thaw under monotonic climate warming would lead to its destruction, with attendant thaw consolidation and

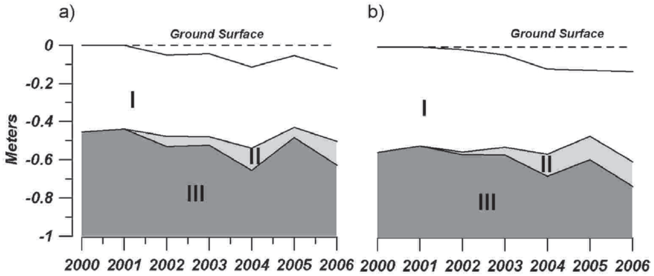

Figure 2. Annual changes in position of ground surface and ALT, as measured by mechanical for representative coastal plain (a) and foothills (b) CALM sites. I- ALT measured by probing; II- ALT, corrected for ground subsidence; III-permafrost. From Streletskiy et al. (2008).

differential subsidence at the surface. Elimination of the most ice-rich parts of the transient layer may be accompanied by an abrupt and long-lasting increase in the thickness of the active layer. Thaw penetration into spatially heterogeneous ground ice in the underlying permafrost triggers differential thaw settlement at the surface.

Simultaneous monitoring of active layer thickness and thaw subsidence have been undertaken at several ice-rich CALM sites in Alaska and Russia (Little et al. 2003, Mazhitova & Kaverin 2008, Streletskiy et al. 2008). To account for ground subsidence in the active layer record at several CALM sites in northern Alaska, annual changes in the position of the ground surface, relative to the level at the beginning of the measurements in the year 2000, were added to the active layer measurements produced by mechanical probing (Fig. 2). Results from two sampling locations in northern Alaska indicate a monotonic increase in thaw penetration over the period of measurement. Similar results were obtained by Overduin & Kane (2006) elsewhere on Alaska's North Slope and in Russia by Mazhitova & Kaverin (2008). Bockheim & Hinkel (2005) found widespread stratigraphic evidence for fluctuations in the position of the transient layer in northern Alaska. Taken together, these results indicate that the CALM program should install instrumentation to monitor thaw subsidence at any site containing abundant ground ice at shallow depth.

Conclusion

CALM is, in the first instance, a global-change program. Its change-detection function remains a critically important part of its mission. As part of this charge, the program is also concerned with differentiating between the impacts of long-term climate change and more localized anthropogenic effects (Nelson, 2003).

CALM data have proven useful in many contexts. Owing to the limited observational record at most sites, however, it is not yet possible to arrive at definitive conclusions about long-term changes or trends in the temperature and thickness of the active layer. The few long-term data sets available from high-latitude sites in the Northern Hemisphere show very substantial interannual and interdecadal fluctuations. The spatial variability of active layer thickness is large, even within geographic areas of limited extent (e.g., 1 km^2). Most sites in tundra environments show a strong, positive relation between summer temperature and the thickness of the active layer. This relation is weaker in boreal environments, but these are understudied and require more investigations (e.g., Hinkel & Nicholas 1995, Viereck 2008). Increases in thaw penetration, subsidence, and development of thermokarst terrain have been observed at some sites.

CALM II continues existing partnerships and collaborations with other international organizations and programs, including GCOS/GTOS, CEON, CliC, ITEX, ICARP, IASC, and the ongoing IPY and IUGS Year of Planet Earth programs (Brown et al. 2000, U.S. Arctic Research Commission Permafrost Task Force 2003). CALM is making significant contributions to International Polar Year 2007–08 as a major component of the *Thermal State of Permafrost* IPY project.

Reflecting its open, community-based structure, CALM II holds annual meetings and round-table discussions in connection with major scientific conferences. The second CALM Workshop is being held in Alaska during June 2008, immediately preceding the Ninth International Conference on Permafrost in Fairbanks. The workshop will focus on creating a research agenda for the CALM III program, with particular attention paid to monitoring in the boreal regions and on instrumentation suitable for extending thaw-subsidence measurements to all CALM sites in ice-rich terrain.

Acknowledgments

A program such as CALM could not exist without the cooperation, ideas, and efforts of a large group of researchers from around the world. CALM investigators, many of whom contribute on an entirely voluntary basis, have created a network of permafrost observatories and databases that has helped to revolutionize permafrost science in ways that could only be hinted at just two decades ago (Barry 1988).

CALM projects in Kazakhstan, Mongolia, Russia, and the United States have been supported by grants from the U.S. National Science Foundation (OPP-9732051 to the University of Cincinnati and OPP-0352958 to the University of Delaware). The University of Delaware provided funding for limited field operations during 2003. Opinions, findings, conclusions, and recommendations expressed in this paper do not necessarily reflect the views of the National Science Foundation. This paper is a contribution to the present International Polar Year, and the Permafrost Young Researchers Network.

Abstract

We investigate bio-geophysical processes causing differential frost heave in non-sorted circles north of Alaska's Brook Range. The main question to be addressed is, "How doest heterogeneity in soil properties and ground surface conditions cause the differential frost heave observed within the non-sorted circle?" We address this question by developing a numerical thermo-mechanical model of a non-sorted circle. A sensitivity study of predicted differential frost heave, with respect to soil physical properties and vegetation characteristics, shows that hydrological and thermal properties, as well as the local heterogeneity in distribution of surface vegetation, have a decisive role in formation of differential frost heave. We applied this model to simulate differential frost heave at the Franklin Bluffs site and obtained a good quantitative agreement with observed soil temperatures, water content, and frost heave. For other locations, such as at the Sagwon Bluffs and Howe Island sites, we obtained qualitative agreement with frost heave measurements.

Keywords: freezing and thawing; frost heave; numerical modeling; patterned ground**;** permafrost.

Introduction

Extensive areas of the Arctic landscape are characteristically patterned into small-scale ground features called non-sorted circles. Non-sorted circles are 0.5–3.0 m diameter patches of barren or sparsely vegetated soil formed by frost action (van Everdingen 2002) and ordinarily develop on poorly drained tundra sites (Fig. 1).

Changes to these features in relation to changes in climate could affect energy and carbon mass exchange at the tundra surface with possible feedbacks to the climate. However, formation, development, and maintenance of such ground patterns and their interaction with vegetation is poorly understood (Walker et al. 2004). The objective of this study is to numerically model observed frost heave in non-sorted circles and gain an understanding of interactions between water fluxes, temperature dynamics as influenced by the plant canopy and the motion of soil particles resulting from the heave of ground surface.

As part of the biocomplexity of the patterned-ground project (Walker 2004), we observed non-sorted circles at several locations near the Dalton Highway in Alaska. We instrumented several non-sorted circles at these sites with sensors that measure soil temperature, moisture content, and the maximum frost heave (Walker et al. 2004). Our measurements revealed that the maximum frost heave in a circle interior was 2–8 times greater compared to frost heave surrounding the circle tundra. This phenomenon is referred to as the differential frost heave.

Our field observations support the idea that the frost heave of saturated soil very often cannot be explained solely by the expansion of liquid water transforming into ice crystals. In this study,we apply a general thermo-mechanical model (Mikkola & Hartikainen 2001) of frost heave to simulate the observed frost heave in non-sorted circles. In this work, we assume that the soil is a homogeneous mixture of liquid water, ice, and soil skeleton. We assume that the skeleton and ice undergo small deformations described by linear elasticity, and the linear momentum conservation principles can be exploited in the quasi-static form. In our model, we also neglect ice flow relative to the soil skeleton. The liquid water is an incompressible and non-viscous fluid that changes its phase and is always in thermodynamical equilibrium with ice. The chemical potential of the liquid water is modified due to adsorption to the soil skeleton.

Based on observations from field experiments and results of our numerical simulations, we conclude that heterogeneity in surface characteristics and soil properties (due to the presence of a heterogeneous plant canopy together with presence of waterlogged conditions) are among the primary requirements necessary for occurrence of differential frost heave observed in non-sorted circles.

Physical Description

In this section, we highlight key physical processes and mechanisms presumably causing the differential frost heave in non-sorted circles. The area surrounding the circle is called the inter-circle area and has a relatively thick mat of vegetation as well as a layer of organically enriched soil (Fig. 1). Incorporation of the organic material into soil leads to heterogeneity in thermal properties, structure, and water-holding capacity of soil. For example, different soil textures indicate distinctive thermal conductivities, soil porosity, and dependence of the unfrozen liquid water content on temperature. Besides variances in thermal and hydrological properties, the non-sorted circle has heterogeneous rheological properties due to structural change that takes place during annual freeze-thaw cycles. This structural change is caused by freezing water that creates a microscopic structure in the form of a sequence of ice lenses.

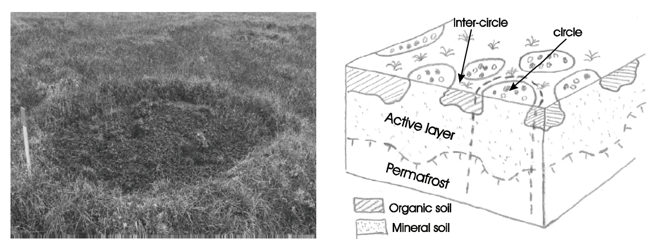

Figure 1. A photography (left) and schematic description (right) of the non-sorted circle.

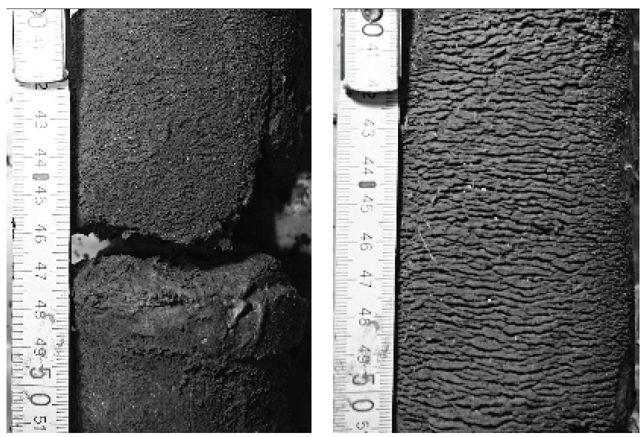

Figure 2. Core samples obtained from the inter-circle area (left photo) and circle (right photo) at the Franklin Bluffs site during winter. On the right photograph, a sequence of horizontally oriented ice lenses can be observed. The vertical scale is in centimeters.

Figure 2 shows the ice lenses in soil core samples from a non-sorted circle at the Franklin Bluffs site, Alaska. Each ice lens separates soil particles, causes the observed lenticular soil structure, and hence lessens structural solidity of soil. In Graham & Au 1985 and Qi et al. (2006), it was shown that soil has a long-term memory of its previous freeze/thaw cycles, which in particular reduces bonding between soil particles. To account for reduction in the bonding, we assume that soil is more structurally solid if it has fewer ice lenses. From a soil core obtained by drilling in winter, we observed that the circle has many more ice lenses than in the inter-circle area, and these lenses can be found even at the significant depth of 0.5 m (Fig. 2). Therefore, we assume that soil in the inter-circle is more structurally solid than in the circle. Despite these heterogeneities, the difference between observed active layer depths (maximum depth of summer thaw) of the circle and inter-circle does not exceed 0.3 m in the majority of cases.

It is well known that frost heave is caused by volumetric water expansion during freezing. However, as mentioned earlier, the observed frost heave heights do not seem to be exclusively dependent on the active layer depth, and on volumetric water content in the soil before freezing. From field observations at the Franklin Bluffs site, we know that the active layer thicknesses for the circle and inter-circle areas are 0.9 and 0.8 m, respectively, and volumetric water content in these areas during summer is almost the same. Thus, if water does not migrate, the frost heave is computable and its height is about 3.0–3.5 cm for both circle

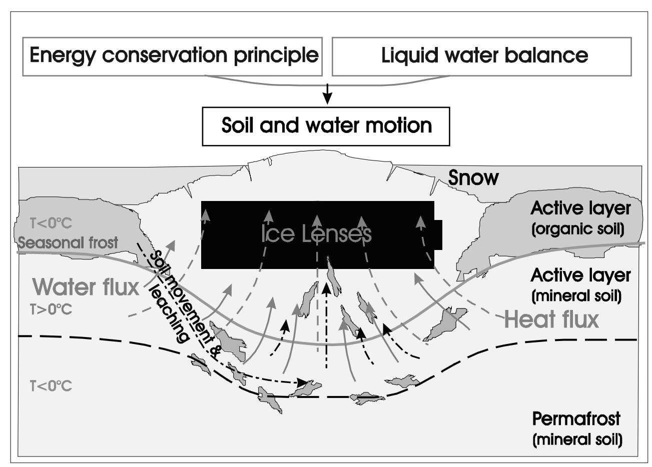

Figure 3. A diagram of fundamental physical processes taking place in a non-sorted circle when it freezes during the fall. Directions of the water flow, heat flux, and soil displacement are marked by solid, dashed, and dot-dashed lines, respectively. Location of the upper 0ºC isotherm is marked by the solid line, whereas location of the permafrost table by the dashed line.

and inter-circle areas. The latter values of the frost heave contradict observations at Franklin Bluffs site, at which the ground heaves by 15 cm in the center of a circle and only by 3 cm in the inter-circle. This significant variation on the local-scale frost heave is called the differential frost heave. We hypothesize that the key physical process responsible for the differential frost heave within non-sorted circles is water redistribution between the circle and inter-circle. The water redistribution is caused by lateral components in the cryogenic suction that pulls water from thawed soil to partially frozen soil. The lateral components in the cryogenic suction are due to heterogeneity in soil properties and in ground surface conditions, first of all in vegetation cover. Figure 3 shows fundamental physical processes occurring in the non-sorted circle in the fall when it freezes.

We describe the nature of these processes and their implications to the observed values of the differential frost heave as follows. When the ground surface temperature becomes lower than 0ºC, water trapped in soil pores starts to freeze. In Figure 3, the direction of the heat flux during freezing is shown by dashed arrows. In several classical works, it was demonstrated that temperature gradients in the freezing ground create cryogenic suction, inducing flow of water towards a freezing region along the temperature gradient (O`Neill & Miller 1985). Since the circle lacks an organic layer, the frost propagates through it faster, causing stronger water migration into the circle, consequently resulting in more intensive ice lens formation and thus higher frost heave in the circle. Over a period of time, the circle heaves significantly higher than the inter-circle area. A secondary consequence of the heave is the reduced thickness of the snowpack above the circle compared to the inter-circle area (Fig. 3). The heterogeneous snow distribution further enhances the thermal heterogeneity of the soil surface. An absence of a vegetation mat within the heaving areas in conjunction with difference in the snow thickness results in

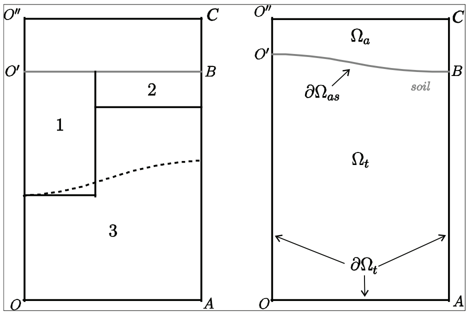

Figure 4. Schematic cross section (left) of the non-sorted circle and its computational domain (right). Segment OO″ is the axis of rotation, AB is the external boundary, and the dotted line on the left shows the upper permafrost boundary.

observed lower winter soil temperatures in the circle than in the inter-circle. The thermal difference between the circle and inter-circle areas creates cryogenic suction and drives water from the inter-circle to the circle (the direction of liquid water motion is shown by solid arrows). Reaching a freezing region, water forms ice lenses, which exert uplifting forces causing deformation of the soil skeleton. We highlight directions of soil particle velocities by dash-dotted arrows (Fig. 3). In our model we exploit a simple rheological model of the soil skeleton and assume that its deformations are well simulated by linear elasticity theory in which the soil stiffness takes into account structural differences and loss in soil bonding caused the ice lenses.

Besides the thermal differences, which cause liquid water migration towards the circle, hydraulic properties of the soil also determine water flux affecting the liquid water migration. One of the key hydraulic parameters is a coefficient of hydraulic conductivity and its dependence on liquid water content, θ_w, for partially frozen ground. According to Konrad & Duquennoi (1993), the hydraulic conductivity increases with an increase of unfrozen water content that is a function of both temperature and porosity. Another hydrological aspect that is important in sustaining water migration is the availability of water inside the non-sorted circle or at its boundary. We note that observations reveal higher values of frost heave that have been measured at poorly drained sites. Hence, lateral boundary conditions play an important role in allowing water to migrate into the circle due to cryogenic suction and to create ice lenses. In our model, we simulate the non-sorted circles either as hydrologically opened or closed systems by setting to zero either the water flux or pressure, respectively, on external boundaries. In the next section, we will briefly describe a general thermo-mechanical model of freezing soil. An interested reader can consult Mikkola & Hartikainen (2001), where the theory is discussed in detail.

Numerical Model

We consider a mixture of several constituents—water, ice, and soil particles—occupying a change in time region. Since a non-sorted circle has an axial symmetry, we solve governing equations in an axisymmetrical domain. In Figure 4, we show the cross-section of the computational domain consisting of three regions. Soil properties for each region are listed in Table 1.

Table 1. Description of soil properties for non-sorted circles along the Dalton Highway in Alaska.

Domain	Soil	Ice lenses	Unfrozen water
1	Mineral	Many	High content
2	Organic	Many	Low content
3	Mineral	Few	High content

We solve the energy conservation principle for the mixture by using two mass conservation principles for soil particles and liquid water, and a quasi-elasticity principle for the soil particles.

Based on the energy conservation principle, we compute the soil temperature T. The temperature consecutively defines the magnitude of the cryogenic suction, f, that forces liquid water from a thawed region towards the partially frozen one. The flux of liquid water, F, is defined such that

$$F \approx \nabla\left(p + \rho_w L \frac{T}{T_0}\frac{\partial f}{\partial \theta_w}\right) + \rho_w L \frac{T}{T_0}\nabla f, \qquad (1)$$

where L is the latent heat of fusion, ρ_w is the water density, and $T_0 = 273.15$ºC. Consequently, the flux F is used in the water conservation principle, i.e., Darcy's Law, and to calculate the pressure, p (Mikkola & Hartikainen 2001). The latter is used to define a force in the quasi-linear elasticity law in order to compute displacement of soil particles. The system is coupled, since the soil particle displacement is used to compute the temperature and the pore pressure. We note that the system pore pressure/soil displacement (up to the coefficients) is common in the poro-elasticity theory. On the ground surface, we specify the temperature and zero pressure. On the lateral boundary, we set zero heat flux, zero pressure/water flux (open/closed system). At some depth (in our case 2.0 m), we set zero heat and water flux.

The system of equation is discretized by a finite element method in a fixed-in-time domain that embeds ground material OABO′ in a heaving non-sorted circle (Fig. 4). The fictitious domain method is used to set physically realistic boundary conditions on the moving ground surface O′B, lateral boundaries AB, OO′ and bottom OA of the non-sorted circle.

In nature, we observe that the maximum frost heave is larger at sites where near-surface ground water is abundant (Walker et al. 2004). To explain this phenomena, we show that liquid water migration towards the partially frozen region as well as the unlimited water supply are both essential to simulate the observed frost heave. Hence, we model two cases. In the first case, we model the zero-pressure boundary condition on AB, and hence water is allowed to pass through this boundary. In the second case, the zero-flux boundary condition is placed on the segment AB, resulting in a hydraulically isolated system.

Due to presence of the cryogenic suction, during freezing there is an induced flow of liquid water from the thawed

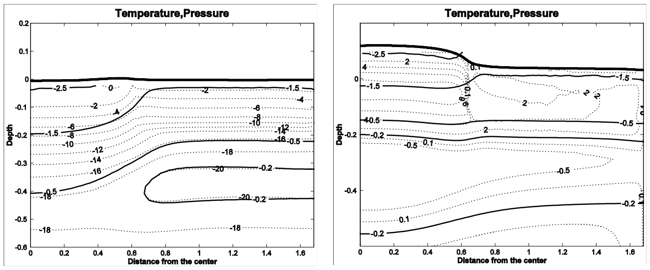

Figure 5. Contours of the temperature in ºC (solid lines) and pressure in 10^5Pa (dotted lines) at the 30th days after beginning of freezing, for hydraulically closed and open systems, in the left and right plots, respectively.

region to the partially frozen zone. As a result, the pressure in the thawed region decreases. In the hydraulically closed system without internal sources of water, the boundaries are not water-permeable, and hence no additional water can appear in the non-sorted circle. Consequently, the pressure can decrease (Fig. 5).

In the hydraulically open systems with suction, the cryogenic suction creates similar effects as in the closed systems. Namely, it forces the flow of water and creates a low pressure zone in the thawed region. However, unlike the closed systems, the pressure on the external boundary is equal to zero, and water can flow through the boundary and compensate deficiency in water volume and, associated with it, negative pressure. Therefore, in the hydraulically open systems, the pressure in the thawed region is slightly negative compared to the closed system (Fig. 5). We observe that the positive-pressure increase exists in the partially frozen region and it creates the uplifting forces which produce the frost heave.

We conclude that the cryogenic suction forces create water flow. The pressure dynamics and the uplifting forces strongly depend on the pressure boundary condition. These results show that the model qualitatively predicts typical physical behavior of hydraulically closed and open systems occurring in nature. An interested reader is referred to Nicolsky et al. (in review) and to references therein, where the governing system of equations is described.

Frost Heave Modeling at the Franklin Bluffs Site

In this section, we apply the general model to a non-sorted circle located at the Franklin Bluffs site (148.7°W, 69.6°N) on the Dalton Highway in Alaska. The non-sorted circle is approximately 0.6 m in radius and is developed in waterlogged non-acidic tundra. In the inter-circle, the organic layer is 0.2 m in depth (Walker et al. 2004). An array of sensors measuring temperature and moisture dynamics in time are installed at several depths and at several locations across it.

The cryogenic suction is calibrated by matching the simulated unfrozen water content to the observed one at 0.35 m depth in the circle and 0.15 m depth in the inter-circle, respectively. Thermal conductivities of the frozen mineral and organically enriched soil are set to be 1.9 and 0.9 W/(mK), respectively. The Young's modulus for the mineral soil inside and outside the circle is $2 \cdot 10^6$ and $2 \cdot 10^7$ Pa, respectively, which are typical values for weakly consolidated and consolidated silt-clay mixture. Since the non-sorted circle is located in a waterlogged area, we model it as a hydraulically open system. Initial soil temperature distribution with depth was approximated by measured temperature on September 12, 2002, and the soil porosity was set to be 0.35. On this day the active layer depths in the center of the non-sorted circle and in the surrounding tundra were 0.80 and 0.60 m, respectively.

We simulated the soil freezing from September 12, 2002, through December 18, 2002, when the temperature in the non-sorted circle became less than -5ºC. On the circle and inter-circle ground surface, we prescribed a 5-day-running average of the corresponding measured ground surface temperature. The calculated liquid water content at 0.35 m depth in the circle and 0.15 m depth in the inter-circle is compared to the measured data (Fig. 6). The difference in freeze-up timing between the observed and modeled ground is less than three days.

In general, the discrepancy between the measured and computed temperature at the depth of 0.35 m in the circle is less than 1ºC (Fig. 7).

In addition to comparing the measured and computed soil temperatures, we show the calculated pressure dynamics at the same point; i.e., at the depth of 0.35 m. Note that initially when the ground surface temperature was above 0ºC, the pressure was zero (we assume there is no gravity and that the pressure on the lateral boundary is zero). However, as soon as ground freezing begins, the cryogenic suction starts

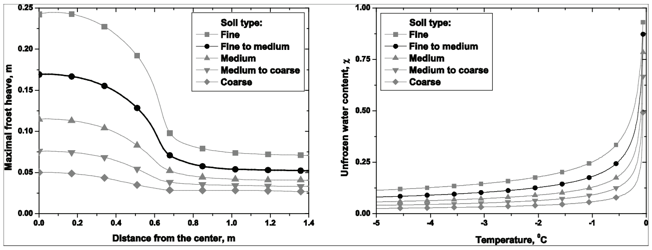

Figure 8. Sensitivity of the frost heave (left) on parametrization of the unfrozen water content (right).

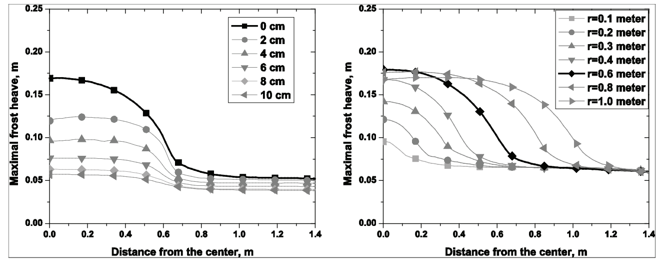

Figure 9. Sensitivity of the maximum frost heave to an addition of organically enriched soil (left) and to the radius (right) of the non-sorted circle.

to force water migration from a still-unfrozen part of the active layer to a partially frozen one. Therefore, the pressure lowers in the entire thawed part of the active layer, and the pressure dynamics have slightly negative pressure at this time (Fig. 7).

When the freezing front reaches the depth/region at which the pressure and temperature dynamics are shown (0.35 m), the cryogenic suction starts to force water migration into this still partially frozen region. Soil porosity consecutively increases (Fig. 7). Due to an increase of the water mass, and due to its expansion while freezing, the pressure continues to increase (Fig. 7). Note that the increased porosity is associated with formation of ice lenses and development of the frost heave (the small decrease in soil porosity is due to numerical regularization of the soil mass conservation principle). The value of the computed frost heave in the center of the non-sorted circle is approximately 0.18 m, whereas in the inter-circle it is 0.045 m. These computed values are in a good agreement with field observation circles heave by 0.15–0.2 m.

Sensitivity Analysis

In this section, we present results from the sensitivity study of the frost heave with respect to unfrozen water content, changes in the organic layer, and geometric dimensions. We define the calculated maximum frost heave at the Franklin Bluffs site as a reference point against which we compare a series of numerical experiments. To simplify comparison, we show the calculated frost heave for the Franklin Bluffs site by a line with circle symbols.

In the first series of experiments, we analyze dependence of the maximum frost heave on the unfrozen water content for the mineral soil. Note that parameterization of unfrozen water content depends on mineralogy, solute concentration, texture, and other factors. For example, the high unfrozen water content is associated with fine-grained ground material. For coarse-grained materials, such as sand, the unfrozen water content depends sharply on temperature near 0ºC (Fig. 8). For each shown parameterization, we simulate freezing of the non-sorted circle and compute the maximum frost heave (Fig. 8). In these numerical experiments, all model parameters except for the parameterization of the unfrozen water content were fixed and equal to the values related to the Franklin Bluffs site.

From the computed results, we observe that the largest frost heave occurs when the soil has a high unfrozen water content. This effect has the following explanation. Hydraulic conductivity of the partially frozen soil increases if the unfrozen water content θ_w becomes higher, and hence more water migrates through the partially frozen region due to cryogenic suction flow F (non-linearly dependent on θ_w) and forms ice lenses. The above-mentioned dependence of the frost heave on unfrozen water content is commonly observed in nature; i.e., that sand and gravel are not frost-heave susceptible soils whereas silt is. Note that clays, which have an even higher unfrozen water content, are typically not capable of developing significant frost heave since they have very small hydraulic conductivity.

In our field experiments, we observe that a thin organic layer is typical on top of some circles. From the physical point of view, this layer represents an additional thermal resistance and changes mean temperatures in the soil. Therefore, in the third series of experiments, we analyze dependence of the maximum frost heave on presence of organically enriched soil in the non-sorted circles. We consider several configurations of organic layers varying in their thicknesses. We additionally place on top of the non-sorted circle an organic layer, which uniformly covers the circle and inter-circle. The soil thermal, hydraulic, and rheological properties of this additional layer are identical to the properties of the original organically enriched soil in the inter-circle for the Franklin Bluffs site. Note that an increase in insulation layer causes a decrease in the active layer thickness. From our field studies, we observed that each additional 0.02–0.03 m of the organic material results in 0.04–0.05 m decrease of the active layer. In the left plot in Figure 9, we show the maximum frost heave developed for various thicknesses of the additional organic layer.

We emphasize that observed results are in agreement with observations at non-sorted circles along the Dalton highway in Alaska. For example, the scarcely vegetated circles at the Franklin Bluffs area heave by 0.15–0.2 m, whereas moderately vegetated circles at the Happy Valley site develop only 0.07–0.1 m of heave during winter. Also, field experiments (Kade et al. 2006, Kade & Walker, in press) at Sagwon Bluffs involved both the removal and addition of vegetation on non-sorted circles. The removal of vegetation at this location resulted in a 1.4ºC increase in mean summer mineral soil surface temperature compared to control, a 6%

increase in the depth of the thaw layer, and a 26% increase in frost heave. The addition of a 0.1 m thick moss layer results in the opposite effect; i.e., a 2.8ºC decrease in the mean summer mineral soil surface temperature, a 15% reduction in the thaw layer, and a 52% decrease in heave. Despite the fact that the numerical model is focused on non-sorted circles at the Franklin Bluffs site, and the field experiments were conducted at the Sagwon Bluffs site, results from these studies show qualitative agreement, and almost similar quantitative behavior of frost heave reduction.

In the fourth series of experiments, we investigate sensitivity of frost heave to the radius of the non-sorted circles. We calculate the frost heave for circles which have 0.1, 0.2, ... 1.0 m radius. Our calculations support observations which reveal that small-scale non-sorted circles heave less compared to the large-diameter ones. The maximum computed frost heave is for circles with the radius of 0.6 m (Fig. 9). For circles with a radius larger than 0.6 m, the maximum frost heave decreases slightly, since liquid water has to migrate to the center of the non-sorted circle longer from the lateral boundary where water is abundant. Smaller values of frost heave computed in the center of the non-sorted circle with a large radius can promote development of live vegetation as observed in nature.

Conclusions

We present a numerical thermo-mechanical model of differential frost heave with special emphasis on simulating biocomplexity of non-sorted circle ecosystems. Unlike many other models that study 1-D ice lens formation, we are concerned with 2-D effects of soil freezing. Heterogeneity in soil properties and surface conditions results in curved frost penetration and 2-D temperature fields. Therefore, the cryogenic suction results in horizontal water redistribution inside the non-sorted circle.

The model was tested using observational data obtained from several sites within the Permafrost/Ecological North American Arctic Transect. We obtained a good comparison between simulated and observed dynamics of physical processes in the non-sorted circle at the Franklin Bluffs. The model also qualitatively represents “non-heaving” non-sorted circles at the Howe Island site.

The simulated frost heave is sensitive to hydrological soil properties, and to changes in the vegetative insulation layer within the circle and inter-circle areas. The results of our sensitivity analysis, with respect to addition/removal of vegetation layer to/from the surface of a circle, are well correlated with field observations where a layer of organic material was either added or removed from the non-sorted circle.

The most active development of differential frost heave takes place for non-sorted circles within waterlogged areas with strong upper-soil-layer heterogeneity caused by living vegetation. The most important driver of the non-sorted circle ecosystem is the presence of vegetation that, over a significant time, changes the soil mineralogy and thermal and hydrological soil properties. This then changes the amount of differential frost heave and reduces or enhances all bio-geophysical processes responsible for the formation and evolution of the non-sorted circles.

Abstract

The permafrost in the Qinghai-Tibet Plateau is characterized by massive ground-ice and high ground temperature. Under the influence of global warming, the permafrost is degrading. At the same time, many linear structures, including highways, gas pipelines, cable lines, electrical transfer lines, and railways, have been constructed during the past 50 years. Such engineering activities along with the rising air temperature have changed the permafrost environment along the Qinghai-Tibet Corridor. Field investigation shows that the main environmental hazards related to permafrost changes have widely developed, such as thaw slumping, thawing settlement, thermokarst, icing, frost mound, etc. The main factors causing these hazards include changes of conditions of the ground surface, the groundwater, and natural slope stability. Engineering treatment for preventing the hazards needs to be based on a good understanding of possible changes of ground thermal regime and water movement, along with their processes.

Keywords: engineering activity; hazard; linear structure; permafrost; Qinghai-Tibet Plateau.

Introduction

Permafrost covers 1,500,000 km^2 of area on the Qinghai-Tibet Plateau (Zhou et al. 2000). On the plateau, many linear structures such as highways, railways, gas pipelines, electricity-transmitting lines, and optical fiber cables have been constructed since the 1950s. The permafrost was initially discovered during construction of the Qinghai-Tibet Highway. Though permafrost was encountered at that time, no special engineering treatment was adopted, and the road embankment was just paved with side soils. During the construction, possible changes to the permafrost were not considered, and the seed for roadbed engineering problems was planted thereby. Environmental change caused by engineering activities can lead to environmental hazards, which simultaneously affect engineering stability. These hazards include thawing settlement, thaw slumping, thawing grooves, thermokarsts, frost heave, etc. The purpose of this paper is to introduce the permafrost situation in the Qinghai-Tibet Plateau, to describe some main thawing hazards and frost hazards along the Qinghai-Tibet Highway (QTH) and the Qinghai-Tibet Railway (QTR), to analyze formations of the hazards, and to discuss their treatments.

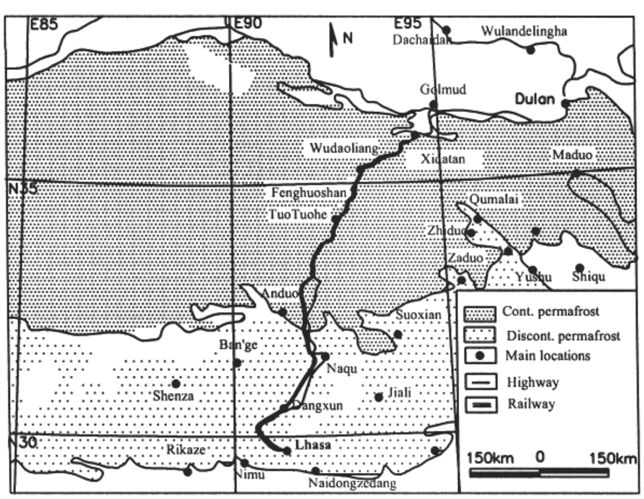

Figure 1. Permafrost distribution and the position of the highway and railway on the Qinghai-Tibet Plateau.

Permafrost and Engineering Activities in the Qinghai-Tibet Plateau

Permafrost comprises 75% of the total land of the plateau; its distribution is shown in Figure 1. The figure shows that along the highway and railway from Golmud to Lhasa, the northern limit of the permafrost is located in the Xidatan Basin north to the Kunlun Mountains. The southern limit is located in the Anduo Basin south to the Tanggula Mountains. The permafrost of the plateau features rich ice and high ground temperature. Take the 550-km-long continuous permafrost along the railway, for example. The section of

Figure 2. Thaw slumping at K3035 mileage of QTH.

permafrost with volume ice content higher than 20% is 221 km. The section with mean annual ground temperature (MAGT) higher than -1.0ºC (warm permafrost) is 221 km. On the whole, the warm and ice-rich permafrost is 124 km long (Liu et al. 2000, Wu et al. 2004).

As the permafrost of the plateau is warm and rich in ground-ice, it is sensitive to global warming and engineering activities. Monitored data from boreholes in the natural ground along the highway showed that the ground temperature at the permafrost table increased by a value of 0.08ºC/a from 1996 to 2001. The table was lowered 2.6 to 6.6 cm/a. According to investigations in past 30 a, the MAGT of the seasonal frozen ground, and the island permafrost along the QTH increased 0.3 to 0.5ºC from the 1970s to 1990s. The MAGT of the continuous permafrost increased 0.1 to 0.3ºC within the period. Under natural conditions, the permafrost area shrunk 0.5 to 1.0 km at the north edge and 1 to 2 km at the south edge. While affected by highway construction, it shrunk 5 to 8 km at the north edge and 9 to 12 km at the south edge (Wang & Mi 1993, Zhu et al. 1995, Nan et al. 2003). Therefore, the degradation influence of engineering activities on the permafrost was much more serious than that of natural forces.

To engineering projects, thawing settlement is the first response to degradation, and some phenomena related to the thawing easily occur, such as thaw slumping and thermokarst. On the other hand, in some cases when the hydrological conditions are changed in permafrost regions, other environmental hazards related to freezing can also occur, such as icing and frost heaving. On the plateau, all projects including highway, railway, cable line and pipe line are near parallel and concentrated in a region called the Qinghai-Tibet Corridor. The earliest project was the Qinghai-Tibet Highway. It was constructed in the 1950s, and repaired in large scale three times, mainly for treating problems caused by permafrost. From 1973 to 1977, a gas pipeline was constructed. The pipeline crossed 560 km of permafrost regions. In 2001, the Qinghai-Tibet Railway began to be constructed after nearly 30 years of intermittent planning, discussion, and investigation. The construction was finished in 2006, and the railway was opened to service in 2007. The electricity-transmitting line was constructed along the railway in 2006. We know that the highway has many problems in the permafrost section, but the railway, in service for one year, was constructed based on cooling-roadbed principles and cost much more than the highway. The railway's roadbed was stable according to our investigation from July to September in 2007. However, some environmental hazards along the railway related to construction activities in the permafrost section have occurred and might influence the roadbed stability in future. Here in this paper, some typical environmental hazards caused by engineering activities were introduced.

Main Environmental Hazards Along the Highway and the Railway

Thawing induced hazards

(1) Thaw slumping

Thaw slumping is commonly caused by slope toe disturbance in ice-rich permafrost regions. On the plateau, well-developed thaw slumping exists on the west side of the highway at K3035 mileage (Fig. 2) in the Kekexili Hill Region between Wudaoliang and the Fenghushan Mountains. In the slope, massive ground-ice with thickness of about 1 m was well developed and buried 2 m deep. The slumping was initially caused by cutting for embankment of the highway during 1990–1992. The failure showed as detachment of the active layer, and consisted of sand and silty clay. After years of repetition of the thawing-collapse-slide, the current 110 m long and 72 m wide landslide area was formed.

To survey the retrogressive process of the landslide area, some monitoring points and boreholes for monitoring the ground temperature, as shown in Figure 3, were installed in 2002. Monitored data of the 8 points near the back wall indicated that, from 2002 to 2006, the longest retrogressive distance at point 1 was 8.0 m. The collapse mainly occurred within a period from July to September, which is the main thawing period of a year. As the grass surface and the soil layers were destroyed when collapse occurred, the ground thermal status was also changed. Figure 4 was drawn with annually averaged ground temperature data obtained from borehole A in the undisturbed natural ground, and borehole B, in the failed zone. The figure shows that the temperature of natural ground at a depth of 0.0 m to 4.5 m was lower than that of the failed zone. Also, the thermal gradient in borehole B was very low, indicating that thermal exchange between the atmosphere and the ground in the failed zone was very limited. This might lead the permafrost in the zone to degrade.

As slope failure of thaw slumping is strikingly influenced by frozen soil, temperature, and groundwater, engineering treatments should fully consider these factors. Reasonable methods should be based on decreasing thermal energy entering the soil and draining groundwater, such as covering the collapsing zone with crushed stone, stacking grass bags filled with earth, re-vegetation, and so on.

(2) Thawing groove

A thawing groove is normally caused by linear cutting or

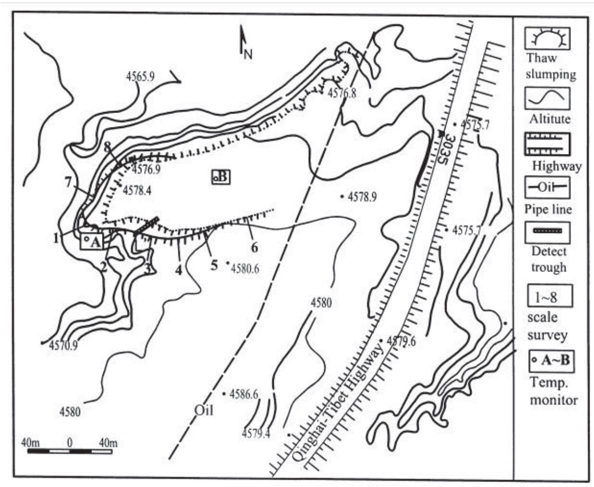

Figure 3. Relief map of the thaw slumping and the monitored positions.

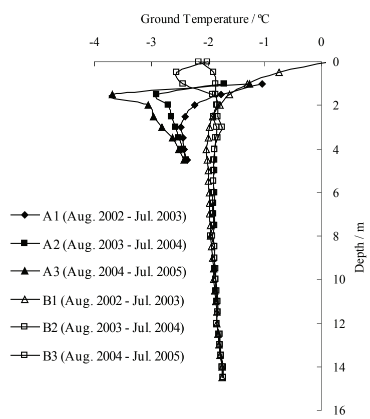

Figure 4. Annually averaged ground temperatures in borehole A and B.

even ground surface disturbance by truck or car driving in wet land in permafrost regions. Figure 5 shows a thawing groove developed along the QTR at K980 mileage south to the Kunlun Mountain. The strata here consisted of 10 m thick fine sand with gravels and the underlying silty clay. The permafrost table was 1.5 m in depth and the permafrost was ice-rich or ice-saturated. The embankment was constructed in 2003, and the slopes were covered with crushed stone in 2006. On the west side a 1.5 m high water barrier and drainage ditch were constructed in 2003. But in 2006, as surface water was gathered between the barrier and the embankment, the barrier was removed and the ditch was covered. According to our investigation, a 180 m long thawing groove along the former ditch developed with a depth of 20 cm in July 2007 (Fig. 5[a]) and then subsided to 40 cm in September (Fig. 5[b]). The gathered water shown in Figure 5(a) was mainly from ground-ice melting according to pit investigations, indicating that the subsidence was caused by thawing of the underlying frozen soils. Figure 6 shows the cross- section of the groove and its relative position to the embankment. Because of the settlement in the groove, many parallel fissures developed along the groove. The nearest fissure

(a)

(b)

(Figure 5. Thawing groove developed on the west side of QTR: (a) Status in July 2007; (b) Status in September 2007.

was 3.5 m from the embankment. Such a hazard needs to be remedied soon, otherwise it continues to develop and even worsen when surface water moves into the fissures and the groove. As it has laterally thermal erosion to the roadbed of the railway, its long existence ultimately affects roadbed stability.

The thawing grooves in some sections along the railway mainly resulted from insufficient understanding of the interaction among the earth surface, ground temperature regime, ground-ice, and melted water. To avoid such problems, engineering construction should be restricted so as not to disturb the surrounding environment. When thawing grooves occur, earth refilling, grass sheet covering, and even sunshine shielding, along with efficient drainage, can be adopted to stop groove development. Basically, the objective is to stop melting of the ground-ice

(3) Thermokarst

Thermokarst results from the thawing of ice-rich permafrost or the melting of massive ice. On the plateau, normal thawing or melting is caused by change or disturbance of the ground surface, as that makes the surface absorb more energy than before. We mentioned above that the embankment of the QTH was initially just stacked with
two side soils. That not only changed the original ground surface, but also left many pits along the way. Now many of the pits show as small thermokarst lakes or where water

accumulates. Thermokarst lakes with characteristic collapses of the shore land were different to surface accumulated water. We investigated the surface waters along the two sides of the highway and classified them into small thermokarst lakes and accumulated water in Table 1. The statistical data in the table show that 69 small thermokarst lakes developed mainly in the regions with ice-saturated permafrost or massive ground-ice. In the regions with low ice content permafrost, no thermokarst lake developed within the investigated 150 km zone. At the same time, surface water did not readily accumulate either.

To intensively investigate the thermal regime of the ground under a thermokarst lake, we drilled boreholes in a lake near the Fenghuoshan Mountain region, where permafrost is rich in ground-ice. The lake shown as Figure 7 was approximately elliptic, 150 m long and 120 m wide. The water in the lake was 2.0 m deep. Figure 7 shows that the shore edge collapsed during thawing time, which is a characteristic of a thermokarst lake. Six boreholes were drilled in the lake and in the shore land, and temperature probes were installed in 2006. Figure 8 shows positions of the boreholes and the local strata. Borehole investigation revealed that the permafrost table was buried 2.1 m deep. Under the table, the massive ground-ice existed with a thickness of about 3 m, which supplied a water source for the formation of the lake by melting.

Figure 9 shows the temperatures of the water and the humus deposits in the lake. The curves in the figure indicate that the lake water at a depth of 0.5 m processed phase change between water and ice. In fact the maximum ice thickness in winter was 0.7 m. The temperatures at other depths were all above 0ºC. The ground temperatures of the six boreholes at maximum-thawed-depth time were drawn in Figure 10. The figure indicates that the ground temperature in borehole 6, which was in the center of the lake, was higher than 0ºC. The permafrost table in boreholes 3–6 was 2.0 m deep, while in borehole 2, it was 7.2 m deep, as the borehole was in the lake area. The figure also shows that the ground temperature decreased from the lake to the land. Also, the ground thermal gradients were different. Such a situation was the same with the lakes studied by Burn at the west Arctic coast, Canada (Burn 2005). In that region, if lake ice freezes to the bottom sediments, it may be underlain by permafrost. Otherwise the thermal talik may penetrate through permafrost. Here, the thermokarst lake was somewhat similar to lakes in the Arctic region. Table 2 lists the calculated thermal gradient and estimated depth of the permafrost base in the different boreholes. The data in the table indicate that no permafrost existed, and there was a negative thermal gradient under the center area of the lake, hinting that the lake water provided a heat source to the underlying sediments. In the other boreholes, the temperature gradients were positive as normal. The permafrost base in the lake near the bank was 32.2 m deep, while far from the lake, the base depth lowered. Such differences revealed that the thermokarst lake has greatly influenced the existence of local permafrost. It also seriously laterally eroded neighboring permafrost. Therefore, if thermokarst existed near a roadbed, with time it would influence the thermal stability of the roadbed along permafrost regions. Engineering experience in permafrost regions of the plateau shows that good drainage systems and no-excavation are effective ways to avoid thermokarst.

Figure 7. Thermokarst lake near Fenghuoshan Mountain.

Freezing induced hazards

In the engineering constructions in the permafrost regions of the plateau, thaw settlement was paid much more attention than frost problems. As the permafrost degraded in the past years and the degradation continues, thaw settlement problems are becoming more serious than frost heave problems. However, when the groundwater seepage conditions are changed, outflow or new movement of the groundwater might cause frost heave problems.

Figure 11 shows an icing incorporated with a frost mound along the QTH in the Unfreezing Spring region (Budongquan region), where both permafrost and seasonal frozen ground exist. Springs are widely distributed and are the main

source of the local river. After the QTH embankment was constructed and some of the groundwater discharge was blocked, icings along with frost mounds resulted. Every winter several icings formed at the two sides of the highway within a 3 km section. Some of them even covered the road surface shown as Figure 11. At the same time, when icings and frost mounds thawed, the roadbed subsided unevenly. To solve such a hazard, groundwater migration routes need to be investigated, and seepage structures are necessary. In a road structure, sometimes a bridge is the final choice.

Conclusions

(1) Permafrost in the Qinghai-Tibet Plateau is in degradation under the influence of global warming. Moreover, in the narrow Qinghai-Tibet corridor, dense engineering projects have intensified the degradation and caused secondary hazards. These hazards mainly show as thawing settlement, thaw slumping, thawing grooves, thermokarst, frost heave, etc.

(2) Thaw slumping is commonly caused by slope toe disturbance in ice-rich permafrost regions. Well-developed thaw slumping along the QTH has developed to about 7500 m^2 in scale in the past 15 years. The permafrost in the slumping zone is under degradation, characterized by ground-ice melting and temperature-rising.

(3) Thawing grooves are mainly caused by linear cutting or even ground surface disturbance. A thawing groove which exists along the QTR subsided 40 cm in 2 years. Long-time development of the groove finally affects the roadbed stability by parallel cracks and lateral thermal erosion.

(4) Thermokarst results from the thawing of ice-rich permafrost or the melting of massive ice. There were 69 small thermokarst lakes in an ice-saturated permafrost section within 150 km along the QTH. Permafrost under a typical thermokarst lake near the Fenghuoshan region has totally thawed. Therefore, lateral thermal erosion of a thermokarst lake needs to be considered if it is near an engineering project.

(5) An icing incorporated with a frost mound along the QTH was cause by embankment blocking of groundwater discharge. The road surface was hard to keep even because the roadbed suffered frost heave and thaw settlement every year.

(6) Restricting ground surface disturbance and excavation, ensuring an efficient drainage system, and keeping the ground frozen are suggested ways to avoid the secondary hazards in permafrost regions of the plateau.

Abstract

The Schilthorn Crest in the Bernese Alps, Switzerland, is a prominent permafrost research site. Topographic and transient effects influence the temperature field below the east-west oriented crest. Measured T(z)-profiles in boreholes, however, do not provide sufficient information for a comprehensive description of the subsurface temperature distribution. We combine ground temperature measurements, electric resistivity tomography (ERT) monitoring, and numerical modeling to investigate the 3-dimensional thermal regime below the crest. The modeled temperature field of a north-south oriented cross section agrees well with ERT results along the same profile. The simulated thermal regime below the Schilthorn is characterized by generally warm permafrost, with the coldest zone below the upper part of the north-facing slope, and permafrost a little below the surface on the south-facing slope. The combination of temperature modeling and measurements and geophysical monitoring bears potential to improve simulation and validation strategies.

Keywords: alpine permafrost distribution; electrical resistivity; thermal modeling; tomography monitoring; transient and topographical temperature effects.

Introduction

Permafrost was first found on Schilthorn summit, Switzerland, when the facilities for the cable car were built between 1965 and 1967. During the construction of the buildings, several ice lenses with a thickness of up to 1 m were encountered. Since then, extensive research has taken place on Schilthorn (e.g., Imhof 2000, Vonder Muehll et al. 2000, Hauck 2001, Mittaz et al. 2002, Hilbich et al. 2008), making it to one of the most intensively investigated permafrost sites in the European Alps. Three boreholes in perennially frozen ground were drilled within the PACE-project between 1998 and 2001 (Harris 2001). These boreholes provide the basis for monitoring and quantification of changes in the permafrost thermal regime.

In mountain areas, the interpretation of T(z)-profiles measured in boreholes with respect to climate signals is complicated by topographic effects (Gruber et al. 2004). The Schilthorn represents an east-west oriented ridge with a warm south-facing and a colder north-facing slope. Even though measured temperature profiles in boreholes enable an initial assessment of topography related and transient effects, they are only representative of isolated local spots. A comprehensive analysis of permafrost distribution and evolution below the crest can only be achieved by integrating additional subsurface data

Figure 1. View of the Schilthorn Crest in the Bernese Alps looking eastward. The ERT-Profile starts just below the meteo station in the northern slope and reaches across the crest approximately to the southern border of the photo.

In this paper, we combine measurements of surface and subsurface temperatures, electric resistivity tomography (ERT), and numerical modeling of a subsurface thermal field for a 2-dimensional investigation of permafrost conditions below the Schilthorn crest. A 2D heat transfer model is forced by measured near-surface temperatures at the upper boundary to simulate the thermal field of a north-south cross section of the ridge. An ERT monitoring system was installed across the same profile, which provides additional information on subsurface conditions, and enables comparison of modeling results for a qualitative validation.

The Field Site

The Schilthorn (2970 m a.s.l., 46.56°N/7.83°E, Figs. 1, 2) is located in the Bernese Oberland in the Northern Swiss Alps. The three boreholes are located on a small plateau on the north-facing slope approximately 60 m below the summit. Air temperatures recorded at the meteo station close to the boreholes indicate an annual mean of -2.8 °C for the years 1999–2007 (Hoelzle and Gruber 2008). The annual precipitation is estimated to 2700 mm and about 90% of it falls as snow (Imhof 2000). As the precipitation maximum occurs during summer and due to additional snow input through wind transport, the snow cover on the northern slope usually persists from October until June or even July (Hauck 2001). The average snow depth since the beginning of measurements at the meteo station in 1999 is around 80 cm. The Schilthorn consists of dark micaceous shales that weather to form a fine-grained debris layer of up to several meters in thickness covering the entire summit region. The ice content of the subsurface material is assumed to be generally low (around 5–10% in the upper meters, as reported from direct observations, Imhof et al. 2000, Vonder Mühll et al. 2000).

Temperature Measurements

Boreholes

In the scope of the PACE project, a 14 m borehole was drilled in 1998 and complemented by two 101 m boreholes in 2000. Today, these boreholes are part of the Permafrost Monitoring Switzerland (PERMOS). The deeper boreholes were drilled vertical and with an angle of 60° to the vertical in order to account for topography-related effects. Temperatures measured in these boreholes point to warm permafrost conditions with temperature values between -1 and 0°C below depth of the zero annual amplitude (ZAA) at approximately 20 m, and to a very small temperature gradient with depth (Fig. 3, left). The temperature gradient in the oblique borehole is slightly greater than in the vertical borehole. Ground temperatures are considerably higher compared to other sites at similar altitude and exposition, which is probably due to the low bedrock albedo, thick snow cover, and low ice content at the site (Hauck 2001).

Ground surface temperatures

In addition to the borehole measurements, 14 temperature loggers were distributed on both sides of the crest in summer 2005 and 2006 to measure near surface-temperatures (see Fig. 2). The loggers were installed at a depth of 30 cm (UTL mini loggers) and 10 cm (rock temperature loggers), respectively, and temperatures are recorded every 2 hours. The accuracy of the temperature loggers is given as ±0.25°C and ±0.1°C, respectively. As the lower parts of the steep southern slope are difficult to access, loggers were only placed in the upper part of the slope. These near-surface temperature measurements provide the upper boundary condition for the numerical heat transfer model presented in the following section. In addition, they can be used to constrain the interpretation of the geophysical results concerning the subsurface thermal regime.

Numerical Modeling of Subsurface Temperatures

General approach

We considered a purely conductive transient thermal field under variable topography in an isotropic and homogeneous medium according to Carslaw and Jaeger (1959). In steep topography, heat transfer at depth mainly results from conduction, driven by the temperature variations at the surface. Processes such as fluid flow are not included in this first step. Subsurface temperatures are calculated for conditions in the hydrological year 2006/2007 (i.e., 1 Oct. to 30 Sept.) based on mean annual conditions at the surface. That is, seasonal variations at the surface are not included, and temperature variations above the ZAA are not simulated.

Ice contained in the pore space and crevices delays the response to surface warming by the uptake of latent heat during warming. This is addressed in our finite-element heat transport model by apparent heat capacity, which substitutes the volumetric heat capacity in the heat transfer equation and includes energy consumed during phase change. We used the approach described by Mottaghy & Rath (2006).

The resulting temperature pattern is expected to be similar for any north-south oriented cross crest profile. Hence, simulations are conducted for a 2D section across the crest and the borehole site on the northern slope. The assumption of symmetry in an east-west direction is supported by first results of a quasi-3D geoelectrical investigation including four parallel and two orthogonal ERT-profiles in the Schilthorn summit area (Krauer 2008). The selected profile was extracted from a digital elevation model (DEM) with 10 m horizontal resolution (Data Source: Swissphoto). The finite element (FE) mesh was generated for this geometry with corresponding 10 m resolution at the surface, and lower resolution at greater depth. The mesh consists of 1468 elements. The software package COMSOL Multiphysics was used for forward modeling of subsurface temperatures.

Boundary conditions

For all near-surface temperature loggers the mean annual temperature for the hydrological year 2006/2007 was calculated and set as an upper boundary condition at the corresponding elevation and side of the modeled profile. The measured thermal offset between the ground surface and TTOP is small at Schilthorn (about 0.3°C; cf. Hoelzle & Gruber 2008) and is, hence, neglected in the simulations.

The years 2006 and 2007 were very warm and clearly above the long-term average. Therefore, measured near-surface temperatures are not representative for the thermal conditions at the surface during the past decades and century. Transient effects are likely to occur and, therefore, initialization of the heat conduction model is required in order to perform a realistic simulation of the current subsurface temperature field. Based on the assumption that surface temperature fluctuations mainly follow air temperatures, we used mean annual air temperatures (MAAT) from the meteo station on Jungfrauoch (3576 m a.s.l., Data source: MeteoSwiss) some 10 km east of Schilthorn to describe the evolution of the upper boundary. For Jungfraujoch, air temperature data is available back to 1933. The total difference in MAAT between 2006 and the mean of the period 1933–1950 is +1.52°C. We additionally assumed a difference in air temperature of +0.5°C between the start of the data recordings and the Little Ice Age (ca. 1850). The model initialization was started in 1850, and daily time steps were taken. A uniform lower boundary heat flux of 0.08 W m^{-2} was set at sea level, and thermal insulation was assumed for the lateral boundaries of the geometry.

Subsurface properties

Subsurface material properties were assigned on the generated FE mesh. In purely diffusive and transient simulations, thermal conductivity, volumetric heat capacity,

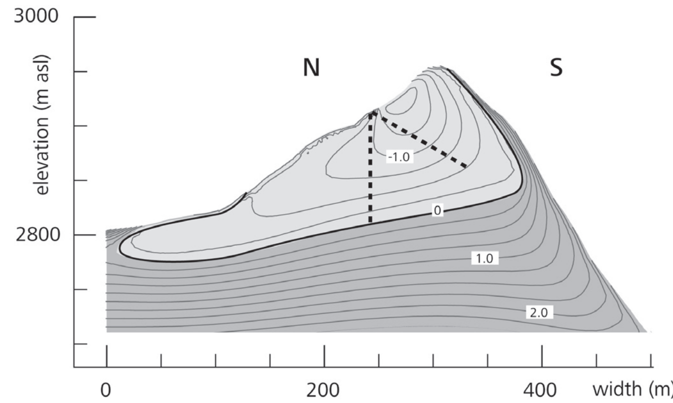

Figure 4. Isotherms of the modeled subsurface temperature field for a north-south cross section of the Schilthorn crest. The 0°C isotherm is depicted in black, and the dashed black lines indicate the boreholes. Light gray areas are permafrost, darker shaded areas are outside permafrost (colored illustration available on CD-ROM).

and the ice/water content are the petrophysical parameters of importance. However, only little is known on the subsurface characteristics below steep topography and the parameters were set based on published values: Thermal conductivity was assumed as 2.5 W K^{-1} m^{-1}, and heat capacity to 2.0 x 10^6 J m^{-3} K^{-1} for the bulk material (Cermák & Rybach 1982).

Based on estimations from geophysical measurements (cf. Hauck et al. 2008) for the upper layers, a uniform ice content of 5% for the entire profile was assumed in the model simulations. The unfrozen water content is described by an exponential function, and the steepness factor was set to 0.2 (cf. Mottaghy & Rath 2006).

Modeling results

The resulting temperature field for the Schilthorn profile is depicted in Figure 4. Maximum permafrost thickness amounts to roughly 100 m below the northern slope and the top of the crest. Isotherms are steeply inclined in the top part, and a lateral heat flow exists from the warm south to the colder north face. Simulated permafrost temperatures are higher than -2°C for the entire profile.

The coldest temperatures exist below the northern and central part of the ridge. The reason is that coldest surface temperatures are found in the steep part of the northern slope (mainly due to reduced solar radiation and longer snow cover duration), and that surface temperatures are higher on the small plateau where the boreholes are located, as well as on the southern side. The southern slope is mainly permafrost-free at the surface. However, due to the cold, northern slope permafrost can be found below the surface. In addition, this is caused by the fact that 20th century warming has not yet penetrated to greater depth in the model, which lowers the temperatures a few tens of meters below the surface compared to present-day steady-state conditions. Similarly, permafrost remains below the surface at the foot of the northern slope. These results point to the importance of transient 2D/3D modeling, as such transient and topography related effects could not be detected using steady state 1D models.

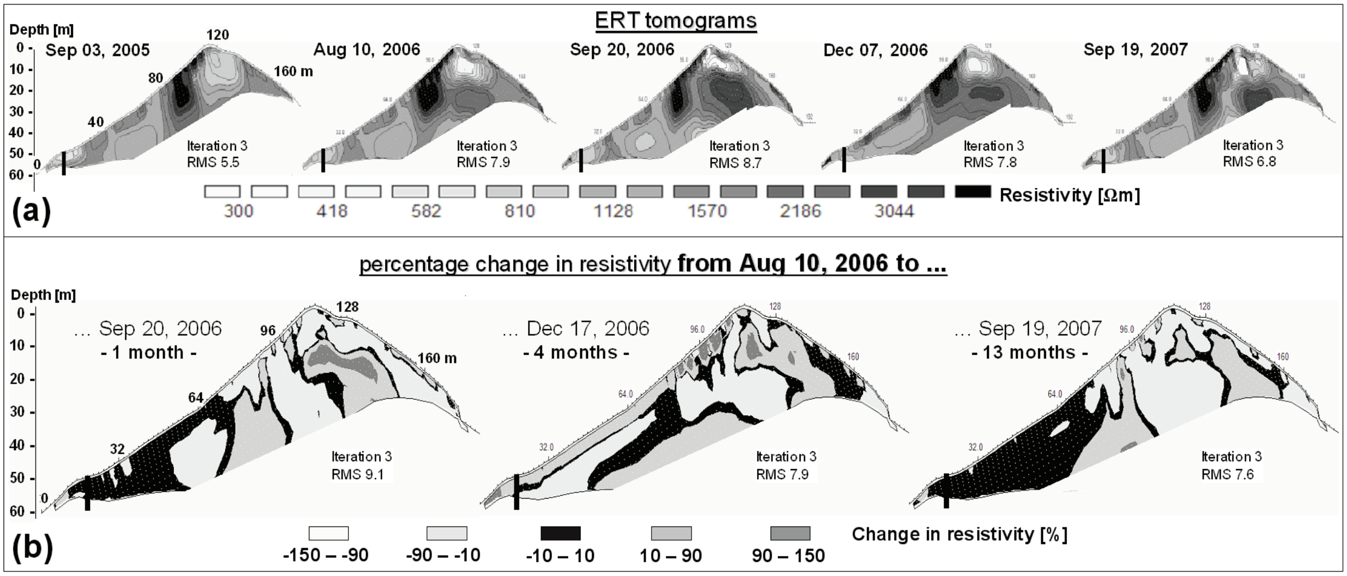

Figure 5. ERT monitoring data illustrated as individual resistivity tomograms for subsequent measurements (a), and as calculated change in resistivity based on the reference profile from August 10, 2006 over one, four, and 13 months (b; colored illustration available on CDRom).

In contrast to ERT profiles (c.f. next section), which mainly allow for a qualitative validation of the general pattern of temperature distribution, comparison with extracted T(z)-profiles at the locations of the boreholes shows the accuracy of the modeled temperature values (Fig. 3). In general, the modeled profiles correspond to the measured data in Figure 3 as temperatures are below -1.5°C for the entire profile, and temperature gradients with depth are small. For both measured and modeled profiles, the oblique borehole shows a slightly more curved profile. However, temperatures of the modeled profile average about 0.2°C colder than the measured values, but range up to 1°C in the upper half of the profile. Further, in the lower parts, the oblique profile is warmer than the vertical profile, which could not be reproduced in the simulation. The results are encouraging given the model error sources, which include: (1) subsurface properties (i.e., ice content, thermal conductivity) are assumed as homogenous for the entire profile and are hardly known at depth; (2) the temperature evolution at the surface may be influenced by effects of solar radiation and snow cover, and, hence, not exactly follow air temperature. In addition, the higher ice content in the limestone scree in the upper meters can slow down the reaction of the subsurface to changing surface temperatures by the uptake of latent heat; (3) small scale variability at the site may cause random errors in logger measurements, and (4) processes such as heat transport by convection are not taken into account.

Geophysical Measurements

Electrical Resistivity Tomography (ERT)

In 1999, a semi-automatic ERT monitoring system was installed on a 60 m line close to the three boreholes in the north facing slope to observe subsurface resistivity changes with respect to ground ice and water content (Hauck 2001, Hilbich et al. 2008). In summer 2005, a second ERT monitoring line (188 m) was installed across the crest, complemented by a quasi-3D ERT survey along four transects across the crest in 2006. Datasets across the crest can be used to analyze the 3D permafrost distribution.

The measured signal is sensitive to temporally variable properties such as temperature, via the unfrozen water, and ice content, as well as unchanging material characteristics, such as lithology and porosity. Repeated ERT measurements, therefore, yield information on the changes occurring in the physical properties of the ground with changing temperature and time (Fortier et al. 1994).

ERT monitoring data of the cross-crest profile (Fig. 2) are available on different time scales: (a) annual measurements in late summer (August/September) for 2005, 2006, and 2007, and (b) seasonal-scale measurements between August and December 2006. Whereas the annual resolution provides interannual resistivity changes between 2005 and 2007, the seasonal scale helps to identify zones with pronounced resistivity changes to delineate ice-free from ice-rich regions. ERT data were processed with the software RES2DINV (Loke & Barker 1995). Besides a qualitative comparison of individual tomograms, a so-called time-lapse inversion of time series of ERT data allows for a quantitative assessment of the resistivity changes.

Results

Figure 5 shows the results of the ERT monitoring across the Schilthorn Crest. In general, measured resistivities are quite low compared to other permafrost sites and do not exceed 4000 Ωm. This is mainly due to the thick fine-grained debris layer covering the summit region. Outcrops of the underlying bedrock also indicate strongly weathered conditions of the micaceous shales with crevices, where water can percolate. In addition to the comparably conductive host material, the low ice content is in accordance with the low resistivity values.

A number of features can be observed in all tomograms (cf. Fig. 6): (A) a relatively homogeneous zone with resistivities between 700 and 1600 Ωm in the lower part of the northern slope, (B) a high resistive zone (>3000 Ωm) in the upper part of the northern slope, (C) a homogeneous intermediary zone in the southern slope with resistivities from 1200 to 1700 Ωm, and (D) a very low resistive anomaly (<500 Ωm) with an underlying high resistive anomaly (>2300 Ωm) at the summit.

The high resistive anomaly in the northern slope (B) may indicate the presence of ground ice and/or firm bedrock. Both possibilities would result in increased resistivity values compared to regions with lower ice contents or more weathered bedrock occurrences, respectively. The low resistive anomaly at the crest (D) is difficult to interpret. In comparable terrain, such low resistivity values are normally associated with very high amounts of unfrozen water or conductive man-made structures (e.g., cables). The presence of such a large amount of water is very unlikely since the crest consists of firm bedrock without a superficial debris cover, whereas metallic remnants from the construction of the summit station (e.g., anchors) are found all over the crest. A man-made low resistive anomaly can therefore, not be excluded. The high resistive anomaly directly below this feature is believed to be an inversion artifact, which is often generated during inversion below a zone of anomalously high or low resistivity values (Rings et al. 2007).

Apart from the high and low resistive anomalies close to the crest, the characteristics of the northern (A) and southern (B) slope seem to be similar. From the qualitative analysis of the individual tomograms no clear indication of differences in permafrost occurrence and ice content between the two slopes is apparent. Calculating the percentage change of resistivities between subsequent measurements (Fig. 6), the tomograms can be transferred into information on seasonally changing properties. From this, zone (A) in the northern slope can be seen as a region with little change in the deeper parts but with pronounced resistivity changes within the upper 4–5 m. This clearly indicates the presence of permafrost with active layer freezing in winter. The deeper parts tend to exhibit slightly lower resistivities in winter, which we interpret as delayed advance of the summer heating (increasing unfrozen water content and therefore decreasing resistivities) into the ground. Zone (B) only yields systematic resistivity changes near the surface, that can be attributed to thawing (decreasing resistivities) between August and September and freezing (increasing resistivities) processes until December. Both processes are similar to the features in zone (A) but seem to be more pronounced. Zone (C) is characterized by a homogeneous resistivity decrease during summer, but shows almost no changes between August and December, i.e., no active layer freezing can be observed. In contrast to the very similar absolute resistivity values, seasonal changes are different in the northern and southern slope. This can be related to differences in subsurface material properties, i.e., permafrost or ice content.

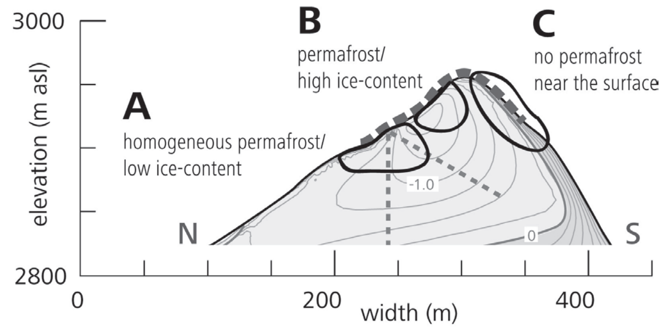

Figure 6. Three features that are addressed in the discussion section are highlighted by black circles: (A) A homogeneous permafrost zone in the lower northern slope with low ice content, (B) a cold zone in the north slope with a high ice content, and (C) no permafrost near the surface on the southern slope. Additionally, grey dashed lines indicate the boreholes and the extent of the ERT profile (colored illustration available on CD-ROM).

Discussion

In both the modeled temperature field and the ERT profiles, three zones in the investigated cross section of the Schilthorn Crest can be distinguished that are particularly interesting (Fig. 6). Cross validation of the results of the two complementary approaches enables an interpretation as follows.

(A) In the lower part of the northern slope, a zone of homogeneous temperatures and resistivities exits. The small variations in temperature in this area may be explained by the fact that temperature values are only little below the melting point and the energy input of the recent warming is consumed by latent heat. Also, the results from ERT monitoring suggest high amounts of unfrozen water and only little ice content (Hauck et al. 2008).

(B) In the upper part of the northern slope a zone of cold temperatures exists. The corresponding zone of high resistivity in the ERT profile is, hence, probably caused by higher ice content rather than by geological characteristics. This is also supported by the larger seasonal resistivity changes pointing to higher contents of ice and unfrozen water than in the lower part of the northern slope.

(C) The permafrost boundary on the southern slope is likely situated only a little below the surface, an effect that can be mainly attributed to surface warming of the past century that has not yet affected greater depths. Seasonal resistivity changes support the hypothesis that there is no permafrost near the surface in the southern slope.

The results of this qualitative validation corroborate the assumption that the general pattern of the subsurface temperature field can be modeled using diffusive and transient 2D and 3D simulations. Using such an approach enables the simulation of temperature fields at greater depths that cannot be reached by geophysical measurements or direct measurements in boreholes. Additionally, the numerical model can be used to calculate scenarios of the evolution of subsurface temperatures and of future permafrost occurrence below the Schilthorn Crest by prescribing the evolution of the upper boundary condition or by coupling the model to a surface energy balance model and/or using regional climate model output (cf. Noetzli et al. 2007).

Conclusions and Perspectives

The subsurface thermal field of a 2D-section across the Schilthorn was modeled assuming a purely conductive and homogenous underground in a first approach. Comparison with measured ground temperatures and ERT profiles leads to the following conclusions:

- The subsurface thermal regime of the Schilthorn Crest is predominantly influenced by both topography and transient effects. The cold northern slope and the recent 20th century warming induce permafrost on the southern side of the crest only a little below the surface.
- The thermal regime of the profile can be characterized by a cold zone below the upper part of the northern slope, permafrost occurrence only a little below the surface on the southern slope and in the lowest part of the northern slope, and rather homogeneous conditions at and below the area of the boreholes.
- The modeled temperature field agrees with the results from ERT monitoring. The three zones mentioned above can be distinguished in the results of both methods.

ERT monitoring on Schilthorn is being continued in the scope of PERMOS. The combination of thermal modeling, temperature measurements in boreholes and geophysical surveys bears potential to further improve modeling and validation strategies. These may include (1) quantitative comparison of numerical results and measured data to estimate model performance, (2) extending single point temperature data to larger scales using 2D or 3D resistivity values, and (3) improving the representation of the subsurface physical properties in the model by incorporating subsurface information (e.g., geological structures, water/ice content) detected by geophysical surveys.

Acknowledgments

We are indebted to Michael Krauer for making available the ERT data measured within his M.S. thesis. Further, we'd would like to thank the motivated students that helped us in the field and the Schilthornbahnen AG for generous logistic support. Part of this study (JN) was financed by the Swiss National Science Foundation as part of the NF 20-10796./1 project, and geophysical fieldwork (CH) was partly financed by PERMOS.

The Effect of Fines Content and Quality on Frost Heave Susceptibility of Crushed Rock Aggregates Used in Railway Track Structure

Antti Nurmikolu and Pauli Kolisoja
Tampere University of Technology, Tampere, Finland

Abstract

The high smoothness requirement of rails does not allow frost action in the structural layers of the track. Long-term experience with the use of crushed rock aggregates in the uppermost layer of the track, the ballast bed, indicates that the aggregates degrade substantially with accumulating traffic loading. In Finland, the use of crushed rock aggregates has recently extended to the lower structural layers (subballast). For the purpose of setting optimal material requirements for crushed rock aggregates, their degradation and its impacts on frost susceptibility have been studied at TUT. Sampling, a total of 132 frost heave tests, and a large number of laboratory index tests revealed that in certain crushed rock aggregate the frost susceptibility at under 15% fines content was directly proportional to the fines content. In the combined analysis of various aggregates, the observation of quality of fines improved the correlation.

Keywords: ballast; crushed rock aggregate; fines; frost heave test; frost susceptibility; pore size distribution.

Introduction

The smoothness requirement of railway tracks is extremely high and is tightening along with increasing train speeds. Even relatively small deviations in track geometry limit the competitiveness of environmentally friendly rail traffic, as travel times increase and traffic capacity diminishes. In cold climates frost action is an essential factor behind the vertical deviations of track geometry. Because structural layers are generally considered to be built of "non-frost-susceptible" materials, the frost action of traffic routes is commonly associated with problems in the frost-susceptible subgrade. However, in the severe loading environment of the track structure, crushed rock aggregates degrade as a consequence of traffic loading, maintenance operations, and environmental loadings. The tendency towards higher axle loads and train velocities further increases the loading applied to structural layers.

Coarse-grained and uniformly graded crushed rock aggregate, ballast (Fig. 1), is traditionally used in the uppermost structural layer of a track. A literature review by Nurmikolu (2005) showed that many studies dealing with the degradation of ballast have been published. As a result of ballast degradation, its water retention, frost susceptibility, and deformations increase. Finally, the effectiveness of the maintenance performed to keep the track geometry at an acceptable level decreases to the extent that the most economical alternative is to clean the ballast with a special sieving machine in the field. Published research data dealing directly with the frost susceptibility of ballast are scarce, though at least in Finland, maintenance operators have distinct experiences of frost action in ballast causing deviations in track geometry. In a recent field study Akagawa (2007) found that degraded ballast causes significant frost heave in a track. Studies dealing with the frost susceptibility of other coarse-grained materials, such as the base course aggregates of roads, have been published in recent years, perhaps due to the increased smoothness requirements, for example, by Guthrie & Hermansson (2003) and Konrad & Lemieux (2005). It is obvious that the frost susceptibility criteria for the crushed rock aggregates of modern railway track structure cannot be determined on the basis of that literature.

Unlike in the case of ballast, there is no experience of the long-term behavior of crushed rock aggregates in the structural layers below the ballast bed. The use of crushed rock aggregates in the intermediate and frost protection layers (subballast) started in Finland with the 74 km Kerava-Lahti double track line finished in 2006. From the degradation point of view, the stress levels in the lower parts of the structure are of course lower than in the ballast but, on the other hand, cleaning of the lower layers in the same manner as the ballast bed is practically impossible. Therefore, a 100-year service life is required of the substructure (Finnish Rail Administration 2005). In order to distribute the loading applied to the subgrade, to diminish deformations and to prevent convective heat transfer (Goering et al. 2000), the material of the frost protection layer must be more fine grained and more broadly graded than ballast. Consequently, the material can become frost susceptible as a result of lesser degradation than ballast.

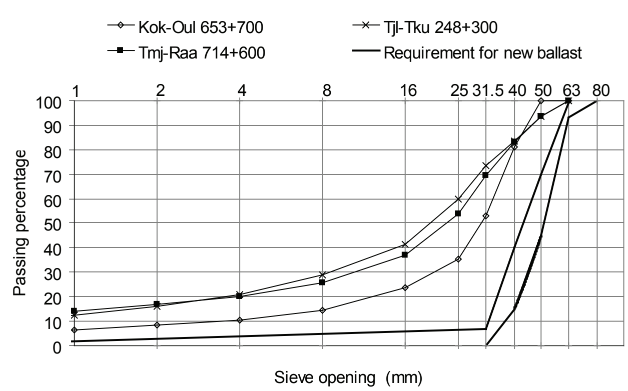

Figure 1. Finnish grading requirement for fresh ballast and examples of degraded samples taken from track structure.

Experimental Studies

Test materials and methods

The degradation of the crushed rock aggregates used in the structural layers of tracks and the quality of the produced fines was studied by long-term cyclic loading tests, ballast bed sampling, and laboratory tests of the samples. The studies concerning degradation have been described elsewhere (Nurmikolu et al. 2001, Nurmikolu 2005) as well as those dealing with the evaluation of the ballast bed's degradation stage by GPR (e.g., Silvast et al. 2007). The samples of the degradation examinations were utilized also in frost susceptibility studies.

The fines generated from ballast in an actual loading environment of a track structure were considered to be the best approximation of the quality of fines possibly produced by degradation of crushed rock aggregates in the lower structural layers. Frost susceptibility examinations were focused on 36 degraded ballast bed samples that had been in service without cleaning for a long time (mainly over 30 years or subject to 40–340 million gross tons of train loading). The sampling points were also decentralized geographically across as much of the rail network as possible to ensure a comprehensive sample of different parent rocks. Also, seven fresh, unused crushed rock aggregates from the quarries and eight natural gravels and sands, mostly from the substructure of the track, were examined. Of the fines of the samples, grain-size distribution (Sedigraph equipment), mineralogy (X-ray diffraction), specific surface area (nitrogen adsorption), pore size distribution (mercury porosimeter), water adsorption, humus content (ignition method), and surface texture (Scanning Electron Microscope) were examined. Of the coarse particles several properties were studied, too, water adsorption being the most important in terms of frost action. A total of 132 frost heave tests were done with the samples with various fines contents and grain-size distributions in the arrangement described next.

Frost heave test arrangement

The frost heave test method has not been internationally standardized. Thus, the results yielded by various arrangements, some of them listed (e.g., by Chamberlain 1981) are difficult to compare. Based on a literature review of the test methods (Nurmikolu 2005), the step freezing test arrangement was considered the most suitable for this research and was set up. In this arrangement the specimens were prepared by the Intensive Compactor Tester (ICT 150RB) into a PVC pipe (inside diameter 150 mm) which served as the specimen mould in the test. The intention was to achieve sample height of 150 mm but, due to fixed compaction effort, specimen heights varied mainly from 145–155 mm. The key decision with regard to minimizing technical testing constraints was to use a cut-up mould pipe (Fig. 2) in the test arrangement, as also recommended by ISSMFE (1989). The frictional force operating at the interface between the mould walls and the aggregate, which is increased by the freezing of water, limits the occurrence of frost heave. Different solutions have been sought for the problem such as discussed by Kujala (1991). In the cut-up mould pipe individual mould rings can separate from each other during frost heave. Then, there is movement between the mould and aggregate only within part of one mould ring, whereby the frictional force resisting frost heave is considerably less compared to a continuous mould pipe. This was obvious also based on the experimental results which showed the frost heave in a cut-up mould pipe to be 2- to 4-fold compared to a continuous pipe using identical sample materials.

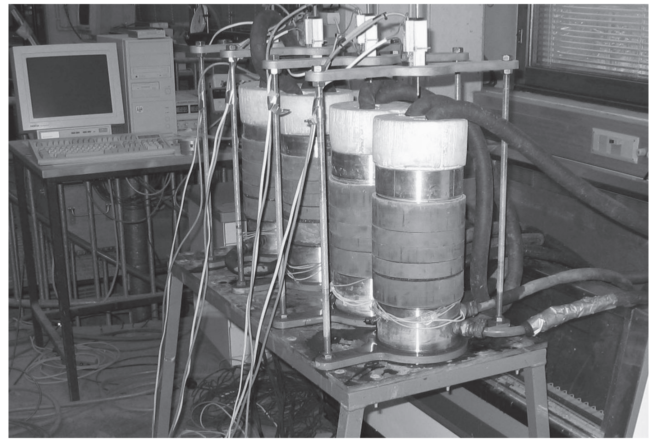

Figure 2. Frost heave test arrangement at TUT.

The equipment built for frost heave testing enabled freezing four samples simultaneously. Before starting the test, seven thermocouples were attached to a specimen at 25 mm intervals. At the beginning of the test the specimens were saturated by keeping them submerged in water for a day. At the same time the specimens were cooled to 1°C–2°C. Then the water level was lowered to about 12 mm above the bottom level of the specimen material, and the specimens were thermally insulated in order to minimize radial heat flows. The specimens were frozen in the natural freezing direction from top to bottom. The temperature of the top surfaces of specimens was controlled by circulation of a cooling agent to -3°C, and the bottom surfaces of specimens with water circulation to +1°C. The supply of additional water for specimens was secured during freezing in line with the view of Konrad and Lemieux (2005), who considered free water flow important in testing the materials of traffic routes. Frost heave was measured during the test by displacement transducers attached to specimen frames. The freezing phase was continued for a minimum of four days. The only load resisting frost action in the tests was the 3 kPa pressure from the caps.

The frost heave specimens made from ballast layer samples were, for the most part, made by proportioning the grain-size distributions (Fig. 3) from sieved fractions as desired to allow comparing the impact of fines quality. The selection of frost heave specimen grain-size distributions was tied to the typical grain-size distributions of degraded ballast bed samples and the recommended grain-size distribution of subballast material and likely progress of degradation (Nurmikolu 2005). Due to the test scale, the maximum grain

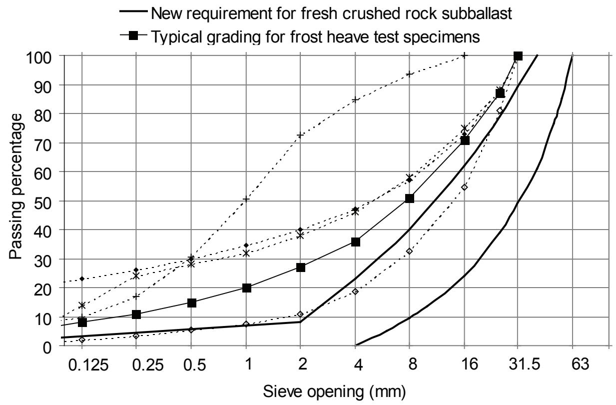

Figure 3. Typical grading curves of crushed rock samples proportioned for frost heave test specimens. Dashed curves depict variation range of tested gradings. New Finnish requirement for grading of fresh crushed rock subballast is presented, too.

size of frost heave specimens was limited to 31.5 mm. Frost heave tests on gravel and sand samples, as well as some of ballast bed samples, were done using their natural grain-size distribution of under 31.5 mm.

Parameters depicting frost susceptibility

Several parameters depicting frost susceptibility were among the analyzed results of the frost heave tests, such as accumulated frost heave, frost heave ratios, and frost heave rates after various freezing periods. A parameter independent of freezing conditions, the segregation potential (presented by Konrad 1980), was not determined, because the flow rate of the additional water into the sample was not measured. Instead, the "frost heave coefficient," which is similar in principle and is used commonly in Finland in frost dimensioning of road structures, was determined. The frost heave coefficient, *SP*, (mm/Kh) is determined from Equation 1, where *v* is the frost heave rate (mm/h) and *gradT_* is the average temperature gradient in the frozen sample section (K/mm).

$$SP = \frac{v}{gradT\_} \tag{1}$$

The primary difference in principle between the frost heave coefficient and segregation potential is that the *v* in Equation 1 indicates the flow-rate of water into the freezing zone instead of the frost heave rate when determining segregation potential (Konrad 1980). Thus, in water saturated material the frost heave coefficient can, in principle, be considered about 1.09-fold compared to segregation potential with the assumption that all the water flowing to the freezing zone ends up thickening the ice lens. However, the in situ frost heave occurring in completely or nearly water-saturated material is accounted for in the frost heave coefficient but not in the segregation potential, which increases the above-mentioned difference in water-saturated material. In an unsaturated state the difference is more difficult to assess since, according to Guthrie and Hermansson (2003), ice segregation may take place due to a material's internal water flow in the absence of external additional water. This kind of frost action cannot be depicted based on the flow rate of additional water into the material, but it is considered by the frost heave coefficient. Another difference in principle between the concepts is that when determining the segregation potential, the temperature gradient should be observed in the partly frozen zone at the frost front, not throughout the frozen layer, which is easier to measure.

As suggested by Konrad (1980) for the segregation potential, the reference value for the frost heave coefficient was determined at the moment the transient freezing phase changes into the stationary freezing phase, that is, as the frost front stops migrating in the sample. Due to the large variations in the frost heave coefficient during the test, it is highly important to follow a systematic practice, although sometimes the moment is hard to determine, as the frost front continues migrating very slowly.

Test Results and Discussion

The impact of grain-size distribution on frost susceptibility

The amount of fine-grained material coarser than fines (>0.063 mm) was observed to have an insignificant effect on the frost susceptibility of crushed rock aggregates within the range of variation normally occurring in the case of materials of the track structure. The impact of the other features of grain-size distribution on frost heave was also found insignificant in practical terms with the examined crushed rock aggregates and the grain-size distribution variation range allowed by the test method (Fig. 3). Observations (e.g., by Konrad 1999) suggest that the frost susceptibility of uniformly graded material may be lower than that of broadly-graded material containing an equal amount of fines. In crushed rock aggregates, however, especially in the case of uniform grain-size distribution and large maximum grain size which allow internal sorting, as with ballast, the finest fraction accumulates at the bottom of the material layer. In fact, internal sorting may result in a non-frost-susceptible material becoming locally frost-susceptible.

The impact of fines content on frost susceptibility

It is natural to start an analysis of the effect of fines content on frost susceptibility with test results on a specific aggregate with different fines contents. Figure 4a shows that after 4 days of freezing (h_{96h}), the frost heave of a specific fresh crushed rock aggregate is fully linearly dependent on the amount of fines in the material within the estimated repeatability limits of the test (Nurmikolu 2005). This applies to fines contents below 15%. The dependence is about the same as regards the frost heave coefficient (SP_o) (the subindex indicates the unloaded nature of the tests) in Figure 4b. Based on all the tests with fines content below 15%, the mutual correlation coefficient (R) between h_{96h} and SP_o was as high as 0.95, but yet h_{96h} correlated generally slightly more closely with the fines content, which is why the following figures only include h_{96h}.

When the analysis of Figure 4a is widened by including

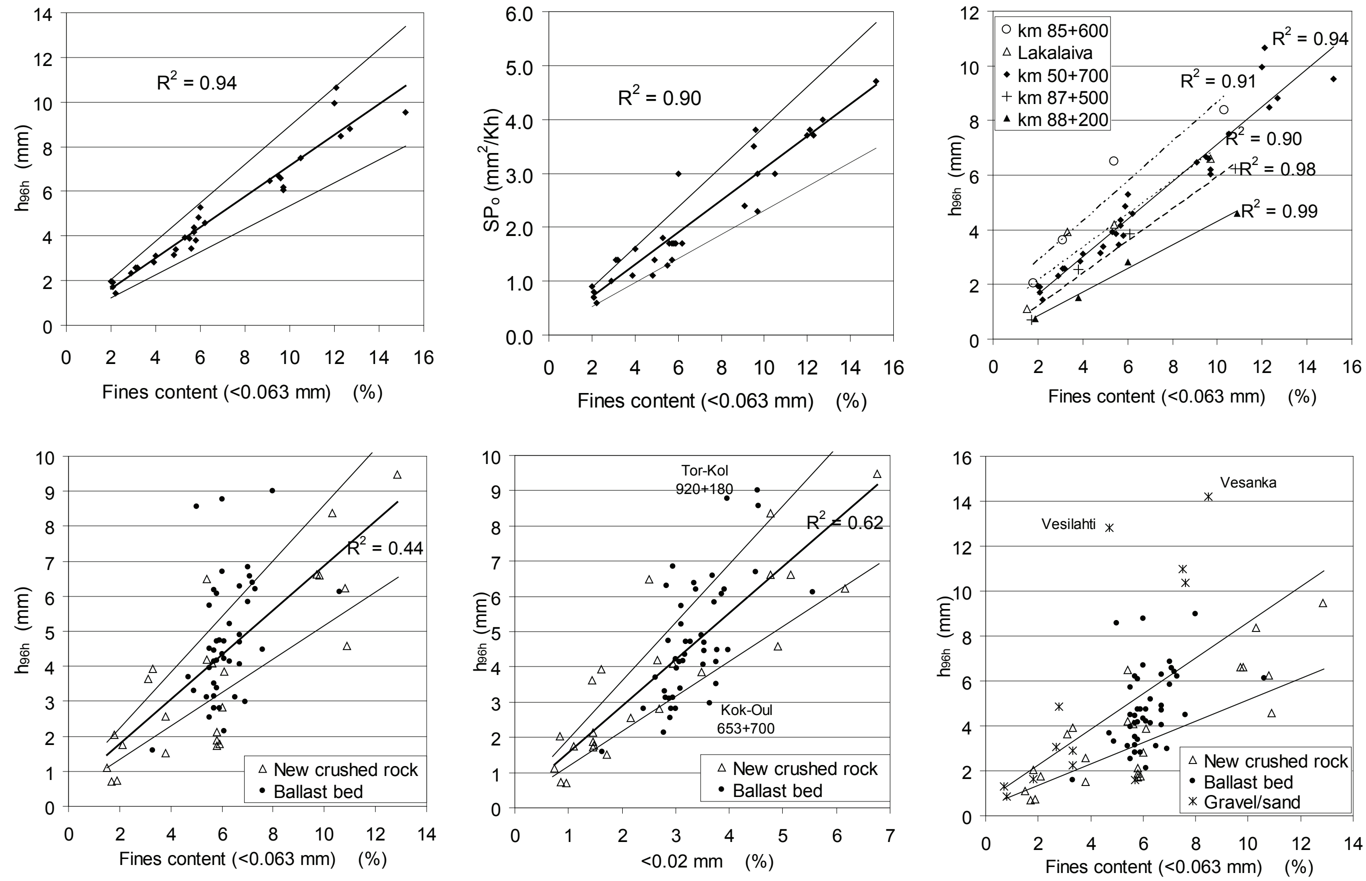

Figure 4. Correlation of parameters depicting frost susceptibility (h_{96h}, SP_o) with fines (or under 0.02 mm material) content applied to: (a & b) only tests on specific (km 50+700) aggregate, (c) different unused crushed rock aggregates, (d & e) all new crushed rock aggregates and degraded ballast bed samples from track, and (f) new crushed rock aggregates, ballasts as well as gravel and sand materials.

the corresponding results for four other fresh crushed rock aggregates, we find that the correlations between h_{96h} and fines content were strong with each aggregate as shown by Figure 4c. The location of the correlation line varied slightly depending on the aggregate, indicating slight qualitative differences in aggregates or their fines.

Figure 4d also includes the results from the tests on degraded ballast bed samples. The large number of observations made during tests on the material of Figure 1 was reduced in order to eliminate its excessive weighting. The correlation between h_{96h} and fines content is clearly weaker than in the above examinations of individual aggregates. This is explained partly by the different internal grain-size distribution of fines as seen in Figure 4e, where the correlation of h_{96h} is much stronger in the content of the finer portion of fines (<0.02 mm). This view is also supported by observations on the frost susceptibility of natural soils by, for example, Kujala (1991) and Vinson et al. (1987). Regression Equations 2 and 3, where $P_{0.02mm}$ is the content of under 0.02 mm material, could be obtained from this combined analysis of all tested crushed rock aggregates.

$$h_{96h} = 1.32 \cdot (P_{0.02mm}) + 0.24 \qquad (R^2=0.62) \qquad (2)$$

$$SP_o = 0.57 \cdot (P_{0.02mm}) + 0.14 \qquad (R^2=0.53) \qquad (3)$$

In Figure 4f the results from the tests on natural gravel and soil materials were added to show that if frost heave is assessed on the basis of fines content, there seems to be considerably more deviation in the case of gravels and sands than with crushed rock aggregates. The frost susceptibility of some gravels and sands was remarkably higher than that of crushed rock aggregates with a corresponding fines content. This can only partly be explained by the internal grain-size distribution of fines.

The impact of particle quality on frost susceptibility

The frost susceptibility of some crushed rock aggregates in Figures 4d and 4e and especially that of gravels and sands (Fig. 4f), which deviated from that evaluated on the basis of fines content, can be largely explained by divergent surface properties of particles. For example, the water adsorptions of the fines of the most divergent materials in Figure 4f (Vesilahti gravel and Vesanka sand) were almost 3-fold compared to the average level of crushed rock aggregates (Nurmikolu 2005). Corresponding differences could be noted, for example, in relation to the specific surface area or pore size distribution of fines as shown by Figure 5. The differences are clearly revealed by the SEM images in Figure 6.

The porosity and water retaining properties of some gravel and sand materials that deviated clearly from those

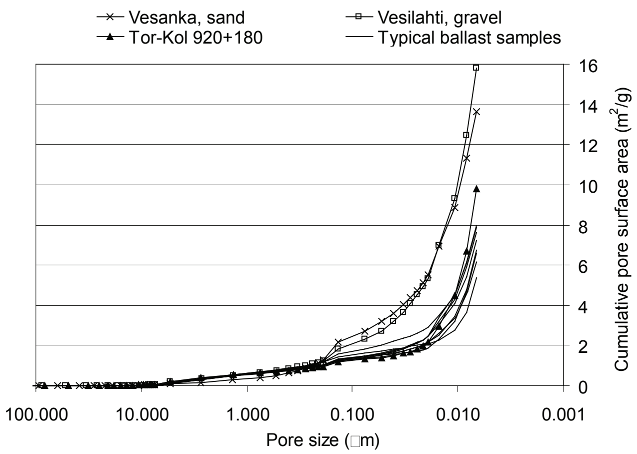

Figure 5. Cumulative pore surface areas in relation to pore size with regular ballast samples and with samples diverging the most from the analyzed fines.

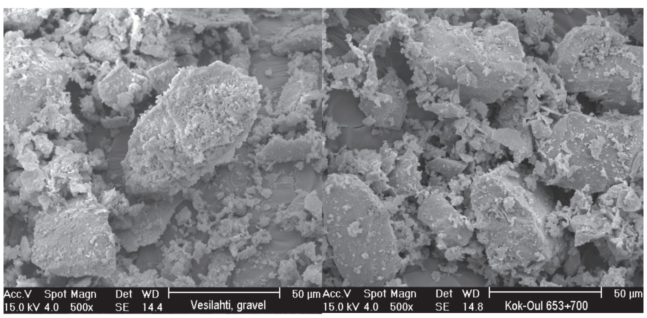

Figure 6. SEM images of the fines of (a) non-frost-susceptible ballast bed sample and (b) weathered, highly frost-susceptible gravel.

of crushed rock aggregates indicate their slight weathering. As a result, their frost susceptibility was higher than that of the examined crushed rock aggregates with corresponding fines content. The environmental loading on the particles of naturally sorted coarse-grained soils over millennia is of a different magnitude than the loading on crushed rock aggregate particles over the few decades since their crushing.

Distinct chemical weathering after crushing could be observed only in one ballast bed sample, where opaque minerals and mica had weathered, causing deposits of iron compounds on grain surfaces. In general, most of the fines in the ballast samples consisted of the most common rock minerals, quartz, feldspars, and amphiboles, whose average share in the mineral fines of the samples was established at about 80% (Fig. 7). This was a positive finding as it proved that despite the thousands of times larger specific surface area of fines compared to coarse grains, hard minerals appear to be resistant to chemical weathering in the structure even in the form of fines. The findings support the idea (Nurmikolu 2005) that degradation of ballast aggregates in the Finnish railway network is mainly the result of mechanical fragmentation and attrition caused by traffic loads and tamping (maintenance), or in a few cases possibly by frost weathering.

The significance of particles' quality on frost heave

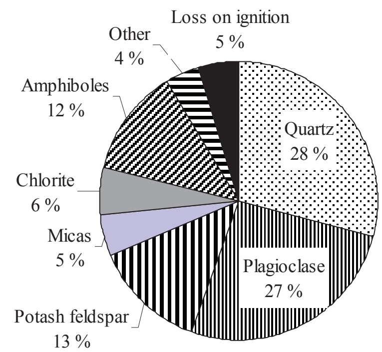

Figure 7. Indicative average mineral content of the fines of 36 ballast samples based on X-ray diffraction analyses.

susceptibility was examined statistically with stepwise regression analysis. The examined determining variables alongside the amounts of fines fractions (<0.063 mm, <0.02 mm and <0.002 mm) were water adsorption, specific surface area, total pore volume and total pore area of fines, as well as water absorption of coarse particles. The outcome of the stepwise regression analysis was clear. Based on the index properties of aggregate particles, the predictability of each parameter depicting frost susceptibility could be improved significantly compared to examinations based solely on the contents of fines fractions. The best correlation was achieved by using as independent variables the content of under 0.002 mm material, $P_{0.002mm}$, water absorption of coarse particles, WA_{24}, and total pore volume of fines measured with the mercury porosimeter, V_{tot}. Both water absorption and total pore volume clearly improved the coefficient of determination. In the case of parameters h_{96h} and SP_o this yielded regression Equations 4 (R^2=0.86) and 5 (R^2=0.80), which explained frost susceptibility in this combined analysis of aggregates nearly as well as fines content in the analyses of individual aggregates. Other independent variables did not improve the attained coefficients of determination.

$$h_{96h} = 6.9 \cdot P_{0.002mm} + 15.8 \cdot WA_{24} + 10.6 \cdot V_{tot} - 8.0 \quad (4)$$

$$SP_o = 2.8 \cdot P_{0.002mm} + 10.0 \cdot WA_{24} + 4.6 \cdot V_{tot} - 3.8 \quad (5)$$

Concluding Remarks

Degradation of the crushed rock aggregates used in the track structure affects their frost susceptibility. Some problems due to frost action can therefore be explained by frost heave in the structural layers instead of the freezing of frost-susceptible subgrade.

The results obtained from various frost heave test arrangements are hard to compare. The test method should be internationally standardized and made rather easy to perform while yet minimizing the technical restraints preventing frost heave from occurring. The arrangement with cut-up mould pipes worked well in this study.

The frost susceptibility of a certain crushed rock aggregate was found to be at the examined under 15% fines contents directly proportional to its fines content. In the combined analysis of various crushed rock aggregates, frost susceptibility correlated better with the very finest, under 0.02 mm and under 0.002 mm, fractions of fines than with the total fines content.

Because significant chemical weathering could not be observed even in ballast bed samples that had been in service for a long time except in one case, the surface properties of mineral particles of crushed rock aggregates varied relatively little with a few exceptions. With the rock types typically used in Finland, the impact of fines on the performance of the ballast bed can, thus, be largely assessed on the basis of their amount.

The porosity and water retaining properties of some gravel and sand materials, clearly more disadvantageous than those of crushed rock aggregate, indicated their weathering and caused their higher frost susceptibility compared to crushed rock aggregates with the same fines content.

Of the examined qualitative properties of particles, water absorption of coarse particles and total pore volume of fines correlated best with frost susceptibility. The regression model building on the under 0.002 mm material content, the water absorption of coarse particles and the total pore volume of fines explained frost susceptibility in the combined analysis of aggregates nearly as well as fines content in the analyses of individual aggregates.

The concept of the non-frost susceptibility of aggregate is mainly theoretical, since minor frost heave, not explained by in-situ frost heave, actually occurs in many materials generally assumed to be non-frost-susceptible. Therefore, it would be more important to deal with the concept of practical non-frost susceptibility. Establishing the limits of it would require field observations or large-scale tests. In their absence, and as a result of the investigations and consideration of the high smoothness requirement of railway tracks, it is suggested that a frost heave coefficient of 1.0 mm^2/Kh and frost heave of 2.2 mm after four days, attained in the described test, be applied to the track structure as the limits of practical non-frost susceptibility. In fines content-based frost heave models of crushed rock aggregates, the suggested limits corresponded to an under 0.02 mm fraction content of 1.5%. In the case of typical crushed rock aggregate this corresponded to a fines (<0.063 mm) content of 2.7%.

Contemporary Permafrost Degradation of Northern European Russia

Naum Oberman
Mining Geological Joint-Stock Company MIREKO, Syktyvkar, Russia

Abstract

This paper discusses the results of permafrost temperature monitoring. Temperatures were recorded over recent decades at a depth of zero annual amplitude at eight geocryological field stations located between the Ural Mountains and the lower reaches of the Pechora River. It is shown that almost all permafrost within this region has been warming. Permafrost temperature increases during the last 20 to 30 years ranged from 0.22°C to 1.56°C. Regional patterns of mean annual permafrost temperature dynamics are analyzed. During the period of observations, new closed taliks appeared, and those existing prior to climate warming increased in thickness by 0.6 to 6.2 m depending on a number of factors. Data presented in this paper suggest that permafrost of this region is more vulnerable to recent climate warming than that in Central Yakutia and West Siberia.

Keywords: monitoring; northern European Russia; permafrost; taliks; temperature; warming.

Introduction

Global climate warming leads to increases in permafrost temperature in many northern regions (Gravis et al. 1988, Haeberli et al. 1993, Pavlov 1994, Osterkamp et al. 1994, Romanovsky & Osterkamp 2001). A number of publications were devoted to the impacts of this warming on permafrost in northern European Russia (Oberman 1996, Pavlov 1997, Kakunov 1999, Oberman 2001, Oberman & Mazhitova 2003, Kakunov & Sulimova 2005, Pavlov & Malkova 2005). Most of the cited publications analyze long-term permafrost monitoring records that were obtained from one or two long-term geocryological field stations in operation during the last two to three decades. The stations are located near the city of Vorkuta in the eastern part of the studied region (Fig. 1, Station #2) and close to the Pechora River delta at Cape Bolvansky in its western part (Fig. 1, Station #11). Data obtained from these two areas are rather different. In the Vorkuta area a rapid warming of permafrost was observed while the permafrost temperatures at Cape Bolvansky remained relatively stable. Given this difference, the interpolation of these data onto the entire region is hardly possible. It was necessary to include in the analysis additional data from other sites within the region where permafrost had been monitored over recent decades.

Therefore, in 2006-2007, the MIREKO Stock Company resumed measurements at six geocryological field stations where measurements were conducted in the past. As a result, the number of field stations where 20 to 38 year-long records are available increased to eight (Fig.1). In this paper we discuss the data from these eight stations. Shorter (10 to 12 years) records from other stations that have not been published before are also included in this analysis. Original observational data used in the paper are from (Kakunov et al. unpublished, Glavatskikh et al. unpublished, Karpovich et al. unpublished, Malkova & Vasiliev unpublished, Romenskaya et al. unpublished, Oberman unpublished).

Study Area and Methods

The study region (Fig.1) is characterized by rather diverse environmental conditions. The Pechora lowland (Bolshezemelskaya Tundra), bordered by the Ural and Pai-Khoi Mountains and their foothills to the east, occupies most of the region. The geological section is represented mostly by Quaternary loam, loamy sand, and sand often overlain with peat. Landscapes with various geneses have different ages that vary from Middle Pleistocene to Holocene. They are dominated by one of these types of deposits or by the combination of different types. Climatic conditions vary within the region. Mean annual air temperature averaged over 1950-2005 declines from -2.4°C in the southwest to -7.5°C in the northeast of the region. Annual precipitation increases from 300-400 mm at the seacoast to 400-500 mm in the continental part of Bolshezemelskaya Tundra and to 500-600 mm and more in the Ural foothills. The long-term means of annual maximum snow depths increase in the same direction from 44 cm at the coast to 59 cm in Bolshezemelskaya Tundra and 78 cm in the Ural foothills. Recent trends in the mean annual air temperature are characterized by higher rates of warming in continental areas and lower rates towards the coast. In the continental areas the rates also decline from east to west (Pavlov & Malkova 2005). Our analysis showed that trends in precipitation and snow depths were similar to those in air temperature, yet better expressed. Excessive humidity is typical for the entire region. Climate is responsible for the region belonging mostly to the tundra zone. Permafrost spatial distribution ranges from isolated patches to continuous permafrost. In the 1970s, permafrost temperatures at the depth of zero annual amplitude varied mostly from -1°C to -3°C, reaching in some places -5.5°C, and permafrost thickness varied from 10 to 700 m, rarely more.

Long-term changes in permafrost temperatures were monitored using mercury thermometers with a scale factor from 0.05°C to 0.1°C. The thermometers were put in cases

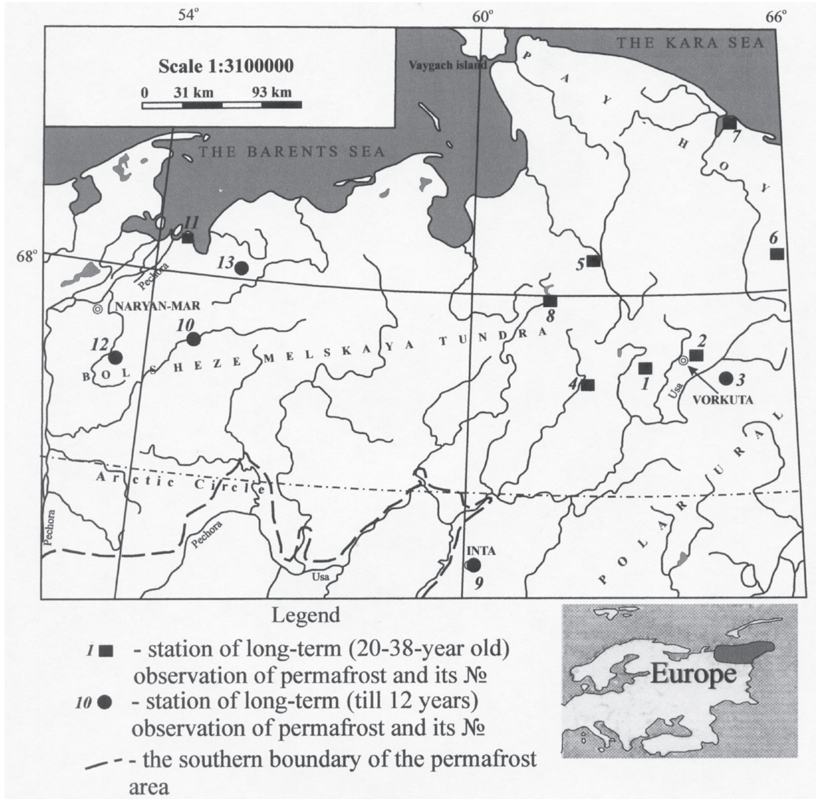

Figure 1. Survey map of the region.

filled with an inert material such as, for example, grease. In 2007, together with a representative from the Geophysical Institute, University of Alaska Fairbanks, temperatures were measured simultaneously with mercury thermometers and dataloggers. Readings differed in average by 0.05°C. Since 2007, boreholes are being equipped with temperature dataloggers. In the past, measurement frequency varied from one to three times monthly to four times annually.

Long-Term Permafrost Dynamics

Multi-year trends in permafrost characteristics were derived from 20-and-more-year-long monitoring records. The record lengths allowed averaging the short-term (decadal) temperature fluctuations (for example, Boreholes ZS-124/124a and ZS-14/227 in Figure 2). These relatively long-term records showed that permafrost temperatures at the depth of zero annual amplitude increased during the period of observations at all eight reference field stations in the region (data from most of them are given in Table 1). At the beginning of monitoring, only one of eight stations (#2) was located in the sporadic permafrost zone, two stations (#1 and #4) were in the discontinuous permafrost zone and the rest of the boreholes were in the continuous permafrost zone (Fig.1).

Permafrost warming over the recent 20 to 50 years has been reported by a number of authors who conducted occasional repeating temperature measurements on certain topographic surfaces in 10 areas within the studied region. The reported rates of warming were similar to those registered at our reference field stations. All available data suggest that permafrost warming from 1950-2000 took place mostly in the second half of this period.

The total increase in the mean annual permafrost temperature varies for different stations from 0.22°C to 1.56°C (Table 1) and depends first of all on the length of observational period. To overcome the effect of different record lengths, the average annual warming rates were calculated. These rates range from 0.01°C to 0.08°C per year. At each field station the maximum rates were usually observed in peatlands and minimum rates were typical for loamy deposits, with sand deposits showing intermediate values.

Generally, the rates of increase in mean annual permafrost temperatures decrease towards the seacoast. In loamy deposits that dominate the region, the rates were 0.031°C to 0.034°C per year at the distance of 165-170 km from the Barents Sea coast. At the same time, these rates were only 0.02°C to 0.028°C per year in the area located 80-85 km from the coast (Fig.1, Table 1: Stations #4 and #1, and Stations #5 and #8, Boreholes KT-5 and 37-6). Similarly, the rates were higher in the continental east of the region and lower in the coastal west, decreasing from 0.031°C-0.034°C per year at Stations #4 and #1 to 0.01°C per year in Borehole 49 (Table 1). The rates of increase in mean annual permafrost temperature (calculated for 1982-1993 at Station #10) decreased from the eastern continental Station #1 to the western continental Station #10, from 0.034°C to 0.013°C per year. Both stations are located at about the same latitude. Owing to the tendencies, the permafrost warming is most

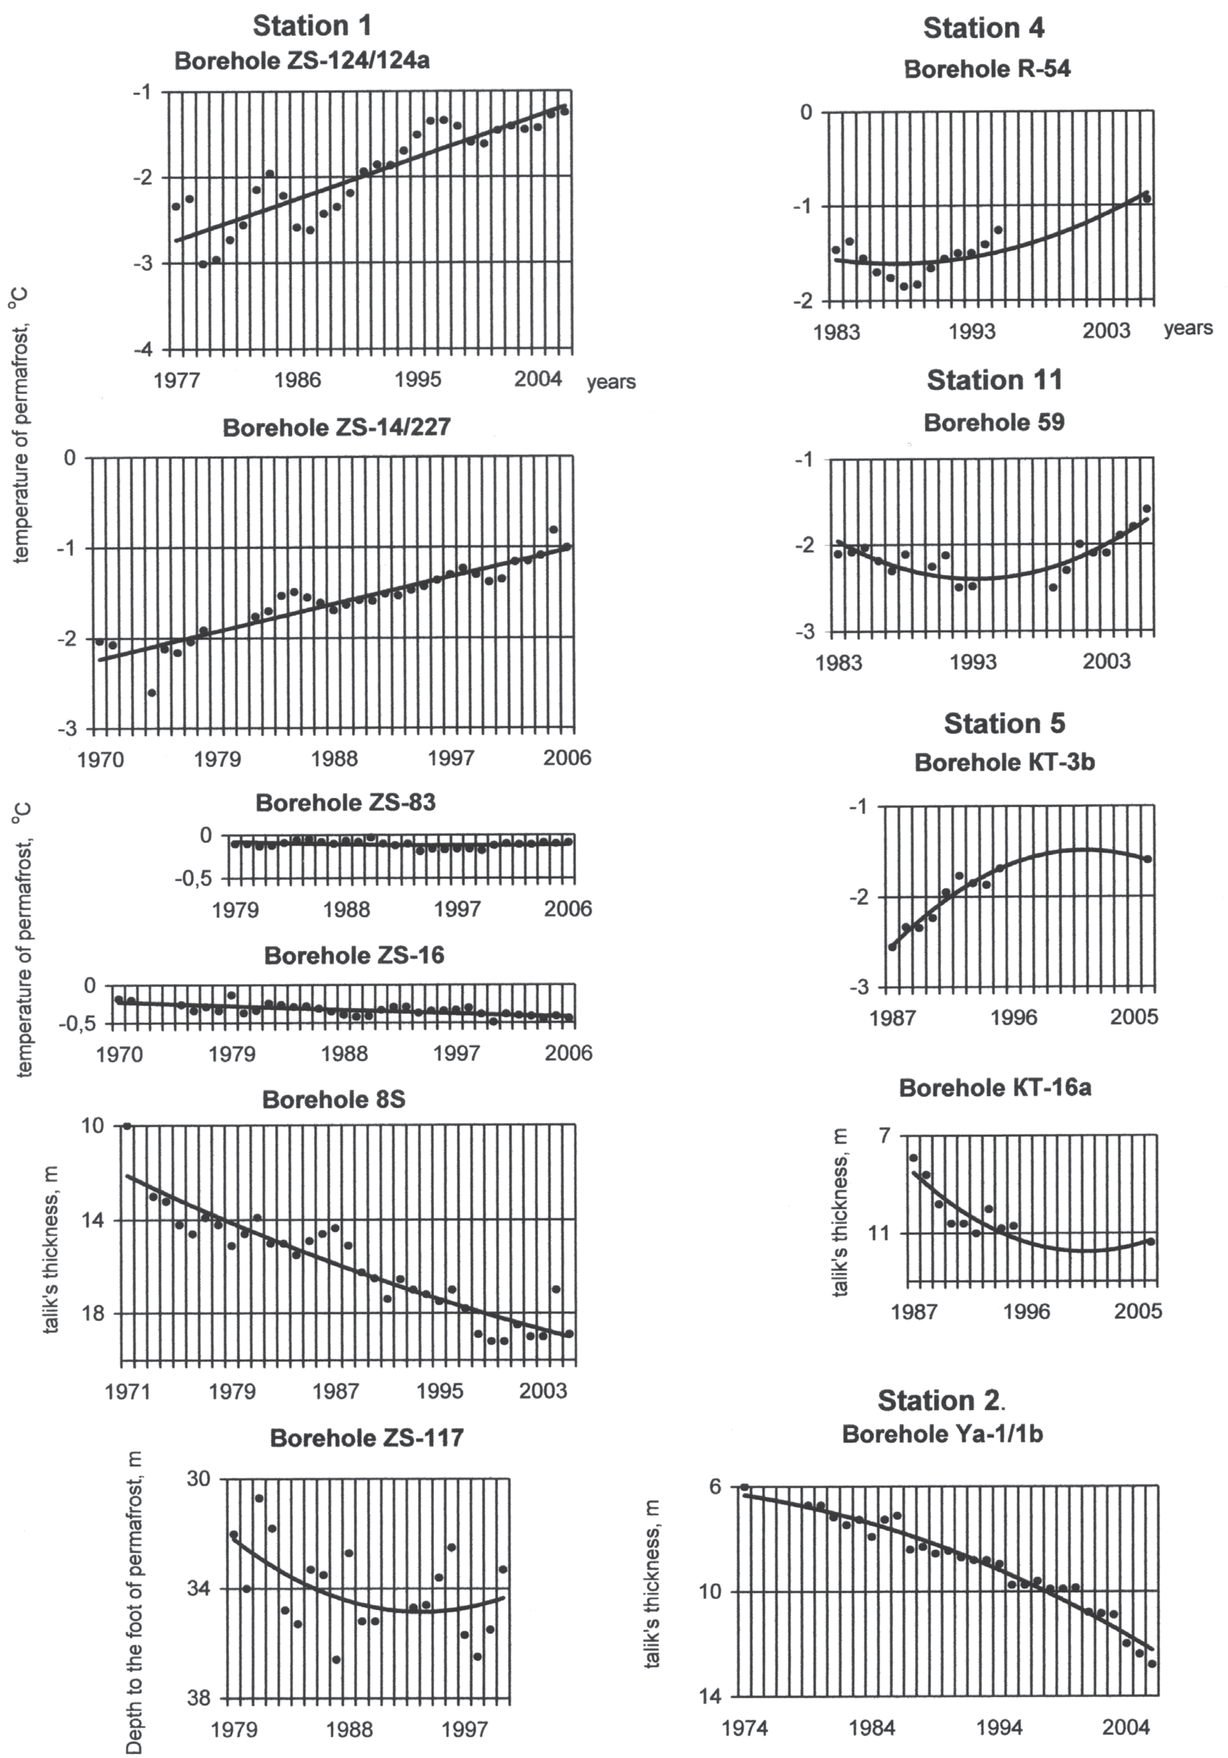

Figure 2. Long-term trends in permafrost characteristics.

pronounced in the eastern continental areas and least in the western coastal regions. The least significant permafrost warming was observed at the westernmost coastal Station #11 (Cape Bolvansky) and was due to the later initiation of climatic warming in this area compared to the rest of the region (Oberman 2007).

The regional pattern of permafrost warming correlates closely with the above discussed pattern of recent trends in major meteorological parameters.

While permafrost warming was a dominant process, permafrost cooling was observed locally, mostly in the areas of complete or partial drainage of thermokarst lakes. Cooling

with the rate of 0.006°C per year (during 1970-2006) was observed in the frozen basal peat layer below the floor of one of the lakes that drained before 1969; i.e., before the onset of pronounced warming (Fig. 2, Borehole ZS-16). Cooling rates observed in the thawed peaty sediments of the lakes drained during the climatic warming were much higher. At an initial mean annual ground temperature of 1.5°C, the rates were -0.042°C per year during 1974-2005 and, at an initial temperature of 2.87°C, they were -0.082°C per year during 1980-2006 (Stations #1 and #4, respectively). The duration of periods of thawed lake sediments rapid cooling prior to relative stabilization was equal for both lakes and totaled 14 years. This similarity in temperature regime between these two lakes occurred in spite of different drainage dates and significant differences in the initial enthalpy of bottom deposits. Similar permafrost temperatures in the surrounding terrain of both lakes can possibly explain the phenomenon.

Anomalous permafrost temperatures that persist during the time of recent climatic warming were observed at the sites where permafrost degradation resulted in the development of closed taliks (Fig. 2, Borehole ZS-83, Table 1). Here, the permafrost table lowered to 8.6 m in 30 years. It lowered even deeper, to almost 16 m, in an area where a newly developed closed talik coalesced with a preexisting lateral talik (Table 1, Borehole EK-67). Taliks existing prior to the recent climatic warming also increased in thickness, though to a smaller degree than newly developed taliks. Reduced rates of ground temperature changes in these taliks were probably due to a deeper permafrost table position and, hence, weakened effects of air temperatures on ground temperatures. Total increases in thickness of the closed taliks developed in Quaternary deposits ranged from 0.6 to 6.7 m (Table 1) depending on the geographical location, genetic type of the particular talik, ice content and lithological characteristics of the bearing sediments, hydrological, hydrogeological and other factors. The thickness of newly-developed taliks decreases northward (towards the sea coast), in accordance with the increasing severity of geocryological conditions and in accordance with already mentioned regional distribution of the recent climatic trends (see the Borehole pairs 8S & KT-16a and 23 & K-41, in Table 1). Thawing of the very ice-rich varved clays (Station #4, Borehole R-53) is accompanied by high heat consumption, and therefore total increases in thickness of closed taliks were minimal (only around 0.5 m) in this kind of deposit. On the other hand, a ground-water-formed closed talik in bedrock with practically zero ice content demonstrated a 25-meter increase in thickness in 31 years (Station #2, Borehole UP-34).

As a result of climatic warming, permafrost patches 10 to 15 m thick (Stations #1 and #2) thawed completely. In the patches where Quaternary deposits were perennially frozen to a depth of around 35 m, the base of the permafrost tended to rise (Fig. 2, Borehole ZS-117). Comparison of small-scale maps based on 1950-1960 data with those based on 1970-1995 data shows a shift of the southern limit of permafrost by several tens of kilometers northwards (Oberman 2001). This also indicates that permafrost is degrading in the southernmost part of the region.

At the same time, newly formed permafrost developed within the bottom of completely or partially drained lakes. This new permafrost was confined either by the elevated parts of the lake floor or by the bottom sections adjoining the frozen lakeshores. At one such site, permafrost developed from 1974 to 2001 to a depth of 14.5 m. To assess the extent of new permafrost formation, an analysis of satellite remote sensing data was performed by I.O. Smirnova (Research Institute for Cosmo-Aero-Geological Methods) for the entire region under discussion. According to her results, the area of lakes drained between 1988 and 2000 comprises only a fraction of a percent of the total area. Moreover, only an insignificant part of the drained area has been freezing recently and forming permafrost. Hence, on a regional scale, the significance of the formation of new permafrost is very limited compared to the predominant permafrost degradation.

Finally, the material presented indicates that permafrost dynamics could be very different within different Russian permafrost regions. Recent long-term increases in mean annual air temperature were several-fold smaller in northern European Russia than in Central Yakutia and West Siberia (Pavlov & Malkova 2005). However, an increase in permafrost temperatures at the depth of zero annual amplitude was several-fold larger than those in Central Yakutia and comparable to those in West Siberia. One reason for these differences could be the two-fold increase in atmospheric precipitation in the discussed region. This, in turn, was associated with an increase in the warming effect of ground waters on permafrost (Oberman 2006a, b). The maximum snow depth increase in recent decades was also reported for the western part of the Russian Arctic (Bulygina & Razuvaev 2007). This increase also contributed to the observed warming of permafrost. Taken together with the relatively high temperatures of permafrost in northern European Russia, all the above-discussed evidence indicate that this region is one of the most vulnerable to further warming. A large extent of permafrost degradation can be expected in this region in the foreseeable future.

Conclusions

In all geocryological zones and major landscapes of northern European Russia, the long-term (20 to 38 years) warming trend in permafrost temperatures at the depth of zero annual amplitude were recently observed. Short-term permafrost temperature fluctuations are superimposed on this trend. Total temperature increases vary from 0.22°C to 1.56°C with annual rates ranging between 0.01°C and 0.08°C per year. The observed warming rates decrease from continental areas towards the coast, and from eastern regions toward the west of the study area. These tendencies correlate closely with the recent intra-regional trends in mean annual air temperature, annual precipitation, and snow depth. Permafrost warming led to formation of new closed taliks and to an increase in thicknesses of pre-existing taliks. The increase in thickness of these taliks range from 0.6 to 6.7 m and depend on the location and genesis of the talik, as well as on ice content in the bearing deposits and other factors. Some thin permafrost patches completely thawed.

Excessive humidity and a recently observed steep increasing trend in snow depths, together with relatively high permafrost temperatures, cause higher vulnerability of permafrost to climate warming in this region as compared to Central Yakutia and, to a lesser degree, to West Siberia.

Acknowledgments

This investigation became possible due to financial support coming from the Russian Federal Agency for Mineral Resources Management (№AM-18/35 pr, 30.01.2006) and, since 2007, from the Geophysical Institute, University of Alaska Fairbanks, USA (the Polar Earth Science Program, Office of Polar Programs, National Science Foundation; ARC-0632400, ARC-0520578).

I wish to thank Prof. Vladimir Romanovsky and Dr. Galina Mazhitova for translating the paper into English and Roman Makov for computer design and formatting of this manuscript.

Abstract

A monitoring program to measure ground and air temperatures was started in autumn 2001 in Dovrefjell (62°15′N, 9°20′E), a mountainous area in southern Norway. Ground temperatures are measured in a transect from deep seasonal frost at 1039 m a.s.l. to discontinuous mountain permafrost at 1505 m a.s.l. in 11 boreholes 9 m deep. This is the first transect of this type set up in Scandinavia. Preliminary results are presented including measurements at 0.2 m and 8.5 m depth. The collected ground surface temperatures (GST) show pronounced fluctuations and large interannual variability. A simple normalization procedure is suggested to relate the observed GST to the reference period 1961-1990. The results suggest that even with an averaging period of 5 years the MAGST could deviate more that 1°C from the 30-year average. The period 2001–2006 is generally found to be warmer than the reference period, suggesting thawing permafrost at sites with discontinuous or thin snow cover.

Keywords: MAGST; monitoring; mountain permafrost; Norway.

Introduction

Permafrost is known to be widespread in the world mountain ranges, but scientific investigations only started during the past few decades (Haeberli 1973, Haeberli & Patzelt 1982, Ødegård et al. 1992, Haeberli et al. 1993). The focus of these investigations has been on degrading permafrost and reduction in the stability of mountain slopes (e.g. Harris et al. 2001). Slow thaw of deeper subsurface materials may provoke larger-scale instability on steeper slopes in areas previously considered stable (Dramis et al. 1995). Other studies are related to buildings and other installations directly affected by ground thawing (Haeberli 1992, Haeberli et al. 1993). Permafrost is sensitive to changes in surface energy exchange; it is therefore important to investigate the marginal permafrost areas. Equally important is an understanding of the dominant processes for permafrost development and degradation in mountain areas.

The use of miniature temperature data loggers (MTDs, Fig. 1) for mountain permafrost studies has greatly increased during the last decade. Large amounts of ground surface temperature data now exist from many mountain areas. Continuous temperature recordings make it possible to determine, for example, the mean monthly and annual ground surface temperature (MMGST and MAGST) at selected sites.

This paper presents preliminary results from a monitoring program to measure ground and air temperatures in Dovrefjell (62°15′N, 9°20′E), a mountainous area in southern Norway (Fig. 2). Ground temperatures are measured in a transect from deep seasonal frost at 1039 m a.s.l. to discontinuous mountain permafrost at 1505 m a.s.l. in 11 boreholes 9 m deep in the period 2001–2006. This is the first transect of this type set up in Scandinavia. The analysis includes measurements at 0.2 m and 8.5 m depth. The collected ground surface temperatures (GST) show pronounced fluctuations and large interannual variability. A simple normalization procedure is suggested to relate the observed GST to the reference period 1961–1990.

Figure 1. Miniature temperature datalogger (MTD) used in this study. This tool is especially designed for rough field conditions. The thermistor in the MTDs is a TMC-1T with a temperature range of −30°C to +40°C and with accuracy given by the manufacturer to be ±0.13°C. The loggers are available from GEOTEST in Switzerland.

Research Area and Previous Studies

The setting and overall scope of the monitoring program in Dovrefjell were presented by Sollid et al. (2003). Key information from the boreholes like position, altitude, surface material, and snow depth are described in this paper.

Ground temperatures are correlated with elevation. The lower limit of the mountain permafrost in Dovrefjell is about 1500 m a.s.l., mapped using the BTS (Bottom Temperature of Snow) method (Ødegård et al. 1996, Isaksen et al. 2002). This limit is representative for areas with a stable snow cover of 1–2 m. Sporadic permafrost is present at elevations down to 1000 m a.s.l. in some palsa bogs (Sollid & Sørbel 1998)

Regression based on 18 climate stations in the vicinity (Aune 1993) indicates that the 0°C isotherm is located at 910 m a.s.l. The mean temperature lapse rate is 0.44°C/100 m (Tveito et al. 2000). The average yearly precipitation is 600 mm (Østrem et al. 1988). Unstable and stormy weather are common in winter, and the dominant wind direction is from the southwest.

Field Data

This study is based on analysis of a subset of the observations including monthly averages from 9 boreholes at 0.2 m depth and 8.5 m depth (Table 1, Figs. 3, 4). DB1, 2, and 6 are located at exposed sites, at main ridge-crest or plateau locations, where winter snow accumulation is minimal. Sites DB5, DB10, and DB11 have discontinuous snow cover in the vicinity of the boreholes. DB 3, 7 and 8 have a maximum snow cover between 0.3 m and 1.0 m as measured in late winter. DB1, DB2, and DB6 are in permafrost; the other boreholes have deep seasonal frost.

Normalization Procedure

In the normalization procedure the monthly scale was selected. The monthly scale improves the correlation between air and ground temperatures (Fig. 5), and captures the overall seasonal variations (Fig. 4). The World Meteorological Organization (WMO) established a standard for a "normal" period to ensure that calculations of climate averages (the "normals") are calculated on a consistent period. A 30-year period is considered long enough to calculate a representative average, and to reduce the impact that one-off, extreme events have on the average. Thus, in this study the official standard normal period 1961–1990 is used.

The normalization procedure starts with the calculation of the MMGST from MTDs by averaging the observations. The second and more complicated step is to obtain mean

Table 2. Difference between observed and normalized air temperatures at Fokstugu (1961–1990).

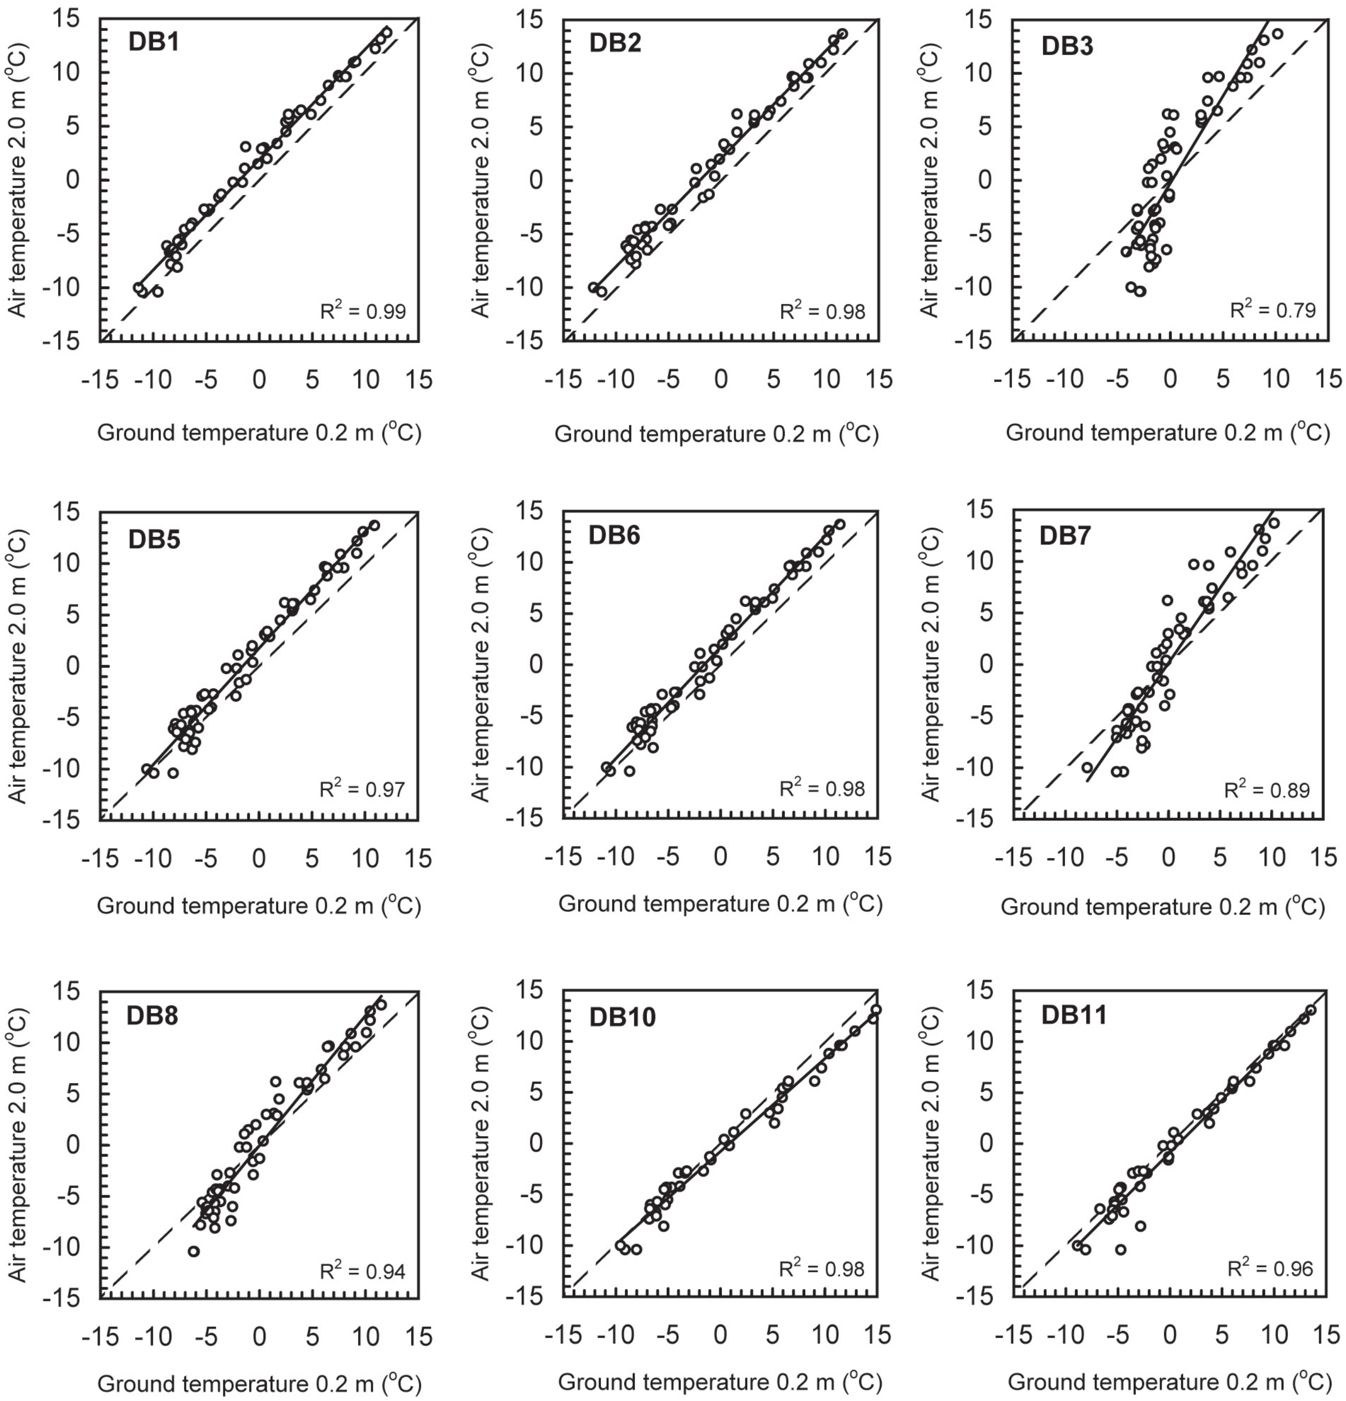

Figure 5. Recorded monthly ground surface temperature for monitoring sites in Dovrefjell vs. monthly air temperature for the weather station at Fokstugu. The snow thickness at several of the monitoring sites is low and for DB1, DB2, and DB6 most of the time snow is completely absent, due to redistribution by wind. Monitoring sites DB3, DB7, and DB8 are highly influenced by snow.

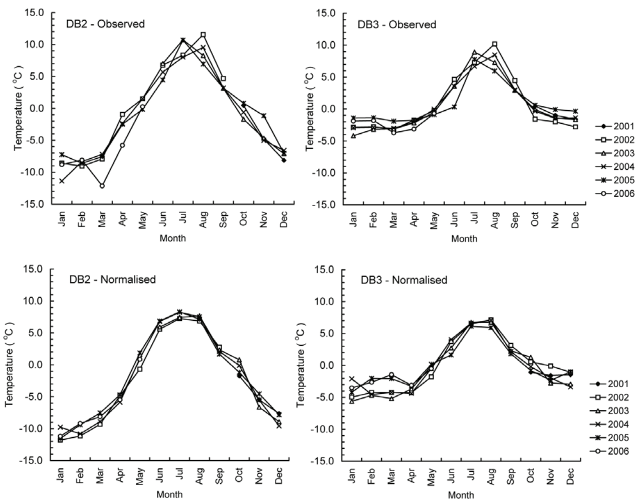

Figure 6. The upper graphs show observed ground surface temperature at selected monitoring sites DB-2 (left) and DB-3 (right). The lower graphs show normalized values for the ground surface temperatures at the same two sites.

monthly air temperature maps and monthly anomaly maps of the air temperature with reference to a standard normal period, in this study 1961–1990.

In Norway 1 km gridded temperature maps and anomaly maps are available from the Norwegian Meteorological Institute (Tveito et al. 2000). The spatial analyses were based on 1247 stations in Fennoscandia using residual kriging. The trend components were defined by a stepwise linear regression.

One alternative method is to obtain air temperature data from a nearby meteorological station having a long time series (e.g. 30-year period or more). A monthly mean temperature anomaly field in a radius of, for example, 30–50 km tends to be quite homogenous, typically within in the range of ±0.3°C.

A high correlation between air and ground temperatures suggests low influence of snow and latent heat effects, which suggests a strong coupling between the air temperatures and the ground surface temperatures. At these sites the monthly air temperature anomalies are simply applied to the MMGST to obtain a normalized estimate.

Results

The normalization procedure outlined above was applied to 6 boreholes (DB1, DB2, DB5, DB6, DB10, and DB11) to obtain the first estimate of MAGST based only on a few years of measurements. The normalization procedure reduces the monthly and interannual variability in the dataset (Fig. 6), especially during summer. At exposed sites with a thin snow cover, the variability in the normalization results during autumn and winter is mainly due to problems with the extrapolation of data obtained from the meteorological stations. For some time periods during autumn and winter, the air temperature in valleys is often lower than in the surrounding mountains because of temperature inversions. This is the case at the Fokstugu meteorological station approximately 15 km from the research area.

For the monitoring period autumn 2001 to spring 2006 the MAGST at exposed sites are on the range 0.6ºC to 1.1°C higher than the 1961–1990 average (Table 1, column 1 and 2).

For determination of MAGST for sites having a thick snow cover the suggested method is not applicable during winter due to the insulating effect of the snow (DB3, DB7, and DB8).

Except DB3 the average ground temperatures observed at 8.5 m depth are higher than MAGST at 0.2 m depth. The averages during the monitoring period range from 0.4°C to 1.2°C higher than MAGST. At DB3 the average at 8.5 m depth is 0.5°C colder than MAGST. This is a good illustration of the complexity of the ground thermal regime in mountain permafrost/deep seasonal frost. The distance between DB2 and DB3 is only 55 m.

Discussion and Conclusions

Observations in 9 shallow boreholes, in warm permafrost (3 boreholes) and deep seasonal frost (6 boreholes), in the period from autumn 2001 to spring 2006 show the limitations of surface measurements in the validation of mountain permafrost models. The results suggest that even with an averaging period of 5 years the MAGST could deviate more that 1°C from the 30-year average (1961–1990). This study shows that a simple normalization procedure based on air temperature anomaly maps could be applied at some sites with a good coupling between air and ground temperatures. A more general normalization procedure would require more sophisticated methods.

The period 2001–2006 is generally found to be warmer than the reference period, suggesting thawing permafrost at sites with discontinuous or thin snow cover.

The ground temperature averages at 8.5 m depth are generally found to be higher than the averages at 0.2 m depth. This is surprising because the conductivity ratio between unfrozen and frozen surface material (Kt/Kf) will cause an offset between the MAGST and the ground temperature at the top of the permafrost. The thermal offset is caused by different thermal properties in the thawed and frozen states (Romanovsky & Osterkamp 1995). These conductivity controlled models show good performance in arctic low-land applications when compared with borehole data (Smith & Riseborough 2002, Wright et al. 2003).

In mountain terrain the surface is often covered with blocks, introducing a top surface layer where non-conductive heat transfer mechanisms are important. Another complication is the redistribution of snow due to wind drift, resulting in a highly variable snow cover, even on scales of just a few meters. This is definitely the case at the observed boreholes and needs to be considered in order to obtain modeling results that can be compared with borehole data. There is also a possibility for lateral heat transfer in a complex soil-water system, but conclusive statements cannot be made based on this study.

The plan is to continue the monitoring for several decades, for the study of permafrost temperatures under future climate development and probable accelerated warming in the mountains of southern Norway.

Acknowledgments

The monitoring program was initiated by J.L. Sollid, University of Oslo, in co-operation with K. Isaksen, Norwegian Meteorological Institute, R.S. Ødegård, Gjøvik College and T. Eiken, University of Oslo. Forsvarsbygg at Hjerkinn by O.E. Martinsen partly financed the drilling operation and assisted in organizing the field work. The authors give their thanks to Mr. Martinsen and to the institutions involved.

Effects of Changing Climate and Sea Ice Extent on Pechora and Kara Seas Coastal Dynamics

S.A. Ogorodov
Lomonosov Moscow State University, Faculty of Geography, Moscow, Russia

Abstract

About half of the Eurasian Arctic coastline consists of ice-rich deposits. The dynamic response of this coastal type is forced mainly by thermal and wave-energy mechanisms. The role of the thermal factor increases with ground ice content. Low ice content makes the wave-energy factor more significant. We present a comparison of the changing influence that wave energy and temperature regimes can exert on coastal dynamics for two types of Pechora and Kara seas coasts. The first type is represented by barriers and spits, which are expressed by sandy deposits with low ice content. For such coasts, a clear dependence between the seasonal wave energy magnitude directed landward and the coastal retreat rate was found. The second type represents the typical thermo-erosion bluff coast composed of sandy and clayey deposits with medium ice content. The dynamic regime of this type of coast is determined by both thermal and wave-energy factors.

Keywords: climate change; coastal dynamics; sea ice; wave energy.

Introduction

The evolution of Arctic coasts over the coming decades will be governed by changes in the natural environment caused by the effects of climate warming. Rising temperatures are altering the Arctic coastline by reducing sea ice and thawing permafrost, and larger changes are projected to occur as this trend continues. In September, 2007, the area of sea ice in the northern hemisphere achieved its historical minimum for the period of satellite observation (since 1978; http://arctic.atmos.uiuc.edu/cryosphere). Less extensive sea ice creates more open water, allowing stronger wave generation by winds, thus increasing wave-induced erosion along Arctic coasts. Therefore, the acceleration of erosion and thermo-abrasion of the coast is attributable to both an increase of air and water temperatures and a possible intensification of wind-generated wave activity. This is an important topic to pursue given the direct impacts to human communities and infrastructure already being felt along Arctic coasts.

In spite of a short active period, dynamic processes in the coastal zone of the Arctic seas are characterized by a very high intensity. The intensity is due to low coastal stability, which is composed of frozen dispersive sediments and is evolving under the influence of thermal-erosion process. About half of the Eurasian Arctic coastline is exposed to coastal erosion processes and undergoes coastal destruction at rates of 1–5 m per year. In general, which processes

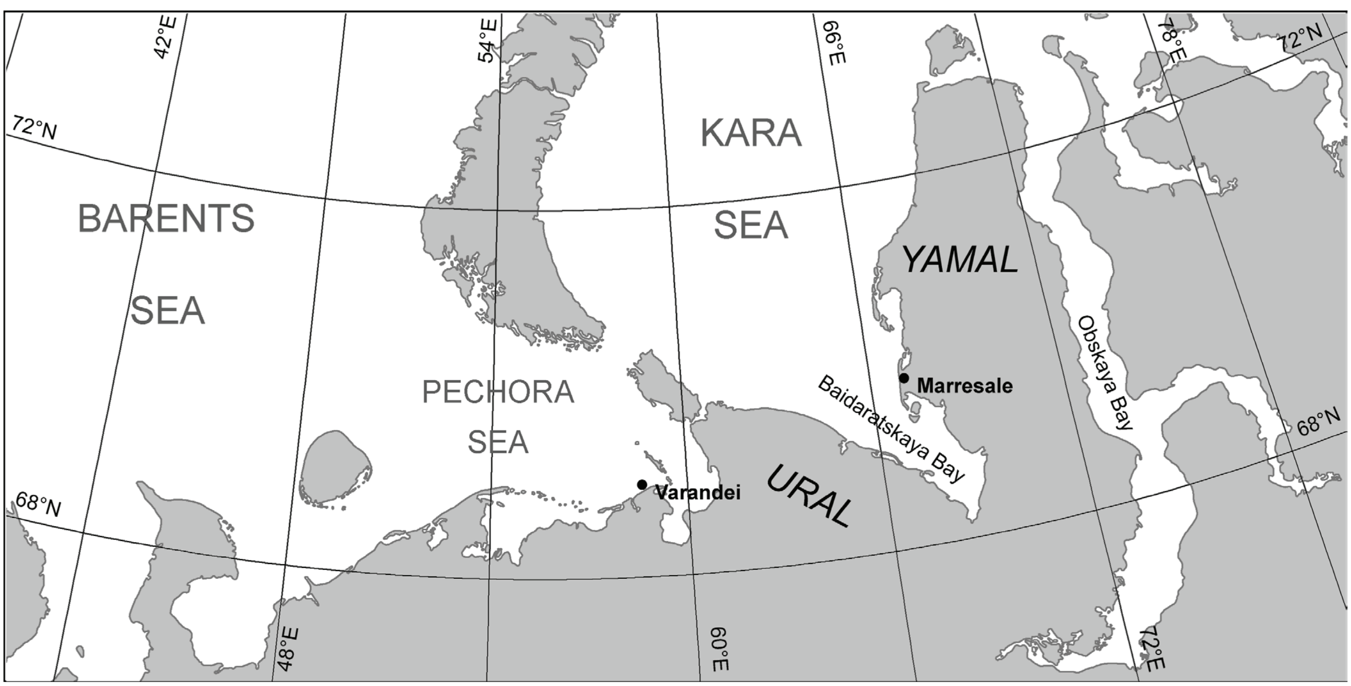

Figure 1. The research area.

affect thermal-erosion coasts, and with what intensity, is determined by a combination of and interaction between thermal and wave-energy factors.

The thermal influence shows itself as energy transmission to the coast, which is composed of frozen sediments, via radiative and sensible heat fluxes from air and water. Accordingly, higher air and water temperatures, together with a longer ice-free period and longer period with positive air temperature, affect the stability of frozen coasts. The role of the thermal factor usually increases with increasing ice content in coastal deposits. In turn, low ice content renders the wave-energy factor more significant.

The wave-energy factor acts via the direct mechanical impact of sea waves on the shore. Correspondingly, the effectiveness of this factor is determined by storm-driven sea surge intensity, as well as by the length of the stormiest period. Conversely, surge intensity substantially depends on the fetch, which is intrinsically linked to sea ice extent since less extensive sea ice creates more open water, allowing stronger wave generation by wind.

We present a comparison of the changing influence of wave energy and temperature regimes on coastal dynamics for two types of coast. These results are drawn from work conducted along the Barents (Pechora) and Kara Sea coasts (Fig. 1), but have much broader implications to coastal regions throughout the Eurasian Arctic.

Methods

Microsoft Excel was used for statistics and correlation analysis. Wave energy flux was calculated using the Popov-Sovershaev (1981, 1982) wind-energy method (Ogorodov 2002). The method is based on the theory of wave processes and takes established correlations between wind speed and parameters of wind-induced waves into account.

For deep-water conditions, when the sea floor does not influence the wave formation, the wave energy flux per second (for 1 m of wave front) at the outer coastal zone boundary is calculated by the equation similar to the one used in Longinov's method (1966):

$$E_{0dw} = 3\times 10^{-6} V_{10}^{3} x \qquad (1)$$

where V_{10} is the real wind speed measured by anemometer at 10 m above sea level [*m/s*], x is the real or extreme distance of wave racing [*km*];, and the dimension of the coefficient 3×10^{-6} corresponds to the dimensions of ρ/g, where ρ is density [g/m^3], g is gravitational acceleration [m/s^2], i.e., $\frac{t/m^3}{m/s^2}$. Thus, E_{0dw} has dimensions, $\frac{tm}{ms}$ or *t/s*, as is the convention in coastal dynamics.

The same equation for the shallow sea zone appears in the following form:

$$E_{0sw} = 2\times 10^{-6}\left(\frac{gH}{V_{10}^{2}}\right)^{1.4} V_{10}^{5} \qquad (2)$$

where E_{0sw} has the same dimensions as in equation (1). Equation (2) is valid under two conditions: for shallow sea basins, i.e., for most of the arctic seas, wave energy is determined in accordance with kinematic index of shallowness, $\frac{gH}{V_{10}^{2}}$, between water depth H along the wind direction and wind speed V_{10}. At $\frac{gH}{V_{10}^{2}} \leq 3$ water depth hampers formation of wind-induced waves.

Another condition is determined by the following: a wave starts to interact with the sea floor when it becomes high enough after it has covered a certain ideal distance without touching the sea floor, when it has developed in the deep-sea basin where equation (1) is valid. Hence, at the boundary between deep-sea and shallow zones both equations should be valid. From this it follows that the ratio between the minimum wave fetch at which the interaction between waves and sea floor begins and the water depth at the distance of that wave fetch is:

$$\frac{x_{\min}}{H} \geq 6.5\left(\frac{gH}{V_{10}^{2}}\right)^{0.4} \qquad (3)$$

where $x_{\min}$ is expressed in kilometers, and H is in meters.

At $\frac{gH}{V_{10}^{2}} = 3$ equation (3) becomes

$$\frac{gx_{\min}}{V_{10}^{2}} \geq 30 \qquad (4)$$

From (4) we can get the value of the extreme wave fetch for deep-sea conditions equal to the value obtained by other means:

$$x_{\lim} = 3V_{10}^{2} \qquad (5)$$

This value could be neglected if other factors limiting wave fetch are absent, for example by sea ice or islands.

To calculate the sum of wave energy of a certain direction from the energy flux per second, E_0 calculated for all wind speeds by wind direction is multiplied by the overall wind duration, for wind of a certain speed range on a monthly or monthly ice-free period, expressed in seconds. The values obtained are summarized for each rhumb line. The rhumb fluxes of wave energy, E_r, are represented by the wave energy sum for all wind speed gradations within a certain rhumb during the dynamically active period.

For delimitation of an ice extent boundary and determination of duration ice-free period http://arctic.atmos.uiuc.edu/cryosphere data are used.

Results and Discussion

The Varandei Coast, Barents Sea example

It is a wide-spread opinion that sea coasts consisting of frozen deposits must develop as thermoerosion (thermoabrasion) type coasts. At the same time, coastal bluffs formed of frozen deposits with low ice content (*the first type*) are not subject to thaw slumping, permafrost creep (solifluction), gully thermoerosion, and thermokarst (Fig. 2). Periodicity of extreme storm surges and the total wave energy activity in the coastal zone during the active dynamic period are the main factors which determine the dynamics of coasts with low ice content. Based on the Actualism method, we can suppose that, in the case of climate warming, low ice content coastal dynamics will have similar features to those which they have in the warmest years and decades at the present. Thus, to forecast the dynamics of similar coasts under conditions of climate change, it is only necessary to predict changes in the regional wind-wave regime. As basic coastal retreat values, one may use the values obtained by direct stationary observations during the period with certain wind-wave parameters.

To substantiate this hypothesis, we performed correlation analysis of the results of stationary observations on coastal dynamics and hydrometeorological data. For Varandei area (Pechora Sea), wave energy fluxes at the external border of the coastal zone were calculated using wind direction and speed for each year between 1981 and 2002. The total

Figure 4. Ural Coast of Baidaratskaya Bay, the second type coast.

value of the wave energy flux from the all wave-dangerous rhumbs for dynamically active period (from July to October) was obtained. Then we calculated correlation indices between the value of the wave energy flux and temperature characteristics, and the value of coastline retreat near the Varandei settlement.

The obtained results permit us to conclude that for coasts of *the first type*, consisting of low ice content deposits (Varandei site), there is a clear dependence between the wave energy volume at the external border of the coastal zone and the coastal retreat rate. The correlation index (R) is 0.8 (Fig. 3).

At the same time, a significant correlation between the temperature regime and the coastal retreat rate was not observed (Ogorodov 2005). There was no determined interrelationship between average temperatures of active dynamic period and wave activity.

Thus, the conditions of the climate change dynamics of coasts formed by deposits with low ice content will be determined more by wind-energetic than temperature regimes.

The Baidaratskaya Bay and Marresale Coasts, Kara Sea example

The second coastal type represents the typical, thermo-erosion bluff coast composed of sandy and clayey deposits with medium ice content (Baidaratskaya Bay and Marresale Coasts, Kara Sea; Fig. 4). The dynamic regime of coasts of *the second type* is defined by both thermal and wave-energy factors. Thermodenudation processes, caused by the thawing of frozen deposits, result in the mass-wasting of unconsolidated sediments that are loosely deposited at the foot of the coastal bluff. This material is easily washed away by the waves and water-level surges that accompany storm events. In the absence of significant melting, a given wave energy level cannot act with the same efficiency on the coastal bluff to remove material, and hence should result in lower coastal retreat rates. Correspondingly, the persistence of the thawed, loose material at the base of the bluff when wave activity is low should reduce the rate of the thermodenudation processes and also coastal bluff retreat.

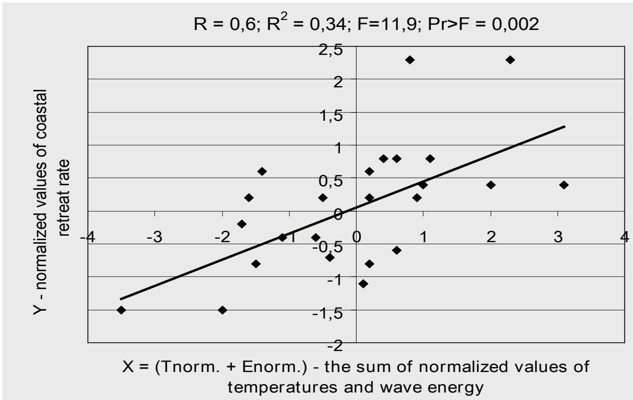

Figure 5. Seasonal erosion response at the second type coast, 1977–2004, with respect to an index combining a representation of seasonal thermal and wave energies (their normalized seasonal values were added and plotted against the normalized erosion response). Results considering the influence of temperature and wave action together showed superior explanatory capacity than temperature or wave energy alone.

For a region with the *second type* of coast (Baidaratskaya Bay and Marresale sites, Kara Sea), we have calculated the sums of temperatures averaged monthly for the mild season (from June to September) for the period from 1977 to 2004, as well as the total value of the wave energy flux. We performed correlation analyses of these data and the results of monitoring of the coastal dynamics. We observed that both factors influence the coastal retreat rate equally. Seasonal indicators of temperature and wave energy returned correlation coefficients (against seasonal erosion) of 0.41 and 0.39, respectively, while together they returned 0.6 (Fig. 5). The maximal coastal retreat rate (2.0–3.5 m/year) corresponds to the years when both average temperature and wave-energy flux approach the maximum values. Such behavior corresponds to the years 1982, 1983, 1988, 1989, 1994, and 1995 (Vasiliev et al. 2005), in particular. The coincidence of minima of these parameters corresponds to the lowest rates of coastal recession (0.5 m/year, for example, during the years 1978 and 1999).

The combined analysis of coastal retreat rate and hydrometeorological parameters specifying the temperature and wave regime seems to be difficult because of the discreteness of monitoring of coastal dynamics. For example, the measurement of the position of the brow of the coastal bluff is usually performed at the end of August and beginning of September, while the high wave energy activity occurs at the end of September and in October. As a result, these measurements give information on the retreat rate of the brow of coastal bluff under the action of thermodenudation processes during the summer of a given year and wave erosion during autumn of the previous year.

Dynamics of coasts consisting of frozen deposits is mainly caused by the two environmental forcing factors, namely, by the thermal and wave-energy mechanisms. As a rule, the role of the thermal factor increases with the ground ice content of the coastal deposits. In turn, low ground ice content renders the wave-energy factor more significant.

Conclusions

Thus, temperature regime and waves, as the major environmental forcing agents determining dynamics of arctic coastal margins have been considered. Rising temperatures are altering the arctic coastline and much lager changes are projected to occur during this century as a result of reduced sea ice, thawing permafrost. Less extensive sea ice creates more open water, allowing stronger wave generation by winds, thus increasing wave-induced erosion along arctic shores. Therefore, the acceleration of erosion and thermo-abrasion of the coast can be caused by both increase of the air and water temperature and possible increasing of wind-wave activity.

Abstract

This paper presents a morphometric and spatial approach, the aim of which is to classify solifluction lobes in Sierra Nevada in southern Iberian Peninsula, to understand the involved geomorphic processes, and to reconstruct their evolution during the Late Holocene. Under the present climatic conditions, solifluction is inactive to weakly active in this massif. According to our findings, water availability in the semiarid environment of Sierra Nevada is the main factor controlling solifluidal dynamics. Only lobes near water channels and those influenced by water supply from late-lying snow patches show displacements. By contrast, thermal and topographic monitoring of a solifluction lobe in the Rio Seco Valley showed that, despite a seasonal frozen layer of 70 cm thickness, solifluction processes remain inactive. However, sedimentological studies on solifluction lobes indicate that during the Late Holocene, periods of increased solifluction processes (e.g., Little Ice Age) alternated with periods of geomorphic stability (e.g., Medieval Warm Period). Present climate may not be cold and/or wet enough to trigger important solifluction processes from 2500 to 3000 m altitude.

Keywords: Late Holocene; seasonal frozen layer; Sierra Nevada; solifluction lobes.

Introduction

Solifluction has been defined as the slow mass wasting associated with freeze–thaw action (Andersson 1906, Ballantyne & Harris 1994). During the last decades, research on present and past solifluction processes was undertaken mostly in high-latitude (polar and subpolar regions) and in mid-latitude mountain environments, where periglacial processes affect settlements, infrastructures, and equipment (Matsuoka 2001).

By contrast, solifluction features in the Mediterranean region have attracted less attention from geomorphologists and geophysicists due to the reduced extension of the periglacial belt and lower demographic pressure at high altitudes. However, studies on present solifluction dynamics in Spanish mountains were carried out by Gómez Ortiz et al. (2005) in Sierra Nevada, by Grimalt & Rodríguez (1994) on the Balearic Islands, by Palacios et al. (2003) in the Peñalara massif, and by Chueca & Julián (1995) in the Central Pyrenees**.**

Since the beginning of the research on solifluction phenomena, studies focused on morphometry and spatial pattern of the lobes (Andersson 1906, Rapp 1960, Washburn 1979), but during the last years, research turned towards the active layer, particularly on chronostratigraphy, processes, sediment flux, and ground temperature monitoring (Harris et al. 1997, Matsuoka 2001, Jaesche et al. 2003). In order to understand the nature of mechanisms, processes, and evolution of solifluction landforms, it is crucial to deal with the causes of solifluction being active in some periods and inactive in others (Gamper 1983, Veit 1988, Matthews et al. 2005).

The purpose of the present paper is to examine the morphometry and palaeoenvironmental changes of solifluction lobes in two study areas on the northern and southern slopes of Sierra Nevada.

Regional Setting

Sierra Nevada, the highest massif in the Iberian Peninsula (Mulhacén, 3478 m), is located at latitude 37ºN between the subtropical high-pressure belt and the mid-latitude westerlies. Mean annual temperature at 2500 m records 4.4ºC, and annual precipitation reaches only 702 mm^{-1}yr

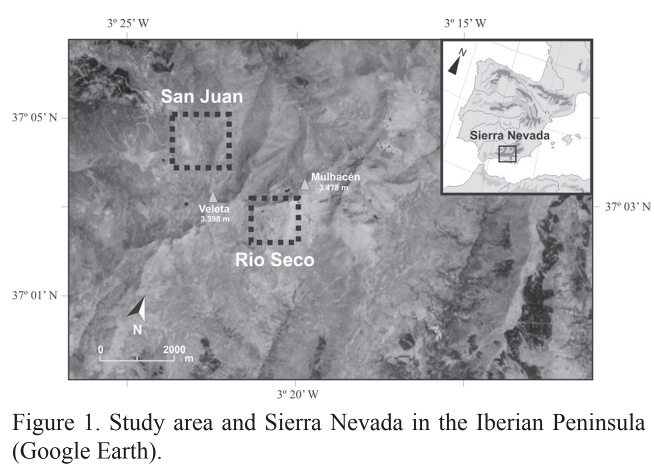

Figure 1. Study area and Sierra Nevada in the Iberian Peninsula (Google Earth).

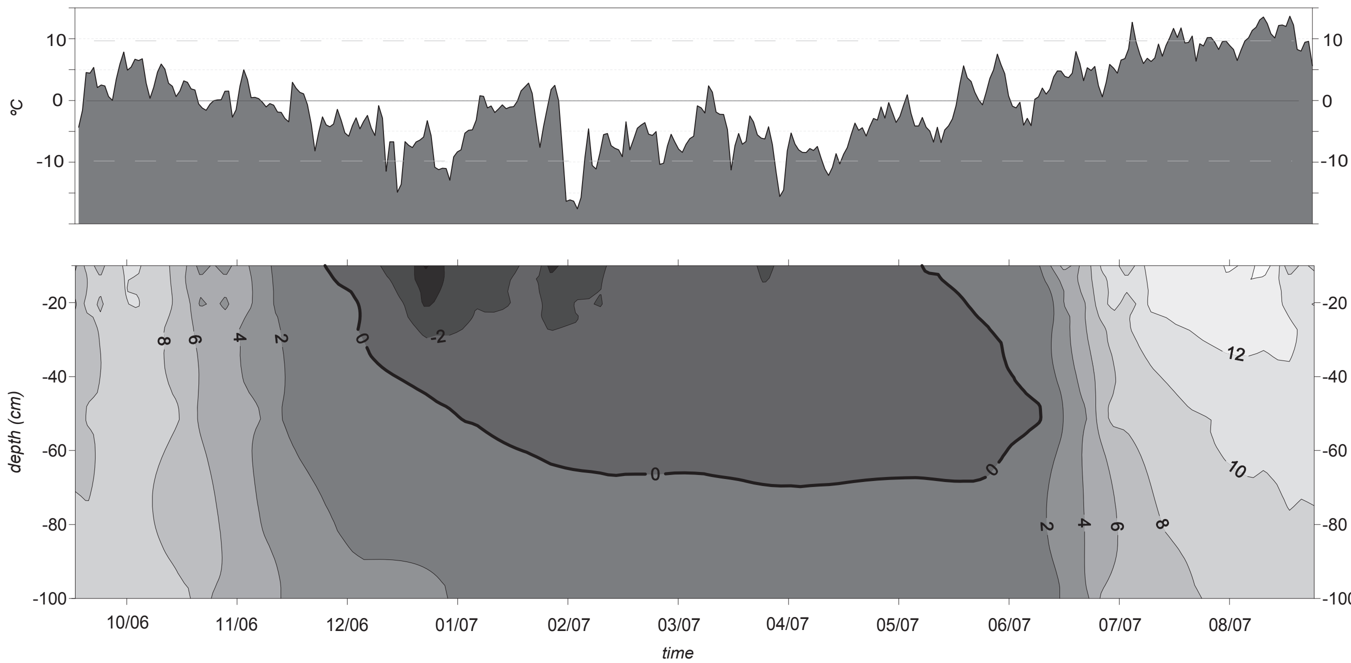

Figure 2. Mean daily air temperature at Veleta Peak, 3398 m (figure above), and ground temperatures of a solifluction lobe of the Rio Seco cirque at 3001 m (figure below) from September 2006 to August 2007.

(1965–1992). 80% of the total precipitation falls between October and April, mainly as snow.

As a consequence of global warming since the end of the Little Ice Age (LIA), the southernmost glacier of Europe located in the Veleta cirque disappeared (Schulte 2002). However, local discontinuous permafrost and active rock glacier dynamics are closely related to remnants of dead ice located in the highest northern cirques of the massif (Gómez Ortiz et al. 2001, Schulte et al. 2002, Gómez Ortiz et al. 2005).

The vegetation cover of the alpine belt in Sierra Nevada is very low, but includes a large number of endemic species (Molero Mesa & Pérez Raya 1987). This sparse vegetation and the low resistance schist, the dominant bedrock in the highest part of Sierra Nevada, enhance solifluction and erosion processes, hence the headwaters of Rio Seco and San Juan valleys show frequent solifluction lobes. In the Rio Seco cirque (southern slope), they are located between 2930 and 3005 m a.s.l. and in the U-shaped valley of San Juan (northern slope) between 2474 and 2911m. Vegetation cover ranges from 1.6% in the Rio Seco cirque to 3.8% in the San Juan valley.

Materials and Methods

More than two hundred solifluction lobes were morphometrically analysed according to the nomenclature of Hugenholtz and Lewkowicz (2002) and Matsuoka et al. (2005), considering 8 variables: altitude, slope, orientation, typology, vegetal cover, length, width, and front height. Universal Temperature Loggers (UTL-1) were installed to measure the ground temperatures continuously every two hours at different depths (2, 10, 20, 50, and 100 cm).

Table 1. Mean stake displacements of monitored solifluction lobes from August 2006 to August 2007.

Valleys	Heights (m a.s.l.)	n	Moving stakes (%)	Horizontal ($cm^{-1}yr$)	Vertical ($cm^{-1}yr$)
San Juan	2793–2911	47	61.8	0.31	0.41
Rio Seco	2935–3001	40	11.8	0.05	0.14

Sedimentological laboratory standard methods were carried out on soil samples extracted from several lobes. Organic carbon was determined with a CN Elemental Analyzer and grain size was measured according to Scheffer & Schachtschabel (2002).

Thermal and Dynamic Control of Solifluction Lobes

From August 2005 to August 2007, displacements of 16 solifluction lobes at different heights were monitored by up to 9 wooden stakes each (50 cm long x 3 cm wide), inserted 45 cm into the lobes. The measurements of the stakes at the lobe fronts and sides may provide sensitive records of active solifluction processes nowadays in Sierra Nevada.

In San Juan, 38.2% of 47 installed stakes did not show any horizontal displacement, reaching 88% out of 40 in the Rio Seco cirque. Furthermore, grass cover, intact root network, soil formation (thin A horizons), and micro-scale geomorphology (clearly defined, steep-sloping lobe fronts) support the interpretation of the inactivity pattern of these lobes.

The rest of the stakes indicate horizontal movement of less than 0.5cm/yr (Table 1) indicating solifluction processes.

Table 2. Different types and characteristics of solifluction lobes in Sierra Nevada.

Type	Characteristics	Nº of lobes (monitorized lobes)	Active / stable	Length (m)		Width (m)		Front height (m)		Slope (º)	
				Range	Mean	Range	Mean	Range	Mean	Range	Mean
Stone-banked lobe-1 STL-1	Abundance of gravels/ rocks > 50%	6 (1)	1 / 0	3-10	5,1	2-5	3,4	0,6-1	0,39	9-19	13,0
Stone-banked lobe-2 STL-2	Abundance of gravels/ rocks < 50%	34 (2)	1 / 1	2-8	5,4	2-8	4,5	0,3-0,9	0,52	7-16	10,3
Low solifluction lobe LSL	Dominance of turf with a frontal height < 80 cm.	104 (4)	2 / 2	1,5-6	4,4	1-5	3,6	0,2-0,7	0,47	7-15	9,8
High solifluction lobe HSL	Dominance of turf with a frontal height ≥ 80 cm	32 (5)	1/ 4	2-10	6,6	2-10	5,3	0,8-1,2	0,9	6-18	11,5
Solifluction terrassettes ST	Low solifluction terrasses	3 (2)	0 / 1	0,6-2	1,1	0,3-1	0,8	0,2-0,3	0,24	6-18	10,0
Stone-mantled lobes MSS	Stone-dominance large lobe ≥ 8 m length	11 (0)	0 / 0	9-15	9,9	8-13	9,5	0,6-1,4	0,86	7-19	14,0
Turf-mantled lobes MST	Turf dominance large lobe ≥ 8 m length	6 (1)	0 / 1	10-18	13,3	10-19	12,7	0,5-1,5	0,78	9-19	13,1
Block STL (block)	Lobe with a rock above	4 (1)	1 / 0	3,5-6	5,0	2-3,5	2,8	0,5-0,9	0,67	6-10	8,0
Mudflow-affected solifluction lobes MSL	Irregular-shaped lobes with muddy matrix	2 (1)	0 / 1	1-6	5,5	5-10	7,5	0,2-0,7	0,67	8-9	8,5

The higher vertical movement rates are due to freeze-thaw uplift. However, the measured surface velocity of the Sierra Nevada lobes is relative slow compared with rates recorded in polar and subpolar regions (Matsuoka 2001).

According to our findings, water availability in the semiarid environment of Sierra Nevada is the main factor controlling solifluidal dynamics. Only lobes near water channels and those influenced by water supply from late-lying snow patches show displacements. Therefore, we expect higher displacement rates during periods of moister climate conditions.

Figure 2 shows mean daily air temperature of Veleta Peak (3398 m a.s.l.) and ground temperature at 10, 20, 50, and 100 cm depth of an inactive solifluction lobe in the Rio Seco cirque at 3001 m a.s.l. from September 2006 to August 2007. The Universal Temperature Logger (UTL-1) at 2 cm depth failed, and no data were obtained.

The formation of the 70 cm thick frozen layer started at the end of November and persisted until the beginning of June. Increased frost penetration was recorded during mid December, the end of January, and the end of March.

This relatively sensitive response of the ground temperature at 10 and 20 cm depth results mainly from reduced snow cover during the winter of 2006–2007. Nevertheless, the persistent conservation of the seasonal frozen layer is due to quite cold late-spring temperatures and a continuous snow cover until the end of May. In contrast to the local permafrost detected in the 3000 m high Veleta (Gómez Ortiz et al. 2005) and Mulhacén cirques (Schulte et al. 2002), the observed pattern of the ground temperature in Figure 2 does not indicate any permafrost regime at the key site of the southern exposed Rio Seco cirque (3001 m a.s.l.).

Morphometry of Solifluction Lobes

In the San Juan valley, 156 lobes were mapped, and 46 were mapped in the Rio Seco Valley. This difference in numbers results from the different amount of water supply and tectonically-influenced valley topography, which explains why there are no solifluction lobes between 2550–2750 m a.s.l. (Fig. 3).

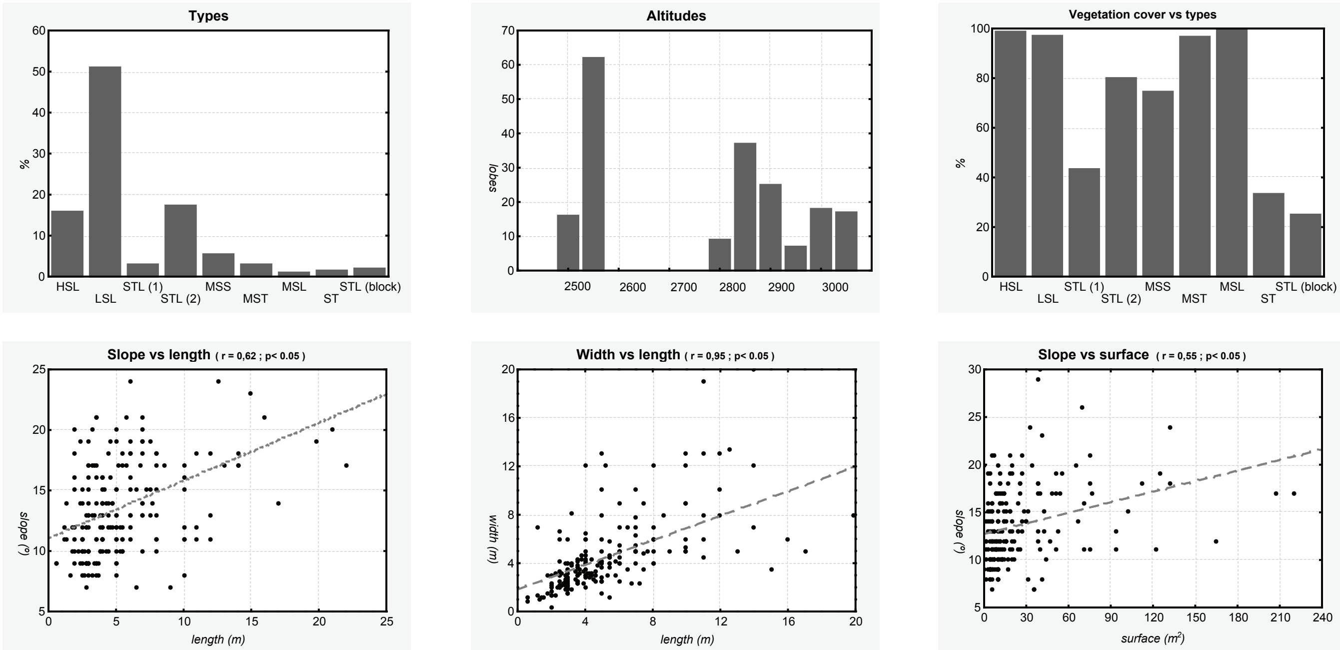

Figure 3. Relations between lobe morphometry, topography and vegetation cover in Sierra Nevada..

In general, a wide range of solifluction lobes can be observed in Sierra Nevada. Types with principal morphometrical and pedological characteristics are listed in Table 2 and can be integrated into two main groups: peat-topped lobes and uncovered stone and block-rich lobes.

There is no evidence that lobe size or other features such as front height, slope gradient, orientation, etc. listed in Figure 3, are related to present solifluction processes. Neither external factors (altitude, slope, and orientation), nor internal characteristics of solifluction lobes correlate with active lobes.

Only vegetation cover may explain the stability or mobility of solifluction lobes, with positive correlations with stable lobes (r = 0.58). Although two well-vegetated LSL also show small horizontal displacements, vegetation seems to impede movement in peat lobes but not in block-rich lobes, which tend to show higher displacement rates**.**

A correlation matrix for lobe morphometry, topography and vegetation cover of solifluction lobes from Sierra Nevada is given in Table 3.

Regarding the lobe morphology, the matrix shows a positive correlation between length and width with slope (r = 0.63; r = 0.54). The height of the riser also shows good correlation with length (r = 0.74) and width (r = 0.71). The surface area is mainly controlled by slope gradient (r = 0.63) and vegetation cover (r = 0.46).

However, orientation does not seem to be an important criterion explaining lobe morphology in Sierra Nevada (r between -0.26 and 0.32). Vegetation cover is mostly controlled by drainage and temperature, showing negative correlations with slope (r = -0.70): the steeper solifluction lobes are, the sparser vegetation cover they have.

Solifluidal Activity During the Late Holocene

Several solifluction lobes in both study areas were examined by macroscopic soil description and geochemical laboratory standard analysis. Figure 4 shows the lithostratigraphy, water content, grain size, and organic carbon content (OC) of a HSL lobe in the Rio Seco cirque at 2945 m a.s.l.

The stratigraphy of the lobe is defined by the alternation of coarse grained stone-rich layers with peat and organic-rich (OC up to 30%). The aggradation of the lobe finished with the development of an organic A horizon. The coarse-grained and sometimes cryoturbated layers are interpreted as solifluidal deposits, whereas the organic-rich horizons represent soil formation under stable geomorphic conditions. Several solifluction lobes in Rio Seco and San Juan valley show a similar lithostratigraphy.

Based on tentative correlations with a solifluction lobe, radiocarbon-dated by Esteban (1994) from 1100 ± 120 yr BP (basal organic layer) to 170 ± 120 yr BP (uppermost organic horizon), we argue that our profile could cover the Late Holocene, from the Medieval Warm Period at the bottom, to the 20th century warming at the top.

The two solifluction layers could correlate with the two main cooler climate pulses of the Little Ice Age reconstructed by Schulte (2002) from ^{210}Pb-dated glacier advances at the nearby Veleta cirque. Historical climate research from documentary data undertaken by Rodrigo et al. (1999) considers that the coldest and wettest phase of the LIA occurred from 1590 to 1650. Radiometric dating and further research is needed to support our chronological model.

Conclusions

This paper presents a morphometric and spatial approach, the aim of which is to classify solifluction lobes in Sierra Nevada in

Table 3. Correlation matrix for lobe morphometry, topography, and vegetation cover of solifluction lobes from Sierra Nevada ($p < 0.05$).

	Orientation	Slope	Vegetation cover	Length	Width	Front height	Surface area	L/W
Orientation								
Slope	0.03							
Vegetation cover	0.31	0.18						
Length	0.05	0.63	0.49					
Width	0.32	0.54	0.61	0.95				
Front height	-0.09	0.29	0.52	0.74	0.71			
Surface area	0.29	0.63	0.46	0.96	0.95	0.62		
L/W	-0.26	-0.22	-0.83	-0.59	-0.74	-0.49	-0.54	

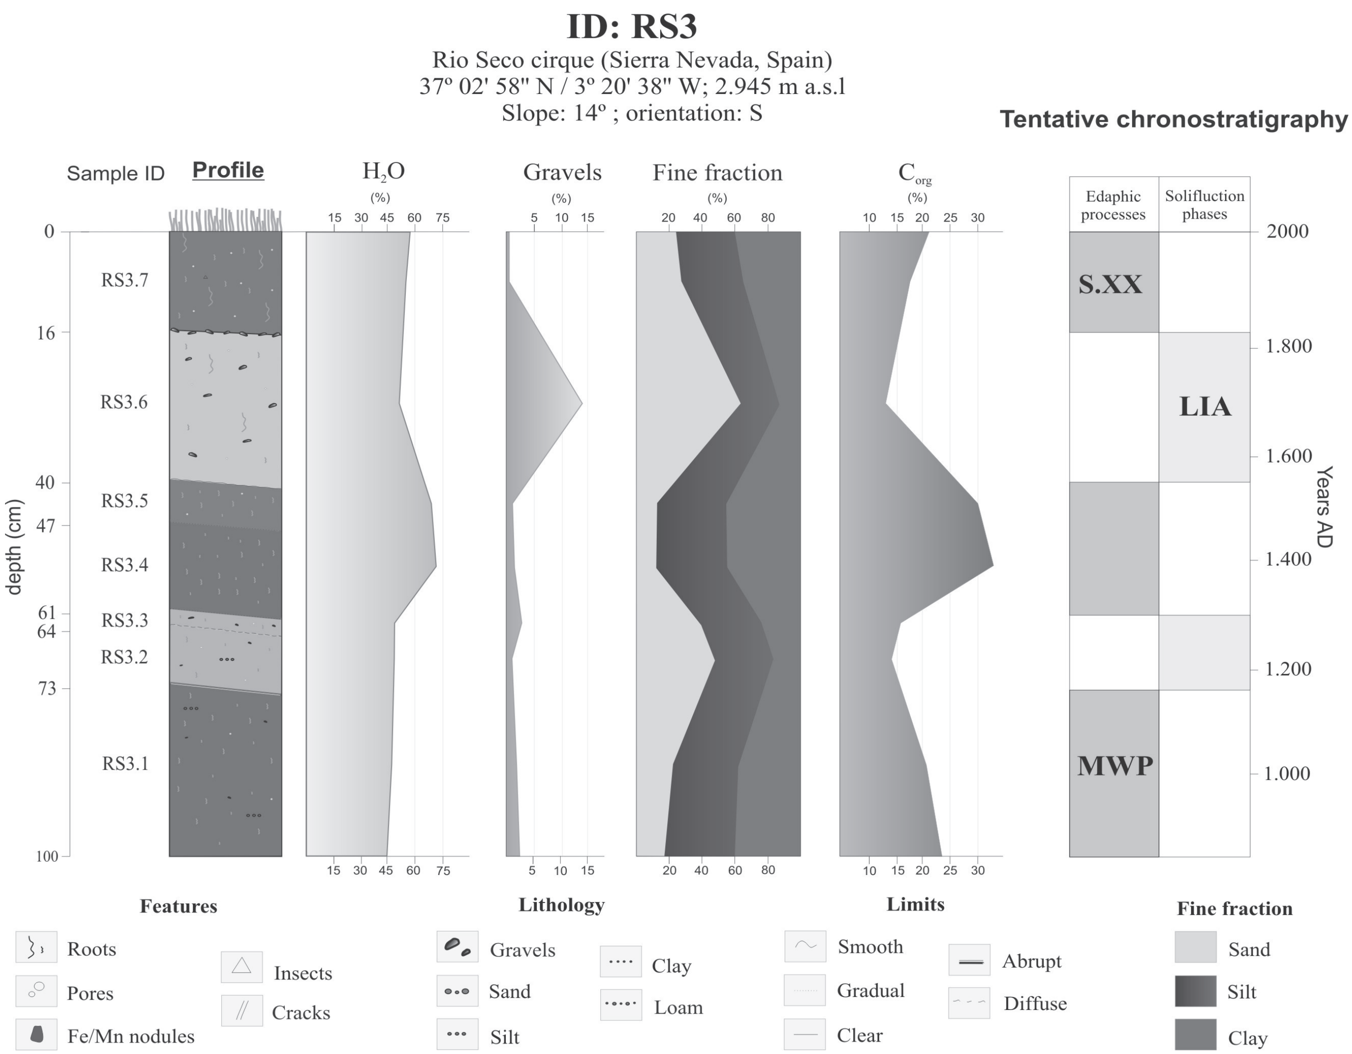

Figure 4. Lithostratigraphy and soil properties of a solifluction lobe of the Rio Seco cirque

southern Iberian Peninsula. Under the present climatic conditions, solifluction is mostly inactive, and only some lobes present small displacements. Thermal and topographic monitoring in the Rio Seco Valley showed that, despite a seasonal frozen layer of 70 cm thickness, solifluction processes were inactive. However, sedimentological studies on solifluction lobes indicate that during the Holocene, periods of increased solifluction processes (e.g., Little Ice Age) alternated with periods of geomorphic stability (e.g., Medieval Warm Period).

We assume that cooler periods in Sierra Nevada could promote solifluction, whereas warmer periods induce soil formation. Present climate may not be wet and/or cold enough to trigger important solifluction processes from 2500 to 3000 m altitude. Future radiocarbon dating will improve our solifluction chronostratigraphy and provide data to precisely identify the timing and environmental conditions of solifluction processes in the alpine belt of Sierra Nevada.

Acknowledgments

This research was financially supported by the Spanish Ministry of Education, project AP-2004-4548 and the Fluvalps-3000 Project (CGL2006-01111). Sedimentological analyses were undertaken at the laboratory of the Department of Geography, University of Berne.

Abstract

Cryptoendolithic microorganisms are widespread in the Canadian High Arctic and show differences in microbial community composition and pH conditions. Laboratory experiments measuring changes in pH and DIC of 15 strains of phototrophic microorganisms (both cyanobacteria and algae) representative of species found in High Arctic cryptoendolithic habitats show clear differences in their ability to generate high pH conditions and uptake HCO_3^- during photosynthesis. Surveys of cryptoendolithic habitats show that microorganisms capable of producing high pH conditions are found within sandstone outcrops that experience rapid exfoliative weathering under water-saturated conditions, suggesting that these microorganisms play a direct role in chemical erosion of the host rock. This is possibly the only known chemical weathering mechanism directly related to photosynthesizing microorganisms in terrestrial silicate rocks, and may have a profound impact on landscape evolution in polar desert environments such as the Canadian High Arctic.

Keywords: biogenic weathering; carbon concentrating mechanism; cyanobacteria; pH shifting; silica dissolution.

Introduction

The abundance and diversity of microorganisms in the subsurface reflect not only their ability to grow under a wide range of natural conditions, but also their capacity to harvest energy from light as well as organic and inorganic substrates. The complexity of these microbial communities depends upon the suitability of a given habitat for colonization, which in many cases exhibit extremes in physical and/or chemical conditions to effectively limit the number of species that can exist within any given ecological niche. An example of this natural selection is found in cryptoendolithic habitats, where microbial colonization is restricted to those organisms able to acquire the necessary resources for growth within the physical confines of pore spaces of rocks. Communities are normally found directly beneath the rock surface (Fig. 1) that consist of primary producers such as algae and/or cyanobacteria as well as consumers and decomposers, including fungi and heterotrophic bacteria (Friedmann et al. 1980, Friedmann et al. 1981, Friedmann 1982, Friedmann & Ocampo-Friedmann 1984, Hirsch et al. 1988, De La Torre et al. 2003, Selbmann et al. 2005, Omelon et al. 2007). They are found in both hot and cold deserts around the world (Friedmann et al. 1987, Bell 1993, Cockell et al. 2003, Bungartz et al. 2004, Omelon et al. 2006) and local areas in temperate regions where climatic extremes limit epilithic colonization (Bell et al. 1986, Ferris & Lowson 1997, Gerrath et al. 2000, Casamatta et al. 2002, Sigler et al. 2003).

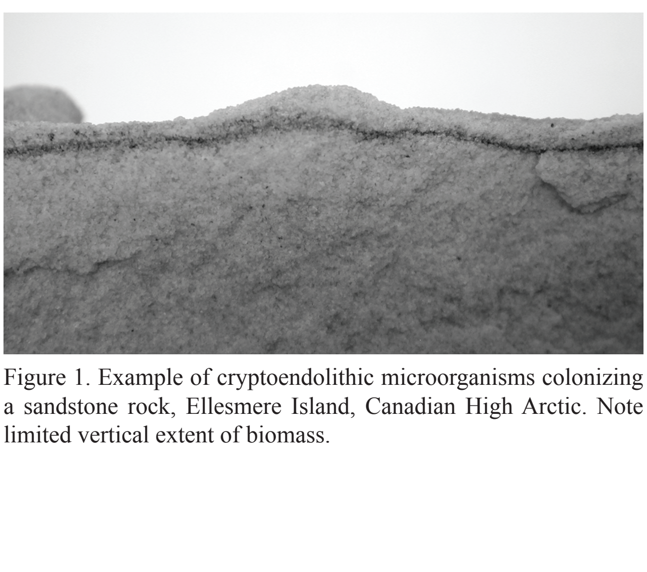

Figure 1. Example of cryptoendolithic microorganisms colonizing a sandstone rock, Ellesmere Island, Canadian High Arctic. Note limited vertical extent of biomass.

Location and site characteristics

Cryptoendolithic colonization of sandstone outcrops are found around Eureka, Ellesmere Island, Nunavut in the Canadian High Arctic (80°00′N, 85°55′W). Microbial communities show marked differences in composition and diversity despite similarities in microclimate, pore space availability, and host rock mineralogy (Omelon et al. 2006). More recently, Omelon et al. (2007) showed that cyanobacteria-dominated communities exist under higher pH conditions in contrast to communities dominated by fungi and algae that are characterized by lower pH conditions, suggesting that the activity of the dominant microorganism(s) controls the pH of the surrounding environment.

It is believed that differences in pH within these cryptoendolithic habitats control weathering rates of the

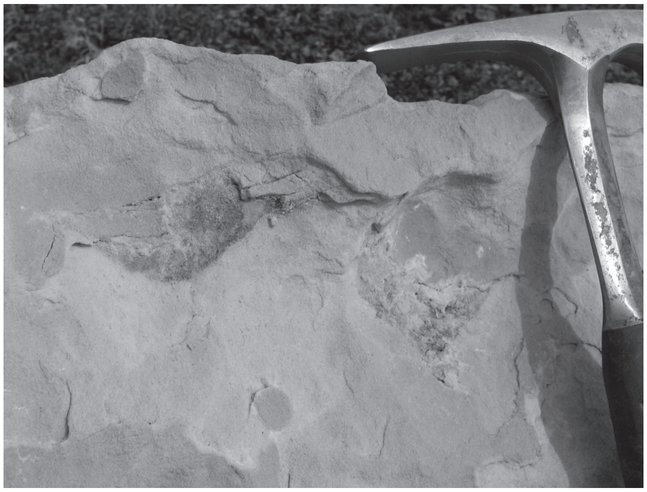

Figure 2. Exfoliative weathering of sandstone rock, with the detachment boundary occurring along the horizon of microbial colonization.

host rock (Omelon et al. 2007). Outcrops dominated by the cyanobacterial species *Leptolyngbya* sp. and *Gloeocapsa* sp. exhibit exfoliated rock weathering through flaking off of surface material, with the origin of detachment occurring along the colonized boundary (Fig. 2). This is in contrast to uncolonized sandstones and those dominated by algae and fungi, which do not exhibit these weathering patterns. This study attempts to relate these observations to cryptoendolithic microbial community structure by examining how microbial activity influences pH, and therefore how cyanobacteria and algae are involved in biogenic weathering of silicate rocks in this polar desert environment.

Biogenic weathering: background

The traditional view of biogenic weathering of sedimentary rocks links the solubilization of cementing minerals to the production of inorganic and organic acids by cryptoendolithic lichens (Friedmann 1982, Hirsch et al. 1995, Wierzchos & Ascaso 1996, Ascaso et al. 1998, Burford et al. 2003, Gaylarde & Gaylarde 2004). Decreasing pore water pH accelerates dissolution of primary silicates and increases solubility (Knauss & Wolery 1986, Knauss & Wolery 1988), while organic acids complex aluminum, and in some cases silica (Bennett & Siegel 1987, Bennett & Casey 1994, Stillings et al. 1996). The net result is the removal of both framework silicates and cements, with the mobilization of nutrients that benefit the microbial community (Bennett et al. 2001).

Bioalkalization

In contrast, cyanobacteria are not known to produce organic acids or acid pore water environments but rather may contribute to silicate dissolution via *bioalkalization* (Budel et al. 2004), whereby high pH conditions are generated in pore waters during cyanobacterial photosynthesis. As with acidic environments, high pH conditions also increase both quartz and feldspar solubility and dissolution kinetics (Brady & Walther 1989, Bennett 1991), resulting in accelerated mineral dissolution that leads to enhanced cycling of elements and nutrients within cryptoendolithic habitats (Johnston & Vestal 1989, Johnston & Vestal 1993, Ferris & Lowson 1997, Blum et al. 2002), and influences residence times of these microbial communities (Omelon et al. 2007).

Cyanobacteria have adapted to changes in temperatures and atmospheric CO_2 and O_2 levels over the past 2.5 billion years (Giordano et al. 2005), which enables them to survive under a wide range of environmental conditions (Badger et al. 2006). Most notable is the evolution of a carbon concentrating mechanism (CCM) to maintain high rates of CO_2 fixation for photosynthesis under conditions of low dissolved CO_2 concentrations (<15 µM) normally found in aquatic habitats (Kaplan & Reinhold 1999, Price et al. 2002, Badger & Price 2003).

The CCM consists of active transport systems to accumulate dissolved inorganic carbon (DIC) within the cell. Specifically, the CCM involves distinct modes of DIC uptake as either HCO_3^- or CO_2 by transporters (Omata et al. 1999, Shibata et al. 2001, Price et al. 2002, Price et al. 2004), to accumulate HCO_3^- within the cell for carbon fixation. A consequence of activation of HCO_3^- transporters for carbon fixation is the production of excess OH^- that is expelled from the cell, resulting in a high pH in the surrounding environment as shown in the equation:

$$HCO_3^- + H_2O \rightarrow (CH_2O) + O_2 + OH^- \quad (1)$$

In the case of silica-rich cryptoendolithic habitats, this mechanism can lead to accelerated weathering of the lithic substrate (Chou & Wollast 1985, Knauss & Wolery 1986, Knauss & Wolery 1988, Brady & Walther 1989, Budel et al. 2004). Observations of pH values >9 in cultures of cyanobacteria from High Arctic cryptoendolithic habitats suggest that these microorganisms use HCO_3^- transporters and are therefore capable of bioalkalization.

Materials and Methods

Cyanobacterial and algal species

Experiments were conducted on a total of 15 species of phototrophic microorganisms; these include 2 species cultured from field samples as well as cultures obtained from the Culture Collection of Algae at the University of Texas at Austin (Table 1) that correspond to the same genus' as those found in the High Arctic cryptoendolithic habitats as described by Omelon et al. (2007). Despite the fact that many algae and cyanobacteria are cosmopolitan in nature, an attempt was made to select cultures from similar habitats (i.e., cold and/or desert conditions) as these species may have adapted their mode of DIC uptake to specific climate and/or microenvironmental conditions. Species were cultured in designated liquid media, aerated with normal air and continuously illuminated at ~60 µmol·m^{-2}·s^{-1} at 20°C.

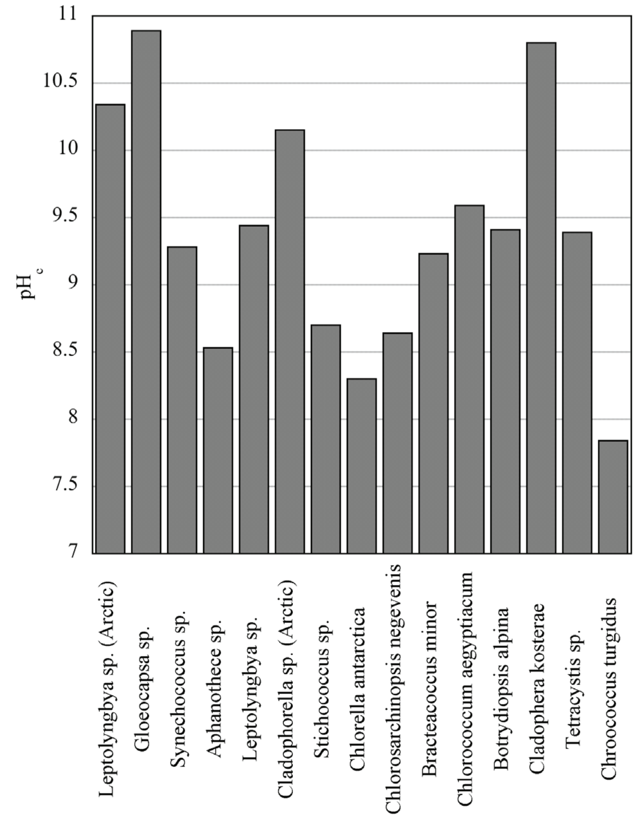

Figure 3. pH compensation points for 15 phototrophic microorganisms. Cultures were incubated at 100 µmol·m^{-2}·s^{-1} and 20°C; pH was monitored until values stabilized.

pH drift experiments

Experimental liquid medium contained 0.25 mmol $CaCl_2$, 0.15 mmol $MgSO_4$, 1 mmol NaCl, 50 µmol KCl, and 1 mmol $NaHCO_3$. Cells were harvested and washed three times in experimental medium by centrifugation at 1000 g for 5 minutes to remove culture media, resuspended in 30 ml of experimental medium in 50 ml Erlynmeyer flasks double-sealed with Parafilm, and incubated at 20°C under saturated photosynthesis light levels (~100 µmol·m^{-2}·s^{-1}) and constant stirring. The pH of the medium was measured periodically, concurrent with the removal of 1 ml subsamples for DIC measurements that were analyzed using a Dohrmann DC-180 carbon analyzer. Experiments were monitored until pH values stabilized, which corresponded to only small changes in DIC concentrations.

Results and Discussion

pH drift

In all cases, the pH of the solution increased from initial pH values (~7–8) as a result of microbial uptake of CO_2 or HCO_3^- for photosynthesis until the pH compensation point (pH_c) was reached, normally within 24 hours of initiation of experiments (Fig. 3). The highest pH_c value recorded was 10.89 by the coccoid cyanobacteria *Gloeocapsa* sp., followed by a pH_c of 10.80 by the filamentous alga *Chladophera kosterae*; similarly high pH_c values were associated with High Arctic cryptoendolithic filamentous cyanobacterial and algal species *Leptolyngbya* sp. (10.34) and *Cladopherella* sp. (10.02). Six species produced pH_c values ranging between 9–10 (two cyanobacteria, four algae), with the remaining five species (one cyanobacteria, four algae) reaching pH_c values <9 that rose only slightly from initial pH values.

DIC measurements

As with pH, uptake of HCO_3^- or CO_2 led to decreases in DIC concentrations in all samples (Fig. 4), with the same species that generated high pH_c values removing the largest amount of available DIC. Uptake by *Gloeocapsa* sp. was the most dramatic, with the removal of 98.9% of DIC, followed by *Cladophera kosterae* (80.2%), the High Arctic *Leptolyngbya* sp. (66.0%), and the High Arctic *Cladopherella* sp. (60.1%). The remaining species removed less that 50% of available DIC from the experimental solution.

A pH_c >9 is the suggested lower limit for activation of a CCM (Kevekordes et al. 2006), however a more definitive value may be a pH of 10, as the concentration of CO_2*(aq)* at this level is <0.06% of total DIC (Banares-Espana et al. 2006) and suggests the use of HCO_3^- transporters over CO_2 transporters.

Based on these guidelines, all species in the current study are able to activate a CCM and therefore utilize HCO_3^- during photosynthesis. *Gloeocapsa* sp., *Cladophera kosterae*, *Leptolyngbya* sp. and *Cladopherella* sp. were the most efficient at removing HCO_3^- from solution with concurrent generation of high pH conditions; in all cases, changes in pH and DIC concentrations occurred within 24 hours. In contrast, the remaining species showed initial increases in pH corresponding to uptake of CO_2 followed by slow changes in pH and lower final pH_c values, suggesting these microorganisms are less efficient in their ability to uptake HCO_3^-.

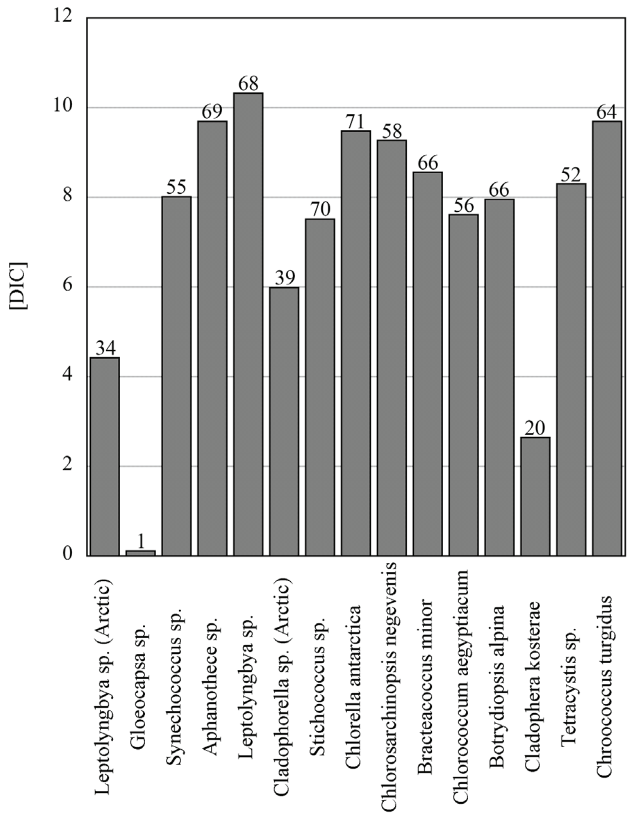

Figure 4. DIC concentrations remaining for 15 phototrophic microorganisms. Cultures were incubated at 100 μmol·m^{-2}·s^{-1} and 20°C; DIC was measured until no further changes occurred. Numbers above columns represent % DIC remaining.

A comparison of these results to the microbial survey of cryptoendolithic communities around Eureka, Nunavut (Omelon et al. 2007) shows that the dominant microorganisms found at sites with high rates of weathering through exfoliation of the overlying rock surface (*Leptolyngbya* sp. and *Gloeocapsa* sp., and to a lesser extent *Cladophorella* sp.) are the same microorganisms capable of producing high pH conditions in laboratory experiments. In contrast, sites with the lowest measured pH values in the field were populated by microorganisms that produced pH_c values <10 (*Chlorella antarctica*, *Bracteacoccus minor var. desertorum*) as well as limited removal of DIC in the current study, suggesting that these microorganisms do not readily uptake HCO_3^- for photosynthesis through a CCM. Although the majority of microorganisms used in this study were not cultured directly from cryptoendolithic habitats in the Canadian High Arctic, many of these microorganisms are widely distributed in nature and likely possess similar physiological traits, such as the presence or absence of a CCM. It is interesting to note, however, differences in pH_c and DIC uptake between the two *Leptolyngbya* spp., suggesting that microorganisms may evolve to adapt to conditions within their specific environment.

Silicate weathering in the cryptoendolithic environment

Although high pH conditions can be generated in aquatic habitats where cyanobacteria and algae consume all available $CO_2(aq)$ and must therefore use HCO_3^- for photosynthesis, there is little knowledge or understanding of the impact of high pH-generated conditions in terrestrial habitats. The data presented here provides information that, when coupled with an understanding of microenvironmental conditions within cryptoendolithic habitats, can explain observations of exfoliative weathering of rocks colonized by microorganisms generating high pH conditions. Previous work by Omelon et al. (2006) showed that High Arctic cryptoendolithic habitats experience warmer temperatures and wetter conditions than the exposed outcrop surface. Temperatures can reach up to 30°C within the cryptoendolithic habitat and were found to exceed 10°C and 20°C for substantial periods of time (753 and 93 h·yr^{-1}, respectively) during summer months, which is likely correlated to substantial net growth in these environments (Omelon et al. 2006). Furthermore, evidence of water infiltration into the subsurface resulting from rainfall or snowmelt and subsequent retention of this moisture in pore spaces leads to increased rates of photosynthesis due to increased light penetration and continuous irridation. The combination of these microenvironmental conditions generates elevated pH within pore waters, whereby rates of OH^- production by cyanobacteria and algae with an effective CCM exceeds rates of diffusion of $CO_2(g)$ into the water-saturated microenvironment. These high pH conditions greatly enhance silicate and quartz dissolution rates—for example, at pH 9.8, the solubility of quartz doubles, and at pH 10.8 it is almost five times the solubility at pH 7—resulting in the solubilization of the rock matrix near these photosynthesizing organisms. In contrast, sites dominated by microorganisms that do not produce high pH conditions experience increased rates of photosynthesis but with apparently negligible production of OH^-.

The sporadic nature of this rock exfoliation highlights the fact that generation of high pH conditions within these habitats requires the presence of liquid water that effectively limits CO_2 diffusion from the atmosphere, thereby requiring activation of microbial CCMs. Given the low number of precipitation events that occur in this region of the Canadian High Arctic, rapid solubilization of intergranular silica-rich cements is restricted to those periods of moisture infiltration into the subsurface. In contrast, during periods of arid conditions, all photosynthesizing microorganisms uptake atmospheric CO_2, resulting in little change in pH in the cryptoendolithic environment.

Direct evidence for silica dissolution through bioalkalization has been found in preliminary ESEM observations of etch pits on quartz grain surfaces overlain by cyanobacterial communities. Further documentation of such features will provide additional evidence for chemical weathering of silica-rich intergranular cements through the generation of high pH conditions by these microorganisms, and will be of interest to studies focusing on mechanisms that lead to the creation of terrestrial biosignatures.

Conclusions

The global ubiquity of cyanobacteria and algae in cryptoendolithic habitats and the generation of high pH conditions by those microorganisms with efficient CCMs suggests that bioalkalization could play a fundamental role in the chemical weathering of silica minerals (Schwartzman & Volk 1989). In addition, this pH shift has important implications for porosity development, release of essential nutrients, and mobilization of metals under high pH conditions. Understanding the biogeochemical dynamics of cryptoendolithic microorganisms is an important step towards a broader understanding of how phototrophic microorganisms control silica dissolution in terrestrial landscapes.

Acknowledgments

The authors wish to thank Canada's Atmospheric Environment Service and the Polar Continental Shelf Project for lodging and logistical support during field seasons. This work is supported by the Jackson School of Geosciences at the University of Texas at Austin, the Natural Sciences and Engineering Research Council of Canada, and the Canadian Space Agency. We sincerely thank the staff of the Eureka Weather Station for their dedicated field support, and Lisa Nguyen of UT Austin's Culture Collection of Algae for laboratory assistance.

Thermal State of Permafrost in Alaska During the Fourth Quarter of the Twentieth Century

T. E. Osterkamp
Geophysical Institute, University of Alaska, Fairbanks, Alaska, U.S.A.

Abstract

Permafrost temperatures in Alaska increased during the fourth quarter of the twentieth century at sites north of the Brooks Range from the Chukchi Sea to Canada, south along a transect from Prudhoe Bay to Gulkana, and at other sites. Tentative results are presented concerning the characteristics of the warming. Meteorological records, permafrost temperature measurements, thermokarst studies, and modeling efforts suggest the warming occurred statewide. Its magnitude along the transect was 3 to 4°C for the Arctic Coastal Plain, 1 to 2°C for the Brooks Range, and 0.3 to 1°C south of the Yukon River. The warming was seasonal, primarily in winter. Active layer thicknesses on the Arctic Coastal Plain did not increase. Thawing at the permafrost surface and base is occurring and new thermokarst terrain has developed. Probable causes of the warming and thawing include changes in air temperatures, snow cover effects, and combinations of these.

Keywords: borehole temperatures; climate warming; permafrost; thermokarst

Introduction

Air temperatures in Alaska warmed from the late 1800s until near the end of the second quarter of the twentieth century (Hansen & Lebedev 1987). There was a cooling during the third quarter and, in the permafrost regions of Alaska, a step-like increase in air temperatures during the fourth quarter (1976/1977, Hartmann and Wendler 2003). This warming peaked in the early 1980s and was followed by decreased air temperatures into the mid-1980s. Temperature trends from the late 1970s to the end of the 20th century were sometimes warmer although many sites had little or no warming or a cooling. From the cooler mid-1980s to the end of the century, most sites showed a warming trend. The first 6 years of the 21st century have been consistently warm, typically about the same as the period around 1980. Snow covers were generally thick during the third quarter and relatively thin during the early 1980s. Snow cover thicknesses during the 1990s were typically much greater than during the 1980s. The recent warming may be the continuation of the long term warming or a new unrelated warming event.

The thermal state of Alaskan permafrost has responded to these climatic changes and perhaps to other factors. It appears there were two permafrost warming events; a long-term warming that was initiated in the early 1900s and a recent warming (since 1976/1977).

Past international conferences on permafrost have examined climate-permafrost interactions and have documented permafrost warming in Alaska. This paper reiterates, updates, and extends reviews of the thermal state of permafrost in Alaska by the U.S. Geological Survey and University of Alaska (Lachenbruch et al. 1982, Lachenbruch & Marshall 1986, Osterkamp et al. 1984, 1987, Lachenbruch et al. 1988, Clow et.al 1991, Lachenbruch 1994, Osterkamp & Romanovsky 1999, Romanovsky et al. 2003, Osterkamp 1983, 2003a, b, 2005, & 2007a, b). The data used herein are from the U.S. Geological Survey studies (Lachenbruch & Marshall 1986, Clow & Urban 2002) and the University of Alaska studies (Fig.1). (See Osterkamp (2003b) for methods and site information.) The paper is primarily concerned with the characteristics, impacts, and causes of permafrost warming during the last quarter of the twentieth century and attempts to provide at least tentative answers to questions regarding this warming. The effort is hampered by the lack of data even in the northwest and along a north-south transect of Alaska where most of the data are concentrated. This makes it difficult to arrive at definitive conclusions about the thermal state of the permafrost. However a better understanding of permafrost conditions is emerging from efforts that combine modeling, weather data, and thermokarst studies with temperature measurements.

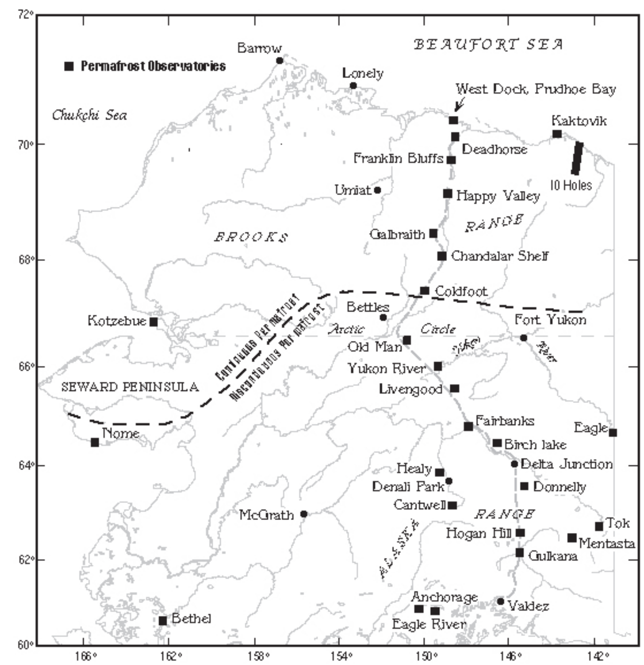

Figure 1. Location of the Alaskan transect and other sites. USGS sites are primarily in northwest Alaska.

Review and Discussion

Effects of climate on permafrost

The effects of climate (here the averaged weather, primarily air temperature and precipitation) on permafrost are difficult to determine because of sparse data and a multitude of non-climatic factors that can influence the thermal state of permafrost. These factors include terrain (topography, slope, aspect, geomorphology), hydrology (surface drainage, site wetness, proximity of nearby water bodies, presence of underground water), vegetation (succession, insulation, insolation, snow interception), geology (type of soil and rock, tectonic setting and geothermal heat flow), and disturbances (human, animal, fire, and flooding events) (Osterkamp & Jorgenson, in press). The factors operate at different time scales (days to millennia) and spatial scales (local to continental). The effects of changes in some of them (e.g., geomorphology, vegetation (succession), disturbances) have the potential for being mistaken for changes in climate as do other related factors (e.g., rapid sedimentation at the ground surface, three dimensional heat flow, and vertical variations in thermal conductivity).

The permafrost surface is separated from effects of air temperatures and other climatic factors by vegetation, snow cover in winter, and an active layer that freezes and thaws annually. Heat and mass transport processes, including coupled and advective processes, and phase change in these materials influence the surface temperature of the permafrost (Outcalt et al. 1975, Goodrich 1982, Smith & Riseborough 1983, Lachenbruch 1994, Zhang et al. 1996, 1997). There are also intricate thermal feedback effects such as the effects of air temperature and moisture on vegetation, the ensuing effects of vegetation and wind on snow cover, and the effects of the resulting snow cover on permafrost surface temperatures. Consequently, the relationships between climate and permafrost surface temperature are exceedingly complex. Even the case of air temperature is not straightforward. Warming of annual mean air temperatures can be a result of a general change in all seasons or seasonal changes such as warmer or longer summers (defined here as the period when the ground is snow free) or warmer or shorter winters (when snow is on the ground). Since winters are longer than summers in permafrost areas, cooler summer temperatures can be offset by warmer winter temperatures resulting in a net warming.

The net result of a snow cover is that it increases mean annual ground surface temperatures. The magnitude of the warming depends on the timing and duration of the snow cover, its accumulation (thickness) and melting history, and the effects of macrostructure (wind slab, depth hoar) on its properties (Goodrich 1982, Goodwin et al. 1983, Zhang et al. 1996, Zhang 2005). Interactions of wind, microrelief, and vegetation with the snow cover also influence the surface temperature of permafrost (Zhang et al. 1997).

The above considerations suggest that, when permafrost warms, the warming cannot be automatically attributed to increasing air temperatures and/or the effects of changes in snow cover thickness. Nevertheless, modeling studies confirm the primary role of air temperatures and the effects of changes in snow cover on the surface temperature of permafrost (Outcalt 1975, Goodrich 1982). Applications of models to field conditions show that, using measured daily air temperatures and snow cover thicknesses as input data to drive calibrated site specific conductive numerical models that include phase change and use realistic thermal parameters taking into account site conditions (wetness and others), typically produces remarkable agreement between calculated and measured active layer and permafrost temperatures (Zhang et al. 1997, Osterkamp & Romanovsky 1997, Osterkamp and Romanovsky, 1999; Romanovsky and Osterkamp 2000). While mass transport, advective, and coupled processes are known to occur in the snow cover, vegetative mat, and active layer, they appear to be of secondary importance in influencing long-term permafrost surface temperatures except in certain settings. The reasons for this are not known but may include cancellation of effects, shortness of their duration, and others.

Characteristics of the warming

For the long-term event, temperature profiles in deep boreholes generally indicate an increase at the permafrost surface of 2 to 4°C in northwest Alaska. Warming did not begin synchronously at all sites, not all sites showed a warming, and the results were not readily contourable (Lachenbruch & Marshall 1986, Lachenbruch et al. 1988, Clow et al. 1991).

For the recent warming during the last quarter of the twentieth century, observations show that permafrost in warmed north of the Brooks Range from the Chukchi Sea Coast to the Alaska-Canada border, south along a transect from Prudhoe Bay to Gulkana and up to 300 km from the transect (Fig. 1, Clow & Urban 2002, Osterkamp 2003a, 2005, 2007a, Osterkamp & Jorgenson 2005). Borehole temperatures at Prudhoe Bay (Fig. 2), thermokarst observations, basal thawing measurements, and modeling investigations elsewhere suggest that permafrost temperatures increased statewide coincident with the increase in air temperatures that began in 1976/1977 in Alaska (Osterkamp 2007a). The initial permafrost warming peaked in the early 1980s and then cooled into the mid-1980s. Arctic sites began warming again about 1986 and Interior sites about 1988 (Fig. 2). The timing of this warming was somewhat later in the western Arctic (Chukchi Sea to the Colville River), not long before 1989 (Clow, personal communication, 2006). Warming generally continued through the 1990s although some sites leveled off or cooled near the end of the century while some continued to warm. The magnitude of the total warming at the permafrost surface through 2003 falls into three latitudinal groups; an average of 3°C for the western Arctic and a range of 3 to 4°C for the Arctic Coastal Plain near Prudhoe Bay, 1 to 2°C along the transect through the Brooks Range including its northern and southern foothills, and 0.3 to 1°C south of the Yukon River (Osterkamp 2005). On the Arctic Coastal Plain, the magnitude of the recent warming is comparable to that of the long term warming but it occurred over a much shorter time period.

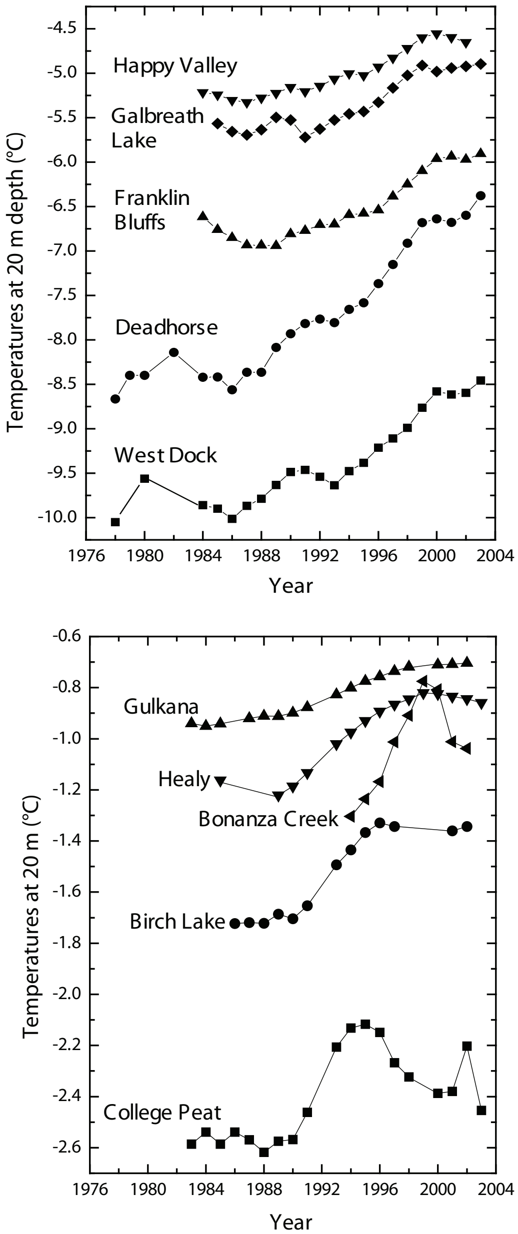

Figure 2. Temperatures (20 m depth) for selected sites.

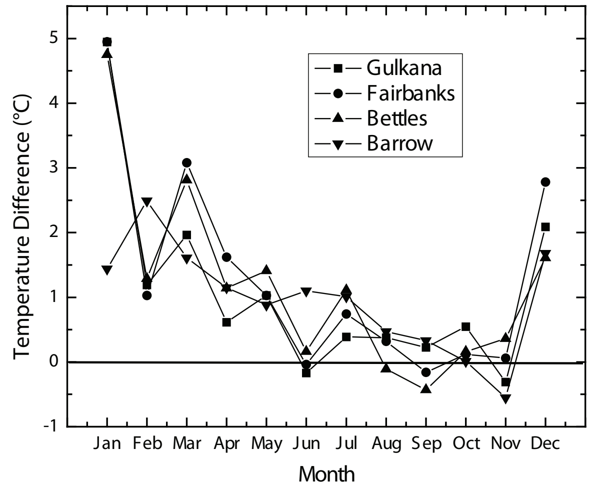

Figure 3. Increases in mean monthly air temperatures for the period after (1977-1996) compared to before (1957-1976) the recent warming.

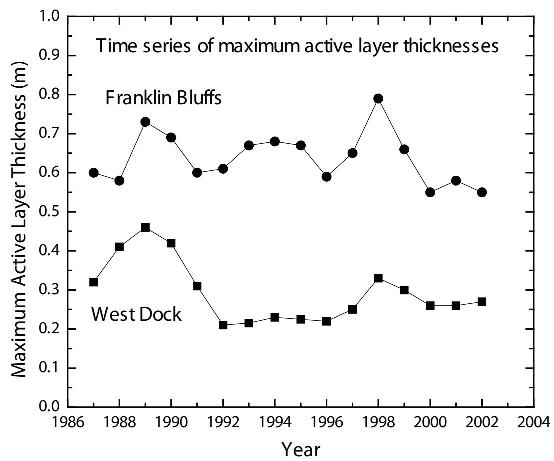

Figure 4. Time series of maximum active layer thicknesses for two sites on the Arctic Coastal Plain.

Measurements show that permafrost warmed north of Kotzebue, near Cantwell, and at Eagle River; sites that are 300 km or more from the transect (Osterkamp 2007a). These observations from widely separated areas coupled with weather data and other observations suggest that the scenario developed above for northern Alaska and the transect may also hold, with some differences in timing and magnitude, in other permafrost areas in the state (Osterkamp 2007a). However, some sites cooled over the same period and a site near Eagle had not warmed by 1994 indicating that there may be other areas that are exceptions to the warming.

The regime shift that occurred in 1976/1977 was seasonal, characterized by increased air temperatures for mid to late winter months (Hartmann & Wendler 2003). There was little change in summer and early winter air temperatures (Fig. 3). This seasonality also occurred in permafrost surface temperatures at the Deadhorse and Franklin Bluffs sites. Again, the general nature of the warming (Fig. 3) suggests a similar statewide seasonality for the permafrost warming with possible exceptions (Osterkamp 2005).

While the permafrost warmed 3 to 4°C, maximum active layer thicknesses at nearby sites on the Arctic Coastal Plain did not show increasing trends from 1987 to 2002 (Fig. 4, Osterkamp 2005). This is a direct result of the observed seasonality in air temperatures. Since the warming occurred primarily in winter, active layer thicknesses would not be expected to be significantly influenced by the warming and cannot be used as an indicator of the warming. The widespread seasonality of the air temperature increases (Fig. 3) suggests that statewide active layer thicknesses may not have been generally influenced significantly by the warming.

Natural thawing of the permafrost from the top downward has been observed to occur in a tundra and a forest site at a rate of about 0.1 m/yr in response to the permafrost warming (Osterkamp 2005). Basal thawing is occurring at four sites with shallow (<40 m thickness) discontinuous permafrost.

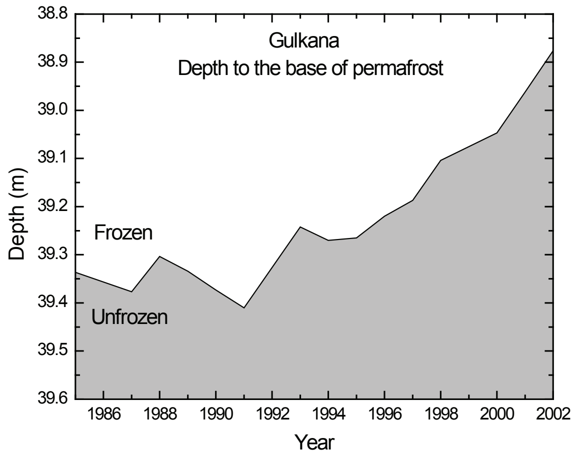

Figure 5. Thawing at the base of the permafrost at Gulkana.

Sites with thicker permafrost (>60 m) are generally warming at depth. At Gulkana, thawing at the base of the permafrost began about 1992 and proceeded at a mean rate of ~ 0.04 m/yr until 2000 when it accelerated to ~ 0.09 m/yr (Fig. 5, Osterkamp 2005). These basal thawing rates are much greater than predicted theoretically. If basal thawing at Gulkana was the result of a step change in permafrost surface temperature, the change would have occurred in 1976 coincident with the statewide warming of air temperatures. Thawing at the boundaries of unfrozen ground with permafrost (taliks in the continuous permafrost and isolated permafrost masses elsewhere) as a result of permafrost warming is predicted (Osterkamp 2003, 2005) but has not been investigated.

Thermokarst terrain was absent at a site near Healy, when the site was established (1985) but now exists in several places throughout the area (Fig. 6). Maximum thaw settlement was about 1.1 m in a pit at the borehole pipe and up to about 1½ m in the surrounding area (Osterkamp et al., submitted). New thermokarst terrain, formed by thawing ice-rich permafrost, has been observed, not only in Interior Alaska, but also in Northern Alaska where old ice wedges have been thawing since 1989 (Osterkamp et al. 2000, Jorgenson et al. 2001, Jorgenson et al. 2006).

Causes

For the recent warming, the data reviewed above suggest that permafrost generally warmed statewide coincident with increasing air temperatures in 1976/1977. There was not a pattern of corresponding changes in snow cover at this time suggesting this initial warming may have been primarily a result of increased air temperatures. Increasing permafrost temperatures in the late 1980s and into the 1990s may have been in response to a series of winters with thick snow covers (Osterkamp & Romanovsky 1999). This appears to be the case for Healy (Osterkamp 2007b) and Gulkana (Fig. 7) and, at least partially, for other sites. At some sites, air temperatures increased less than permafrost surface temperatures implicating snow cover effects in the observed warming. At Barrow, modeling results have shown that snow cover effects were involved in the century-long warming and the recent warming (Zhang & Osterkamp 1993). Stieglitz et al. (2003) have shown that about half the recent warming there was due to air temperature changes and half due to snow cover effects.

Figure 6. Photos showing thermokarst and changes in surface mophology over two decades at the Healy site.

Since new thermokarst was observed at Healy coincident with warming permafrost, it appears that permafrost thawing and development of thermokarst terrain was also a result of snow cover effects there (Osterkamp et al. submitted).

Summary

This paper uses borehole temperature measurements, basal thawing measurements, thermokarst observations, modeling results, and weather data in an attempt to reconstruct the thermal state of permafrost in Alaska during the last quarter of the twentieth century. This effort is hindered by the sparsity of long-term permafrost temperature data and the lack of interpretive studies which make the conclusions tentative.

During the last quarter of the twentieth century, permafrost warmed north of the Brooks Range from the Chukchi Sea to the Alaska-Canada border, south along a transect from Prudhoe Bay to Gulkana and up to 300 km from the transect. Sporadic measurements also show that permafrost warmed at other widely separated sites including north of Kotzebue, near Cantwell, and at Eagle River. It appears likely that permafrost temperatures increased statewide coincident with the statewide increase in air temperatures that began in 1976/1977. Some sites did not warm indicating there may be other sites that are exceptions to the warming.

The initial permafrost warming peaked in the early 1980s

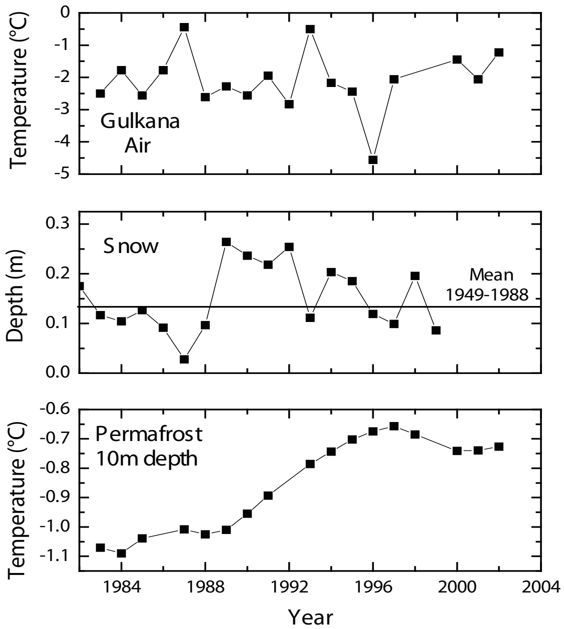

Figure 7. There was a trend of increasing permafrost temperatures at the Gulkana site (1989-1997) while air temperatures decreased and snow covers were thicker than the long term average.

and then cooled into the mid-1980s. Arctic sites began warming again about 1986 (Western Arctic prior to 1989) and Interior sites about 1988. Warming generally continued through the 1990s although some sites leveled off or cooled near the end of the century while some continued to warm.

The magnitude of the total warming at the permafrost surface was up to 4°C for the Arctic Coastal Plain, 1 to 2°C along the transect through the Brooks Range including its northern and southern foothills, and 0.3 to 1°C south of the Yukon River.

Increased air temperatures in the two decades after 1976/1977 were seasonal, a result of warmer winter temperatures with little change in summer conditions. This seasonality also occurred in permafrost surface temperatures at the Deadhorse and Franklin Bluffs sites. It is suggested that this was likely the case for other areas of the state. While permafrost temperatures increased by 3 to 4 °C, maximum active layer thicknesses did not show an increasing trend.

Thawing at the permafrost table and base has been observed in shallow permafrost and new thermokarst terrain has been observed.

Warming of the permafrost in the Arctic Coastal Plain in the late 1970s was probably caused primarily by increased air temperatures and, in Interior Alaska during the late 1980s and into the 1990s, primarily by increased snow cover thicknesses. At a few sites in Interior Alaska and for certain time periods, the permafrost warmed entirely because of snow cover effects. Generally, both air temperatures and snow cover effects appear to have contributed to the permafrost warming.

A thorough study of the effects of past snow conditions is needed. However, due to the complex and non-linear nature of snow cover effects, calibrated site-specific numerical models are required to quantify the relative contributions of snow and air temperatures to warming and thawing of the permafrost.

Field Trials of Surface Insulation Materials for Permafrost Preservation

James M. Oswell

Jack R. Everts
Exxon Mobil Development Company./Imperial Oil Resources Ventures Limited, Calgary, Canada

Abstract

Two test sites were initiated to examine the use of several insulating-type materials for potential use as thermal mitigation strategies on the Mackenzie Gas Project. The Woodenhouse test site, located northeast of Slave Lake, Alberta, was constructed in March 2005. The Norman Wells, Northwest Territories, test site was constructed in March 2006. At both sites, flax straw bales and white reflective surfaces were being tested. A test cell of shredded wood was also tested at the Woodenhouse test site. Each test cell was approximately 20 m by 20 m in plan area. A control cell was also present. Temperatures were measured at the ground surface and at selected depths to 10 m. All temperatures were recorded on dataloggers. The performance of the test materials was examined from several perspectives including thermal performance, degradation/deterioration, and imported weed growth. Compared to the control cell, straw bales provided the best thermal protection, followed by shredded wood. The reflective surface was marginally better than the control.

Keywords: monitoring; pipeline; surface insulation; thermal mitigation.

Introduction

The Mackenzie Gas Project (MGP) is intended to transport natural gas from the Mackenzie Delta area in northern Canada through the Northwest Territories to connect with distribution pipelines in northern Alberta. The proposed pipeline will have an initial capacity of about 0.8 billion cubic feet per day (bcfd), with a fully expanded capacity of nearly 1.8 bcfd. Along the route, the pipeline will traverse approximately 200 km of continuous permafrost and about 1000 km of discontinuous permafrost. The pipeline will be designed as a fully buried system.

Right-of-way clearing and pipeline construction will alter the geothermal character of the permafrost within the right-of-way, which if not mitigated, will inevitably result in permafrost warming, deepening of the active layer and other effects. For sloping terrain along the route, these geothermal changes could result in instability of the slopes, if not mitigated. There are approximately 160 identified slopes along the route that may require mitigation to ensure long-term stability.

Slope stability issues along pipeline routes underlain by permafrost have been addressed in the past. Perhaps the most important case history for mitigation of the effects of thawing permafrost on slope stability was the Norman Wells oil pipeline, owned and operated by Enbridge Pipelines (NW) Inc. This pipeline is fully buried in discontinuous permafrost along its 868 km route that somewhat parallels the proposed Mackenzie gas pipeline between Norman Wells and Alberta. To address the thawing of permafrost on slopes and related instability that could result, a layer of wood chips was installed on approximately 33% of Norman Wells pipeline slopes. The design and performance of the wood chip-covered slopes was documented by Hanna and McRoberts (1988), Hanna et al. (1994) and Oswell et al. (1998).

Given the design, construction and operational differences between the Mackenzie gas project and the Norman Wells pipeline project (for example, right-of-way width, pipeline operating temperatures, diameters, ground temperatures), the MGP decided to conduct field tests to assess the thermal properties of several surface insulation materials that may be useful in mitigating permafrost degradation.

Surface Insulation Field Trials

Test materials

The field trials tested the following three different materials:

- Shredded wood
- Straw bales
- Reflective surface (geotextile)

The shredded wood material consists of well-graded wood fibers ranging in lengths from about 200 mm to about 50 mm. This material differs from the wood chips used on the Norman Wells pipeline, which were typically flat wood particles being circular to elongated and up to about 25 mm to 40 mm in diameter.

The straw bales were standard rectangular flax straw bales sized at about 0.4 m high, 0.51 m wide and 1.1 m long, and weighing about 30 kg. Flax was selected because it was very slow to decompose and it was of low palatability to animals such as moose and caribou.

The reflective surface material consisted of a white geotextile, intended to reflect the summer solar radiation from the ground surface while allowing the cold winter temperatures to penetrate the ground. Reflective materials have been used to reduce snow and ice ablation (Poplin et al. 1991).

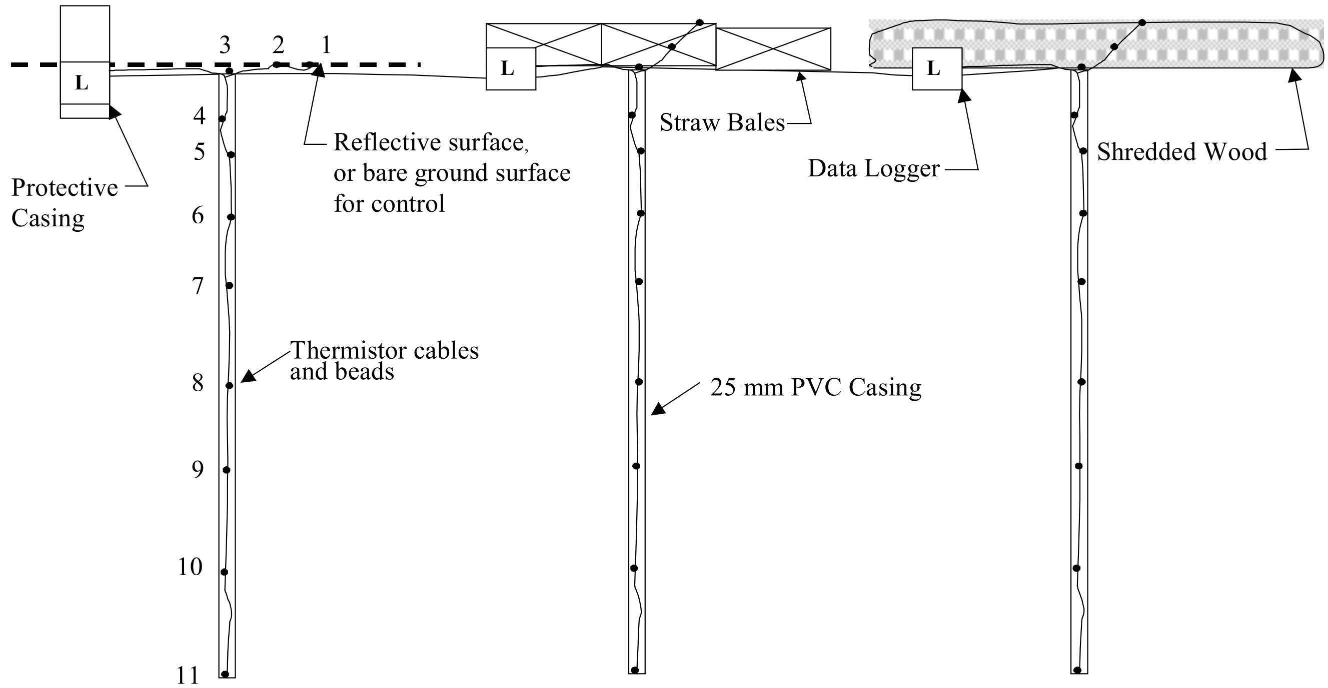

Figure 1. Layout of test cells (not to scale) and associated instrumentation.

Test site and set-up

Two test sites were established; the first site was in northern Alberta, near the community of Slave Lake, at a compressor station site named Woodenhouse. The mean annual air temperature was about +1.3°C. The test site area was previously cleared of all vegetation and the ground surface consisted of granular fill over unfrozen mineral soil. The second test site was in Norman Wells, Northwest Territories, which has a mean annual air temperature of about -5.5°C. This site was initially forested with sparse spruce trees, but was cleared of trees at the start of the test program. The ground surface consisted of the native organic mat underlain by mineral soils that was frozen, but considered to be warm permafrost.

The Woodenhouse test site consisted of three test cells plus a control. The test cells were straw bales, shredded wood and a reflective surface, each 20 m by 20 m in plan dimensions. A control cell was installed to provide baseline data for comparison. The Norman Wells test site was the same as the Woodenhouse site except that there was no shredded wood test cell.

The ground temperatures were monitored using an eleven bead thermistor cable attached to a data logger, recording temperatures at 12-hour intervals. The temperatures were measured at the following depths: 0 m, 0.5 m, 1.0 m, 2.0 m, 3.0 m, 4.5 m, 6.0 m, 8.0 m, and 10.0 m. In addition, two thermistor beads were attached to a "pig-tail" that would monitor the temperatures at the mid-point and top surface of the straw bales and shredded wood layers. Air temperatures were monitored at 1.0 m above the ground surface at the control cell.

The Woodenhouse site was installed in February 2005 and the Norman Wells site was installed in February 2006. The sites were prepared by site clearing, including snow clearing, installing the test cells and then drilling boreholes to install the thermistor cables. Figure 1 presents the typical test cell and thermistor cable lay-out showing the thermistor bead numbering.

Initial thermal performance

This paper only reports initial results from the Woodenhouse test site in northern Alberta. Data collection from the Norman Wells site has experienced a number of challenges, and as a result full analysis of these datahas not been completed. For the Woodenhouse test site, temperature data has been regularly downloaded since testing began.

Thermistor beads 3 (0 m), 4 (0.5 m depth) and 5 (1.0 m depth) provided the most representative data on the near surface geothermal reaction of the surface cover. Bead 9 (6.0 m depth) provided ground temperatures at a moderate depth.

Figure 2 shows ground surface temperatures for all of the test cells at Woodenhouse. The ground surface temperatures at the control test cell and the reflective surface test cell were similar to each other. The ground surface temperatures for the straw bales and shredded wood materials were dampened compared to the atmospheric temperatures. That is, the effect of the straw bale and shredded wood layers was to reduce the day-to-day temperature variation in ground temperature compared to the air temperatures. Furthermore, the straw bales and shredded wood materials experienced a time lag in responding to atmospheric variations. This time lag was about one month, although more data is necessary to more accurately quantify the lag-period.

The time lag experienced for temperatures under the straw bale and shredded wood test cells compared to the control test cell was more apparent at depths of 0.5 m (see Fig. 3)

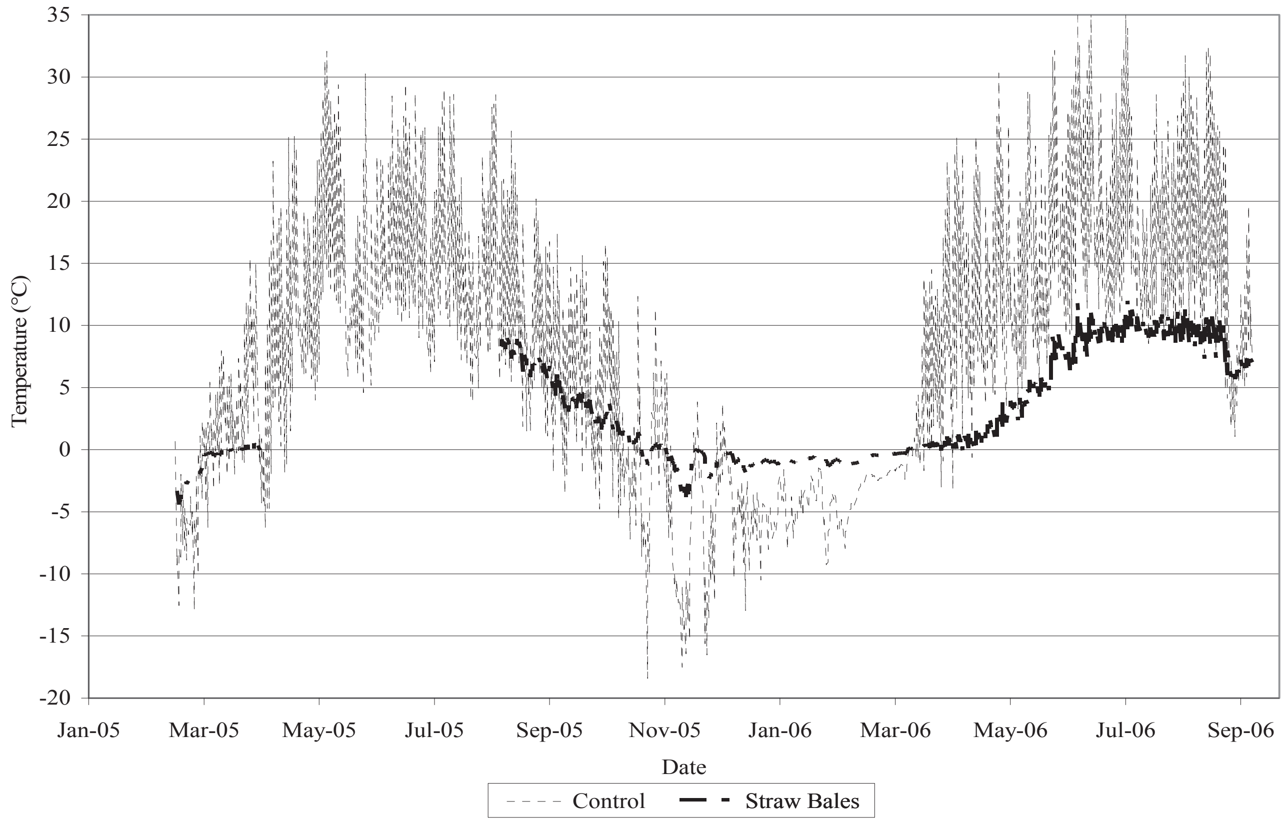

Figure 2a.

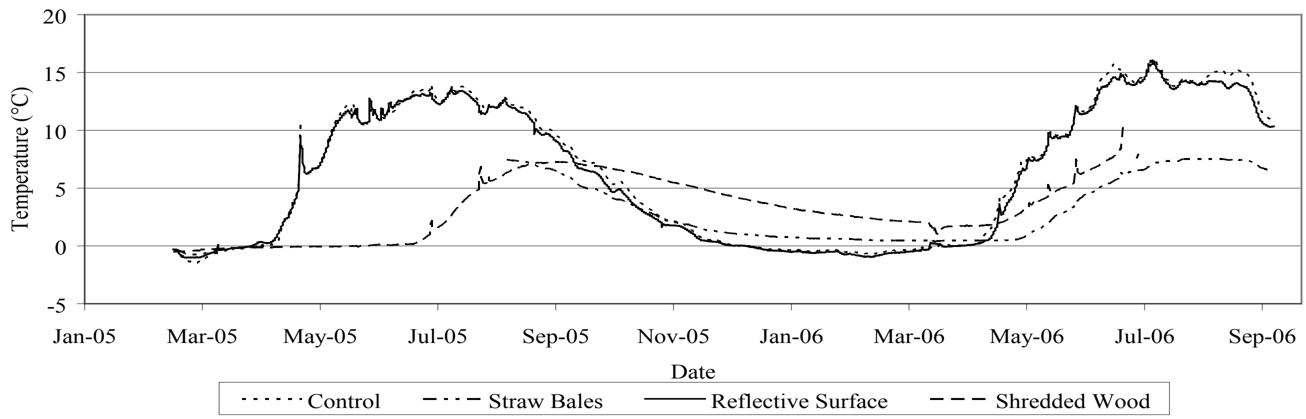

Figure 4. Temperature data from Woodenhouse test site, at 1.0 m below ground surface.

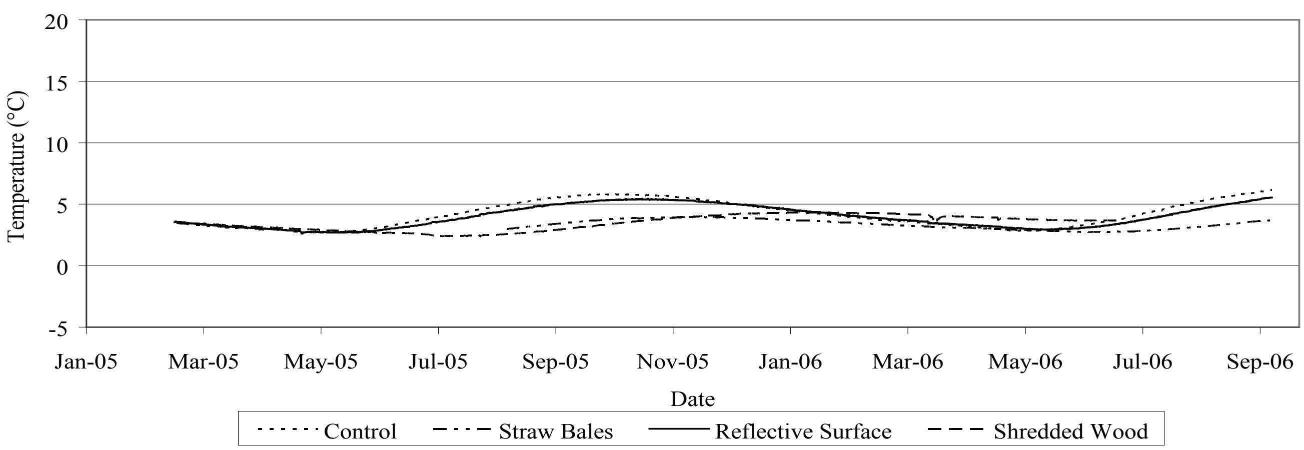

Figure 5. Temperature data from Woodenhouse test site, at 6.0 m below ground surface.

Table 1. Annual degree-day analysis of Bead 3, ground surface temperatures at Woodenhouse.

Test Cell Section	Analysis Period	Calculated Annual °C-Days	Percent of Control	Efficiency Compared to Control
Control	August 31, 2005 – August 30, 2006	2,174	100	1.0
Straw bales	August 31, 2005 – August 30, 2006	1,090	50	2.0
Reflective surface	August 31, 2005 – August 30, 2006	1,945	89	1.1
Shredded wood	July 17, 2005 – July 16, 2006	1,711	79	1.3

and 1 m (see Fig. 4). The time lag was particularly evident during the summer of 2005 and 2006 and lasted about one month. At the end of the winter of 2006, the shredded wood test cell showed a minimal time lag in May 2006 in terms of responding to warmer air temperatures, while the straw bales experienced a time lag of about two weeks before the ground started to warm.

With depth, all ground temperature responses to air temperature changes are dampened. This dampening is a result of the thermal resistance of the mineral soil. Based on the temperature data from thermistor Bead 9 at a depth of 6 m (see Fig. 5), it appears that the influences of the surface insulation material are nearly completely moderated by the overlying soil cover. That is, the temperature response at 6 m depth for each of the test cells and the control are nearly the same.

There were only small differences in the average winter temperatures for any of the test cell materials at Woodenhouse, compared to the control cell temperatures. Between November 2005 and April 2006 winter temperatures measured as follows:

• Under the straw bale and shredded wood test cells, ground temperatures were several degrees warmer than the temperatures under the control cell.

• In the cell containing the reflective surface material, ground temperatures were slightly colder than the temperatures under the control cell.

The warmer average winter temperatures experienced by the shredded wood test cell was because of the long time lag in the response of the ground temperature to the seasonal change in air temperature. This was most apparent in thermistor Bead 5 at 1 m depth (see Fig. 4) and thermistor Bead 9 at 6 m depth (see Fig. 5). In summer 2005, the ground temperatures under the shredded wood lagged behind the ambient temperatures by at least one month. The warmer ground temperatures developed in the summer and early fall of 2005 were carried well into the late fall and early winter 2005–2006, which caused an overall warmer average winter soil temperature.

Ground temperature responses in the summers of 2005 and 2006 also showed differences between the straw bale and shredded wood test cells, and the control cell. The ground temperatures under the reflective surface test cell during the summer of 2005 and 2006 appeared to be close to those of the control cell. Both the straw bales and shredded wood cells recorded average ground surface and near surface (0.5 m depth) temperatures that were less than one-half of those measured in the control cell.

The effectiveness of the test materials could be further examined by a degree-day analysis using Bead 3, which measured the ground surface temperature. This analysis is shown in Table 1.

The data from the degree-day analysis reinforced the observations from the temperature plots. The straw bales achieved one-half the number of annual degree-days of the control section, whereas the shredded wood achieved only 79% of the annual degree-days. The reflective surface material had a minimal effect on the ground temperatures.

Physical performance of test materials

The examination of physical performance of the test materials focused on degradation and loss of integrity of the materials, as these issues will ultimately affect the long-term suitability of the insulation materials used. Observations from the Woodenhouse and Norman Wells test sites were both considered.

Visual examination of the straw bales at both the Woodenhouse and Norman Wells test sites revealed that the bales had shrunk since their initial installation. This shrinkage was first identified at the Woodenhouse test site in the summer of 2005. Consequently, for the Norman Wells straw bale test cell, a thin layer of loose straw was spread over the test cell prior to placement of the bales so that if shrinkage occurred, bare earth (or the organic mat) would not be exposed.

The shrinkage of the straw bales probably resulted from moisture loss from the straw. It would be reasonable to expect that drying would cause the straw bales to shrink in height and length, but less in width because of the anisotropic structure of the straw stalks.

One concern expressed in the planning phase of the study was that foraging by animals, particularly ungulates, would damage the straw bales. However, visual observations at the Woodenhouse and Norman Wells test sites indicated that animals were not eating the straw bales.

The physical performance of the reflective surface materials at the Woodenhouse and Norman Wells test sites appeared to be good. Inspection of the material in the fall of 2006 did not reveal any substantive deterioration of the geotextile reflective material. Some discolouration at the Woodenhouse site had occurred likely associated with airborne dust from adjacent exposed areas. The Norman Wells test site did not have exposed mineral soil near the test cells. Consequently, this site provided a good contrast to the Woodenhouse test site in terms of darkening of the reflective fabric.

Visual observations at Woodenhouse indicated that animal traffic, if any, had not damaged the reflective surface material. No evidence of animal traffic has been found at the Norman Wells test site.

Importation of noxious weeds at test sites

The importation of noxious weeds to sites in the Northwest Territories should be avoided. As part of the initial program to establish the test sites, the straw bales were tested for weeds by an agricultural laboratory. The test results for noxious weeds were negative.

Plants have started to grow on and between the straw bales at Woodenhouse. The weeds observed at the site were stinkweed and tartary buckwheat, species that were common in Alberta, but were not on the noxious weed list. These plants were annuals that were reproducing from seed on new surface disturbances. However, they are not expected to persist more than a few years on the bales at Woodenhouse. If these weeds were imported to the Mackenzie Valley, they would not likely produce seed because of the short growing season and would likely die out after the first year.

Plants were also observed to be growing through seams of the reflective surface material at the Woodenhouse test site. These plants are likely the result of airborne seeds or regeneration of rootstocks that were present on the ground surface when the reflective surface material was installed.

Observations and Conclusions

From the preliminary field testing and analysis, one can conclude the following:

• Although the straw bales shrunk in volume during testing, further temperature measurement and analysis is necessary to determine whether this shrinkage is sufficient to materially affect their thermal insulation properties when used as an insulation system.

• The anchoring system proposed by the manufacturer of the reflective surface material was inadequate for the application at the Woodenhouse test site, where there was exposed mineral soil. However, a revised anchoring system was successfully implemented at the Woodenhouse site but was then found to be inadequate for the Norman Wells test site, which consists of an organic layer overlying hard or frozen mineral soil. The “third generation” anchoring system used at Norman Wells appears to be performing well.

• As measured in terms of ground surface annual degree-days, a single layer of straw bales provided the best thermal performance compared to the control, being about twice as effective as the control cell. The 0.5 m layer of shredded wood performed about 1.3 times better than the control cell. Both materials showed value as ground surface insulation materials.

• Both the shredded wood and straw bales experienced a time lag in response to seasonal ambient temperature changes. In the case of the shredded wood test cell, this time lag appears to help increase the average winter temperature of the ground surface above the average air temperatures measured.

• In comparing the ground surface temperatures of the reflective surface material to the control cell, the reflective material experienced a small, but measurable reduction in ground surface temperature during the thawing period compared to the control cell at the Woodenhouse test site. A reduction of about 10% in ground surface annual degree-days was achieved by the reflective surface compared to the control cell. However, additional monitoring from one or more thaw seasons is needed to confirm the effectiveness. If long-term reduction in ground surface heating can be confirmed, then the applicability of reflective surfaces can be evaluated from a cost-benefit perspective.

Abstract

Permafrost in the nearshore zone is affected by sea bottom temperatures, formation of bottom-fast ice, ice movement, formation of brines through freezing, and diffusion of salt water into the sediment. Subsea permafrost drilled on- and offshore along a north-south transect in the Laptev Sea yields sediment temperature, state and pore-water salinity to show salt diffusion into the sediment and its effect on phase state. Since inundation, the permafrost has been separated from atmospheric temperature and radiation fluctuations by a 0 to 6 m water column and, in winter, by sea ice. Nearshore development of bottom-fast ice concentrates brines at the sea bottom and leads to the penetration of a saline front that exceeds seawater salinity by a factor of at least 2. Subsea permafrost pore space can contain a mix of ice and pore-water solution that is primarily determined by salinity.

Keywords: brine; coastal zone; continental shelf; permafrost; subsea.

Introduction

Permafrost beneath the ocean floor is the result of relative sea level rise inundating the land surface. Inundation changes the heat flux at the upper boundary of the permafrost, generally leading to warming and eventual degradation. Nearshore seabed temperature records covering the annual cycle are rare, but measured temperatures are usually negative. Sufficiently saline pore waters can thaw subsea permafrost at negative temperatures. Methods of estimating permafrost distribution include bathymetric delineation (Brown et al. 1998) and heat transfer modeling (Romanovskii et al. 2005). Modeling uses inferred climate histories and simplified heat transfer. Models of permafrost evolution after inundation have been refined by including salinity effects (Swift & Harrison 1984, Hutter & Straughan 1999, Outcalt 1985), but these have not resulted in improvements to regional or global permafrost distribution estimates. Unknowns affecting distribution include regional glacial and sea level histories, the effect of spatial heterogeneity in terrestrial permafrost (esp. thermokarst) on subsequent degradation, and processes affecting sea bottom temperature and salinity (esp. bottom-fast ice). Based on the consequent spatial variability (Overduin et al. 2007b), public domain direct observations of the distribution of ice-bearing subsea

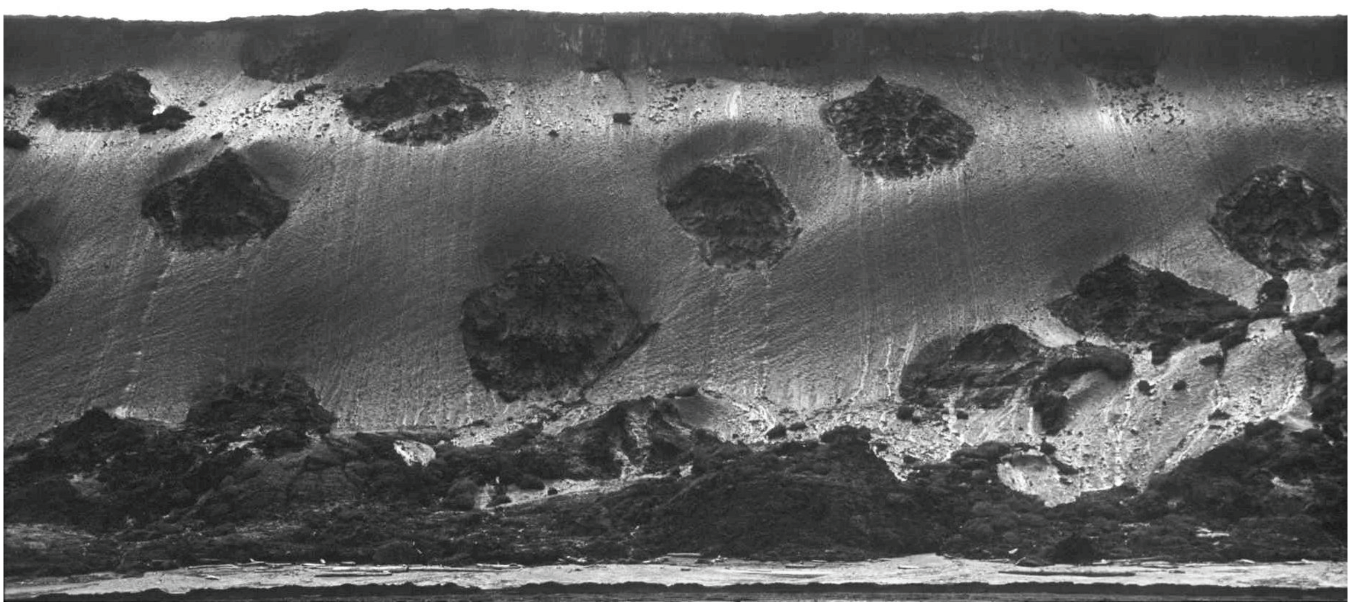

Figure 1. A straight-on view of the eroding Laptev Sea coastal bluff at Cape Mamontov Klyk. The bluff is about 20 m high and is composed mostly of ice with inclusions of organic-rich soil (photograph by Hanno Meyer, 2003).

Figure 2. Map showing the location of Cape Mamontov Klyk (above) in the Western Laptev Sea.

permafrost, particularly at water depths shallower than 10 m, provide poor predictive capability for regions where no observations have been made.

In this study, sediment from the Laptev Sea is examined to determine changes in permafrost following submergence. Modeled subsea permafrost is thick (700-1000 m) and ice-bearing and extends over 400 km from the modern coastline (Romanovskii et al. 2005). The shallow inclination of the shelf and the absence of localized glaciation during the last glacial interval create a suitable test bed for subsea permafrost studies. We seek to identify processes determining the rate and distribution of permafrost degradation in the nearshore zone.

Site Description

Located midway between the Anabar and Olenek Rivers, Cape Mamontov Klyk was named for the discovery of mammoth tusks emerging from its thawing coastal bluffs (Figs. 1, 2), which currently reach over 25 m in height with a ground ice content up to over 80% by volume. The bluff stratigraphy is part of the Siberian ice complex deposits formed during the Late Pleistocene (Romanovskii 1993). The coastal bluff contains mostly silty sand, with relatively high organic content (Schirrmeister et al. submitted). The coastal plain stretches from the Pronchishev Ridge about 30 km to the south of the coast, lies 25 to 55 m a.s.l. and inclines to the north-northeast at 0.1°-0.2° at the cape. Thermokarst depressions and lakes up to several km across cover about 50% of the coastal plain in the region (Grosse et al. 2006). The coastline bisects some of these features, and they likely affect the bathymetry and subsea permafrost table (Romanovskii 2000). Available nearshore bathymetry is not precise enough to show these features, but the seafloor continues at less than 0.05° for at least 13 km from shore (Fig. 3). Modeling of permafrost development suggests that thermokarst terrain extends out to at least the 55 m isobath, and probably much further (Romanovskii & Hubberten 2001). Based on bathymetry from Russian maps and field data, the sea level rise inundated the shelf from a point over 200 km north of Mamontov Klyk over the past 11 ka (Bauch et al. 2001). Sea level rise over the past 2 ka was less than 2 mm a^{-1}, but there is little information on recent changes in coastline position, which is currently retreating at about 4.5 m a^{-1} (Arctic Coastal Dynamics Project Team 2008), and average erosion rates of ice complex coastlines in the Laptev Sea are about 2.5 m a^{-1} (Grigoriev & Rachold 2003).

Methods

In April 2005, a coastal and offshore drilling program drilled five cores along a north-south transect (Overduin et al. 2007a). Coring sites extended from onshore (core C1) to 12.5 kilometers offshore (cores C2-C5) and 6 m water depth (Fig. 3). A dry, hydraulic, rotary-pressure drilling technique was used and a borehole casing prevented infiltration. Depths of penetration are shown in Figure 3 and listed in Table 1, along with the state of the sediment as determined upon recovery. Recovered sediment material remained frozen during transport and storage.

Sediment temperature was measured using calibrated thermistors. Measurements were made from 1 to 11 days after drilling at the depths shown in Figure 4 (Junker et al. accepted). The dry drilling technique allowed temperature equilibration within 3 days at the bottom of C2. A thermistor string was permanently installed at the onshore site (C1). Mean annual temperatures for C1 were calculated using hourly measurements for the time period June 1, 2005-June 1, 2006 (Fig. 4). The temperature profiles for C2, C3 and C4 were measured at least 96 hours after drilling, C5 was measured one day later.

Pore water salinity was measured by thawing the sediment and extracting pore water using small suction lysimeters with 0.2 µm pores. Thawing and extraction took up to three days, depending on sample grain-size. The extracted pore water salinity was measured to a reference temperature of 25°C. Uncertainty in salinity depended on the measurement range with an upper limit of ±0.1‰.

At low salinity, the ice content in cryotic sediment mostly depends on grain-size and temperature. At higher salinities, however, the salinity of the pore water is more important. For low-salinity samples (<5‰), we used the total water content of frozen samples as a proxy for volumetric ice content (θ_i). For high-salinity samples (≥5‰), volumetric ice content was estimated as the difference between total (θ_{tot}) and liquid water content (θ_l). Total volumetric water content (ice and water) was measured using the weight (w_{fr}) and water displacement (V_{tot}) of sealed frozen samples and the weight of the sample after freeze-drying (w_{dry}).

Uncertainties were ±5 x 10^{-5} kg in weight and ±5 x 10^{-5} m^3 in volume. The error introduced by ignoring liquid water content in fresh water samples is small for these sediments (<5%) relative to absolute variations in ice content between samples, since grain sizes are not small and segregated ice is present in much of the profile.

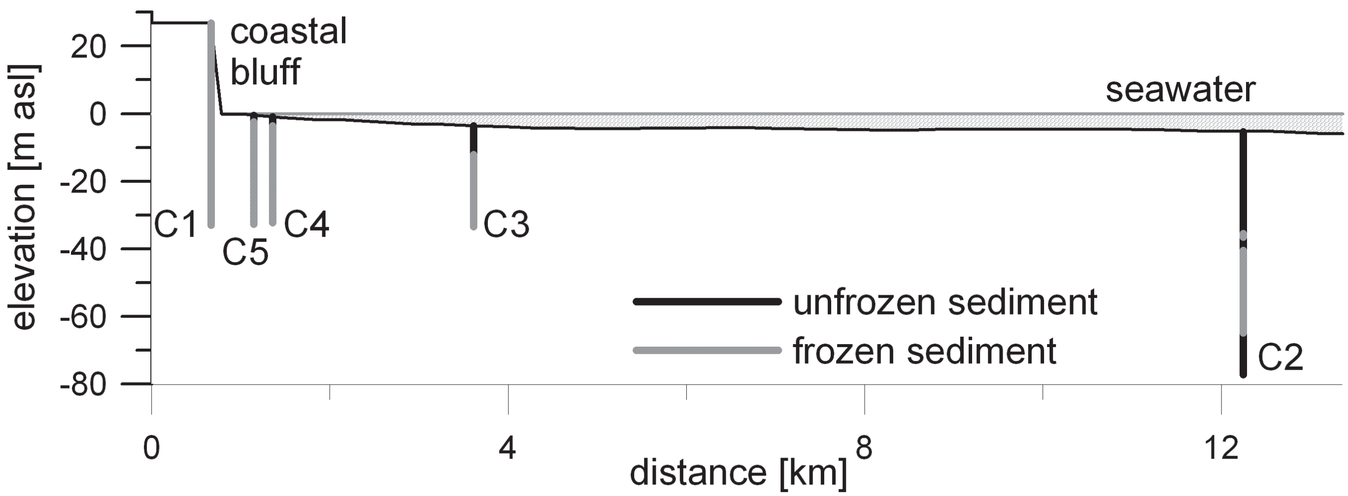

Figure 3. The locations and elevations (in meters relative to sea level) of cores along the transect are shown, along with the field-determined state (frozen/unfrozen) of the sediment (adapted from Overduin et al. 2007a).

Sediment liquid water content lay between 4 and -25°C in the laboratory using 7 cm time domain reflectometry (TDR) sensors in a 100 mL cell, which had been calibrated in air and deionized water. A Campbell Scientific TDR100 was used to generate waveforms, which were analyzed for bulk relative dielectric permittivity. Liquid water content was estimated using a mixing model for the relative dielectric permittivity of a porous medium. We assume that the sediment may be represented as a rigid three-component medium (ice, soil, water). The mixing model gives the composite relative dielectric permittivity (ε_c) based on the volumetric fractions and dielectric permittivities of the components:

$$\varepsilon_c = \left[(1-\eta)\varepsilon_s^{\ \alpha} + (\eta-\theta_l)\varepsilon_i^{\ \alpha} + (\theta_l)\varepsilon_l^{\ \alpha}\right]^{1/\alpha} \tag{1}$$

where η is the porosity, and the subscripts, *i*, *s* and *l* refer to ice, soil and liquid, respectively (Roth et al. 1990). The exponent, α, is related to the geometry of the components in the mixture. Soil and ice relative dielectric permittivities are assumed to be similar at the frequency of measurement ($\varepsilon_m = \varepsilon_s \approx \varepsilon_i$), leading to an expression for the liquid water content that is equivalent to a two-component model:

$$\theta_l = \left[\varepsilon_{comp}^{\ \alpha} - \varepsilon_m^{\ \alpha}\right]\left[\varepsilon_l(T)^\alpha - \varepsilon_m^{\ \alpha}\right]^{-1} \tag{2}$$

Changes in pore solution dielectric permittivity as a result of changes in solute concentration are ignored, as are temperature dependencies of the soil and ice dielectric permittivity. Temperature was varied using an external cooling bath and a pump, which circulated the cooling fluid around the sample cell. Liquid water content was measured during multiple warming and cooling cycles. Temperature was monitored in the sediment sample using PT100s with an accuracy of better than ±0.1°C.

Table 1. Borehole and sediment characteristics for each drill site.

	C2	C3	C4	C5	C1
Distance to coast [km]	11.5	3	1	0.5	0.1
Water depth [m]	6.0	4.4	2.2	1.5	--
Ice thickness [m]	1.35	1.85	2.1	1.5	--
Core depths [m relative to sea level]	to -77	to -31	to -32	to -31	+26.2 to -34
Bottom water salinity [‰]	29.2	30.0	32.2	>100	--
Bottom water temp. [°C]	-1.5	-1.6	-1.7	-6	--
Frost table depth [m]	35	12	3.9	2.8	--

Results

The exposed coastal profile is described in Schirrmeister et al. (submitted), and consists of silty sand, organic-rich ice complex deposits overlying silty sand to fine sand deposits. The subsea sediment is composed of silty sands to fine sands. Based on available analyses, we cannot distinguish between unfrozen sediment that has been redeposited and sediment that has thawed in place. The upper thawed subsea sediment shows weakly layered structure, and has probably been reworked in its upper portion by redeposition and wave action. Below the frozen-unfrozen interface, the presence of freshwater ice, ice wedges, composite ice wedges, ataxitic layers indicating the presence of an active layer with seasonal thawing and layers of organic debris and twigs suggest terrestrial and shallow water environments. These features were found in C1 (25.5-12.8 m r.s.l.), C5 (2.8-14.5 m r.s.l.), C4 (3.9-14 m r.s.l.) and C2 (40.3-64.7 m r.s.l.), roughly corresponding to the upper portion of the frozen sediments for the subsea cores in Figure 3. In each core, these sediments are underlain by sandier, cryotic sediments without significant segregated ice.

Water depth decreased gradually with distance from the shore (1.5, 2.2, 4.4, 6.0 m at C5, C4, C3 and C2, resp.). C5

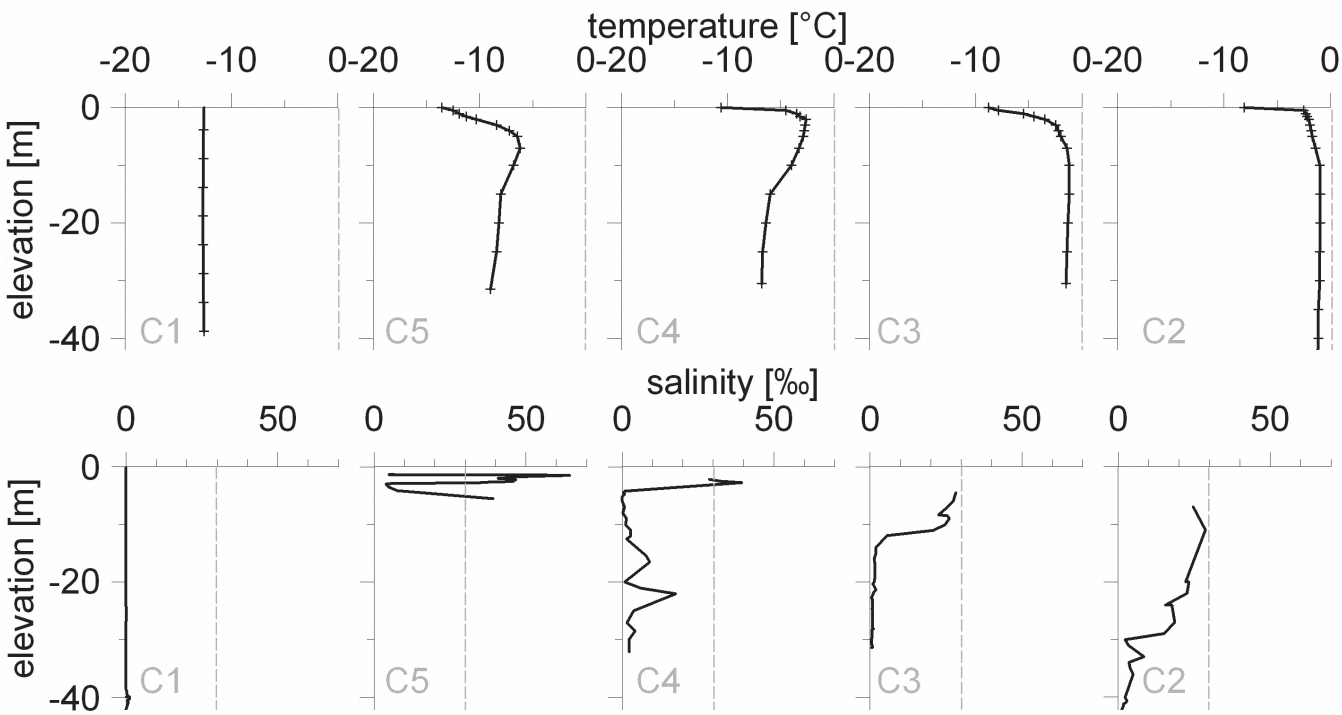

Figure 4. Profiles of sediment temperature (top) and pore water salinity (bottom) from onshore (at left) to furthest offshore (at right; some data taken from Rachold et al. 2007). Available data for the depths from 0 to 42 m below sea level are presented for all cores.

was therefore located in the bottom-fast ice zone. Bottom water salinities decreased with distance from shore, while temperatures increased (Table 1). The interface between unfrozen and frozen sediment was located at successively lower depths within the sediment column with increasing distance from the coastline (2.8, 3.9, 12 and 36 m at C5, C4, C3 and C2, respectively). Sediment temperatures at 20 m below sea level increased from an almost constant mean

Annual value of -13°C onshore (C1), to -8°C, -6°C, -1.5°C and -1°C with increasing distance from the coast (Fig. 4). The temperature gradient over depth in C2 was almost flat over the upper 40 m of the sediment profile. The temperatures at the frozen/unfrozen interface were -8.4, -2.8, -1.2 and -1.1 in C5, C4, C3 and C2, respectively. The salinity of pore water extracted from the sediment varied between 0 and 65‰ (Fig. 4). Salinities exceeding that of bottom water measured in August 2003 (17.3‰ to 20.7‰) and below the ice in April 2005 (29.2‰ to over 100‰) were found in C5 and C4. In C3 and C2, a saline pore water front was observed at depths of about 12 and 36 m, respectively. Frozen sediment generally had pore water salinity less than 5‰. Higher salinity found below the uppermost salt water front in C4 (around 16 and 22 m), and the variability in C5 salinity, suggest irregular brine production or migration.

Figure 5 shows the ice content as a function of temperature for four sediment samples. The sediment samples vary in terms of grain-size, sediment composition, and pore-water salinity. Differences in salinity are large enough (12, 25, 45 and 65‰) to make grain-size differences negligible in determining volumetric liquid water content at temperatures less than about -2°C. Increasing salinity decreases the sediment volumetric ice content. Ice content is shown for both cooling and warming temperature histories of all four samples. Hysteresis is clearly visible for the two lower salinity samples, but results in no more than a 4% ice content difference between warming and cooling at 45‰, and negligible differences at 65‰. For the latter, warming and cooling curves are superimposed. For the lowest salinity sample, the rate of change of state with temperature is low at temperatures below -5°C. At higher salinities, any addition or removal of heat results in significant phase change (around 2% K^{-1}), rather than temperature change.

Measured total volumetric water contents in core C2 range from 14% to 100%. Ice content in C2 increased with depth from a low value of 3% (based on temperature and pore-water salinity) to a maximum of 20% in the unfrozen zone. In the frozen sediment, ice contents ranged from 17% to 100%. Values in excess of 40% (based on core volume and weight loss on drying) corresponded to depths which were identified as frozen in the field and contained segregated ice. Segregated ice occurred as ice lenses, injection ice, ice wedges, and composite ice wedges. Values determined by weighing dried samples match to within 15% of adjacent freshwater samples.

Discussion

Previous results from this campaign were based on field observations (Overduin et al. 2007a+b, Rachold et al. 2007). In this paper, we add laboratory analyses performed on pore water and sediment samples to describe the position and temperature of the frozen-unfrozen interface in the subsea

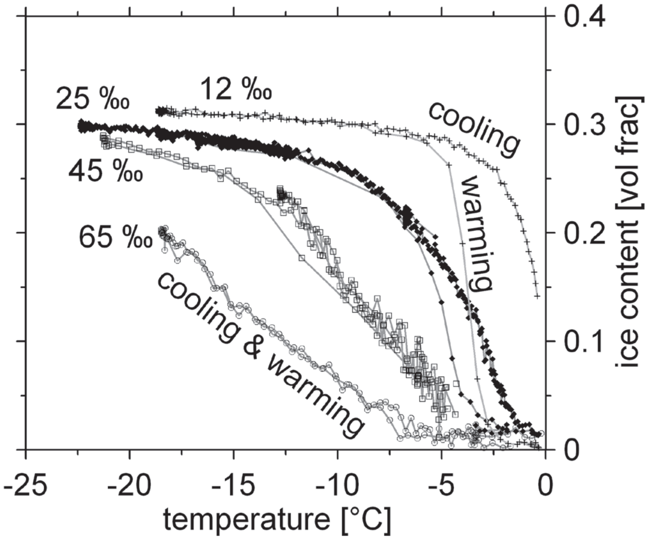

Figure 5. The volumetric ice content of four sediment samples (salinities: 12, 25, 45, and 65‰) as a function of temperature. Data were collected during cooling and warming for all four samples.

sediment. Coastal erosion and the subsequent inundation of the land at Cape Mamontov Klyk result in a large geomorphologic change in the upper permafrost, including thermoerosion, reworking of the eroded material, transport and redeposition offshore. These processes currently result in the thawing, removal, and redeposition of about the upper 25 m of permafrost. Redeposited and underlying unredeposited (in-situ) sediment is considered permafrost, as it remains cryotic. The boundary between the two is not yet clear, but must lie at or above the frozen/unfrozen interface. The actions of thermoerosion, thermokarst basin flooding, and wave action on the shallow sea bottom (Are et al. 2001), will have attenuated any topographic reflections of the previous thermokarst topography in the transition from terrestrial to marine.

The depth within the sediment of the frozen/unfrozen interface is difficult to determine. The classification of sediment as frozen or unfrozen in the field is highly subjective, since it rests upon a determination of plasticity. The determination is generally made by examining core sections at the surface, after they have been subjected to drilling and passage through the borehole. In some studies, the sea bottom was probed, akin to a permafrost probe, until sufficient resistance was encountered (Osterkamp et al. 1989). The temperatures at the interface observed here ranged from -1.1°C to -8.4°C, with inferred ice contents between 5% and over 25%, based on salinity and temperature. The transition from ice-free to ice-bearing to ice-bonded is likely to be gradual in most settings. Sediment ice and liquid water content depends strongly on pore water salinity over a wide temperature range (from 0°C to -20°C). As a consequence of this and the low temperature gradient, the phase boundary (the zone between ice-free sediment and sediment unaffected by saline solution) in C2 is almost 30 m thick, and covers a range of ice contents from 3% to over 20% by volume. Detection methods sensitive to step-like transitions in material properties over a short depth range, such as seismic or geoelectric methods, are thus confronted with a poor reflector.

The high salinities observed in the uppermost sediment at C5 (Fig. 4) strongly suggest that salt exclusion during sea ice formation results in brine formation. In this case, the brine formed was under positive pressure, and flooded and flowed out of the borehole 8-10 hours after drilling (Rachold et al. 2007). The salinity profile for C5 suggests the diffusion of at least one brine front down a strong concentration gradient into the sediment, which may be due to the formation of a seasonal active layer (Osterkamp et al. 1989). The progressive diffusion of the brine front into the sediment pore water is evident from the salinity graphs of Figure 4. Applying a mean ice thickness of 1.7 m, the bottom-fast ice (BFI) zone extends over 2 km from shore. Under current coastline retreat (4 to 4.5 m a^{-1}), this translates to seasonal brine production over a period of 440 to 500 years. The low inclination of the seabed in the western Laptev suggests that even longer periods are common, since coastal retreat for the Laptev Sea is 2 to 2.5 m a^{-1}. Both coastal retreat rates and the nearshore shore face profile will be important in determining the rate of descent of the salt front into the sediment, and differences may help to explain the variability observed in the position of the frozen/unfrozen interface. Provided that sediment could be removed from the shoreface effectively enough to account for increased erosion, increases to sea level rise will lower the rate of permafrost degradation by seawater penetration.

Conclusions

The saline-freshwater interface in the sediment column was identified in cores drilled off the coast of Mamontov Klyk in the Laptev Sea. Bottom-fast ice results in highly concentrated sea water being produced at the ice-sediment interface, and probably accelerates the degradation of subsea permafrost. Saltwater diffusion into the sea bottom results in the presence of ice-free sediment at sub-zero temperatures down to a depth of 40 m in subsea sediments, 12 km offshore. The transition from ice-free to ice-bonded sediment occurs over a depth range of about 30 m 2.6-6.0 ka after inundation. The energy requirements for the permafrost to become near-isothermal are reduced by the diffusion of salt water into the sediment. Changes in phase as a result of salt water intrusion and warming change the effective thermal properties of the sediment and affecting the rate of further degradation.

Acknowledgments

We gratefully acknowledge the help of all those involved in the field and lab work, including Alexander Derevyagin, Antje Eulenburg, Katja Hockun, Viktor Kunitsky, Franziska Merker, Gunter Stoof, and Maria Winterfeld. This work was supported by the German Ministry for Education and Research (BMBF). We thank Dmitry Melnichenko, director of the Tiksi Hydrobase, for providing logistic support. Improvements to the paper were suggested by two reviewers and William R. Bolton.

Sources of Discrepancy Between CCSM Simulated and Gridded Observation-Based Soil Temperature Over Siberia: The Influence of Site Density and Distribution

Abstract

Soil-temperature climatologies determined at different depths from simulations with the Community Climate System Model version 3 (CCSM), capture the annual phase of gridded soil-temperature climatologies based on observations for 1951–1980, 1961–1990, and 1971–2000, but not the amplitude; some of these discrepancies can be attributed to simulated forcing (PaiMazumder et al. 2007). By using soil-temperature data simulated by the Weather Research and Forecasting (WRF) model, it is shown that some of the discrepancies between CCSM-derived and gridded observed climatologies may result from the interpolation required for gridding and/or network design (density and distribution of sites).

Keywords: climate simulation; network design; soil-temperature evaluation; Siberia; uncertainty.

Introduction

Accurate simulation of soil temperature in Climate System and Earth System Models is essential because soil temperature influences high-latitude hydrology, biochemical processes, and ecosystems. Soil temperatures are mostly controlled by the surface water and energy balance, which explains the strong connection and feedback between soil and near-surface atmospheric conditions. In the Arctic and Subarctic, the onset, duration, thickness, density, and structure of seasonal snow cover strongly influence soil temperatures (e.g., Zhang et al. 1996, Mölders & Romanovsky 2006).

Soil temperatures simulated at different depths by the Community Climate System Model version 3 (CCSM) (Collins et al. 2006a) are evaluated over Siberia for three climatologies (1951–1980, 1961–1990, 1971–2000) by means of observational data (PaiMazumder et al. 2007) provided by the National Snow Ice Data Center (NSIDC) (Zhang et al. 2001). PaiMazumder et al. (2007) also evaluated CCSM-derived climatologies of near-surface temperature, cloud fraction, precipitation, and snow depth with those from ERA40 reanalysis, the International Satellite Cloud Climatology project (ISCCP), the Global Precipitation Climatology Center (GPCC), and the NSIDC, respectively, to examine the sources for discrepancies between simulated and observed soil-temperature climatology. Inaccurate simulation of near-surface temperature, cloud fraction, precipitation, and snow depth may have some influences on discrepancies between CCSM-derived and observed soil-temperature climatology, but do not explain all discrepancy found. Sensitivity studies with slightly altered plant functional types and percentage of sand attributed marginal discrepancies from incorrect percentages of sand and/or plant types (PaiMazumder et al. 2007).

Typically, climate models like CCSM provide soil temperatures that represent a volume average of several hundred square kilometers in horizontal extension of several centimeters in thickness. It is obvious that soil temperatures simulated for such a volume are difficult to compare to measurements at a site (point measurements). Therefore, it has become common practice to interpolate available measurements to the grid of the climate model (e.g., Li et al. 2007). It is obvious that such interpolation may introduce uncertainty into the grid-cell averages; hence, the evaluation. Since the gridded soil-temperature climatologies are based on measurements projected onto the CCSM3 grid by Cressman interpolation (PaiMazumder et al. 2007), some discrepancies between CCSM-derived and gridded observed climatologies may result from interpolation and/or network density and distribution. Observational networks are often designed with accessibility and ease of maintenance in mind. Most of the Siberian soil-temperature sites are long-term agricultural monitoring stations. Consequently, the observational network follows agricultural-used land along major haul ways and is not uniformly distributed. Hence, the density and/or design of network may bias the regional averages estimated therefrom. Mitchell et al. (2004) assessed accuracy and reliability of gridded data and concluded that observed gridded data (1901–2000) are not appropriate for climate change. They also describe the development of high resolution (0.5°) of gridded dataset (Climate Research Unit [e.g., CRU TS 2.0] data) for the globe derived from climatological observations and transient coupled atmosphere-ocean general-circulation-model (GCM) simulations. The gridded dataset depends on the applied interpolation algorithms, and always has to be associated with an assessment of the accuracy of the grid point values. Therefore, it is essential to assess the uncertainty in regional averages resulting from the density and/or design of an observational network. The aim of our case study is to exemplarily investigate this uncertainty to further assess the discrepancies between CCSM-derived and observed soil-temperature climatologies found by PaiMazumder et al.

(2007). In doing so, the Weather Research and Forecasting (WRF) (Skamarock et al. 2005) model is used to provide a dataset of soil temperatures that will be considered as "reference" for determination of regional averages to which data from a real network and artificial networks are compared to assess the accuracy of gridded datasets based on station data, and to develop recommendations for network design to optimize their use for model validation.

Experimental Design

Brief model description

The CCSM is a fully coupled climate model to simulate the Earth system over broad ranges of spatial and temporal resolutions. It consists of the Climate Atmospheric Model, version 3 (CAM3) (Collins et al. 2006b), the Community Land Model version 3 (CLM3) (Dai et al. 2003, Oleson et al. 2006), the Community Sea Ice Model version 5 (CSIM5) (Briegleb et al. 2004), and the Parallel Ocean Program version 1.4.3 (POP) (Smith et al. 1992). These four components exchange data via a coupler without flux correction.

CCSM is run with 26 vertical layers at a spectral truncation of T42 corresponding to a spatial resolution of ≈2.8° x 2.8°. CCSM is started with the ecliptic conditions of 1-1-1950 and CO_2 concentration of 355 ppmv. Each model component is spun up separately. Based on these simulations, we determine three climatologies, 1951–1980, 1961–1990, and 1971–2000.

The WRF is a mesoscale non-hydrostatic model. Out of the variety of physical options, we use the following model setup: Cloud formation and precipitation processes at the resolvable scale are considered by Thompson et al.'s (2004) five-water class (cloud-water, rainwater, ice, snow, graupel) mixed-phase bulk-microphysics parameterization. The Grell-Devenyi (2002) ensemble parameterization considers subgrid-scale convective clouds. The Goddard shortwave-radiation scheme and the Rapid Radiative Transfer Model (Mlawer et al. 1997) are applied. The Yonsei University scheme (Skamarock et al. 2005) is used for simulating atmospheric boundary layer processes. Monin-Obukhov similarity theory is applied for surface-layer physics. Soil temperature, volumetric ice and water content, snow temperature and density and the exchange of heat and moisture at the land-atmosphere interface are determined by a modified version of the Rapid Update Cycle land-surface model (Smirnova et al. 1997, 2000).

The WRF domain encompasses Siberia by 70 x 150 grid-points with a grid-increment of 50 km and 31 vertical layers from the surface to 50 hPa. Soil conditions are determined at six levels. In the presence of snow, five snow layers are considered. The time step is 200s. The National Centers for Environmental Prediction (NCEP) 1.0° x 1.0° and 6h-resolution global final analyses (FNL) serve as initial and boundary conditions. For our case study, we perform simulations for July and December 2005. They start daily at 1800 UT for 30 hours of integration. We discard the first six hours as spin-up time.

Analysis

To estimate uncertainty due to network density and design, WRF-simulated soil temperatures serve to represent data from an optimal, dense, and equally distributed observational network. Regional averages of soil temperatures determined from the WRF output for July and December 2005 are considered to be the "reference."

Regional averages of soil temperature are determined for the 411 sites of the actual historic observation network used in PaiMazumder et al.'s (2007) CCSM soil-temperature evaluation. Herein, the soil temperature simulated for a WRF grid cell wherein a site falls is taken as the soil temperature for that site. This procedure is common practice in mesoscale modeling (e.g., Narapusetty & Mölders 2005). Four artificial networks are assumed with 500, 400, 200, and 100 arbitrarily taken WRF grid cells as "sites." These networks are denoted 500-, 400-, 200-, and 100-site networks hereafter. Soil temperatures obtained from WRF simulations at the 500, 400, 200, and 100 sites are used to calculate the regional averages for these networks. These regional averages are compared with the reference regional averages to assess the contribution of network density and design to uncertainty in gridded data used for evaluation of climate model data.

Since systematic and nonsystematic errors can contribute to any simulation result, as well as to regional averages obtained from different networks, performance measures like bias, standard deviation of errors (SDE), root mean square errors (RMSE), and correlation coefficients (e.g., Anthes 1983, Anthes et al. 1989) are calculated at different spatial and temporal scales for the various networks. The performance measures and correlation coefficients are determined to evaluate the discrepancies between the regional averages obtained from the "reference" and those of a network. They are calculated for all networks for the daily and monthly course.

To estimate the uncertainties in regional averages resulting from the density and design of networks, we compare the regional averages of soil temperature obtained from the WRF simulation ("reference") and various site networks (500-, 400-, 200-, 100-site network and historic networks). In this case study, we consider the accuracy of soil temperature measurements to be within ±0.5 K for the reasons discussed in PaiMazumder et al. (2007). The regional averages of soil temperature estimated from the "reference" and the different networks will be considered to be in good agreement if regional averages obtained from the different networks lie within the above-mentioned uncertainty range to the "reference."

In a next step, we compare the uncertainty determined as described above with the discrepancies found between CCSM-derived and gridded-observation-derived climatologies by PaiMazumder et al. (2007) to assess how much the network design may explain some of these discrepancies.

Results

Impact of network design on regional averages

Regional averages of soil temperature obtained from the artificial networks are highly correlated with those of the reference (>0.972) at all depths in both months. Regional averages of soil temperature obtained from the historic network are more highly correlated with the "reference" in December (R = 0.921) than in July (R = 0.732) at 00 UT, 06 UT, 12 UT, and 18 UT at all depths.

In both months, the daily spatial standard deviations of soil temperatures obtained from the historic network are higher than those of all other networks. The standard deviations of soil temperature obtained from the various networks are higher at all depths in December than in July. In December, in general, soil temperatures vary strongly in space due to the large horizontal differences in snow cover and/or thickness. Thus, taking measurement along the haul ways leads to larger standard deviations of the regional averages in winter than summer because of snow conditions and terrain height of the site. In July, for given insolation and soil type, soil heating/cooling varies less in space than in December, when differences in snow cover/thickness may strongly affect soil temperatures. Consequently, taking the measurement along a haul way has less impact on the regional average and its standard deviation for Siberia in summer than winter.

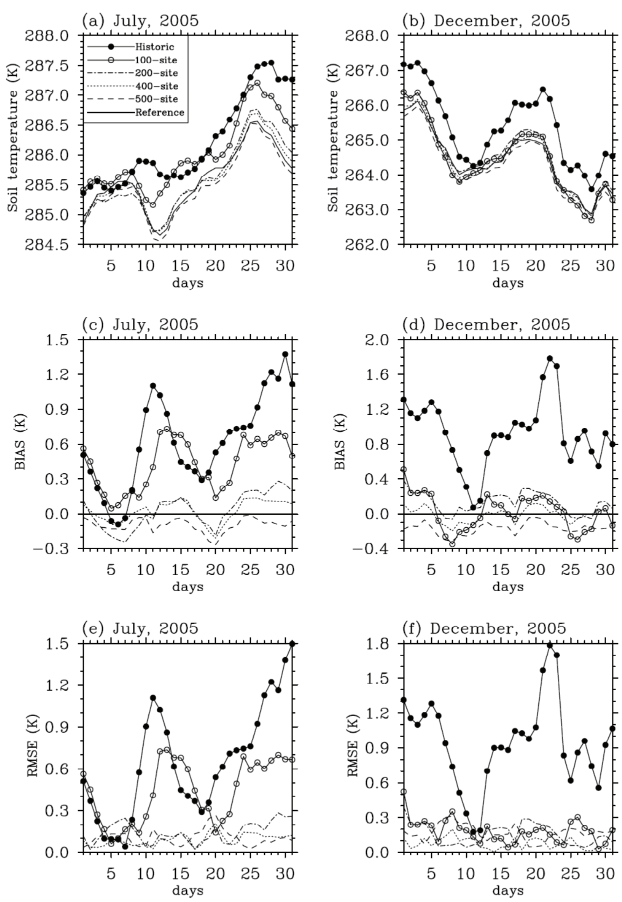

Figure 1. Temporal behavior of (a) regionally averaged soil temperature at 0.2-m depth obtained from the "reference," 500-, 400-, 200-, 100-site network and the historic network for July 2005 and (b) December 2005. Biases for (c) July and (d) December and RMSE for (e) July and (f) December between the "reference" and 500-, 400-, 200-, 100-site network and the historic network. Note that in (c) to (f), labels on the y-axis differ. In (c) and (d), the thick line serves to better visualize the positive and negative bias.

At 0.2-m depth, soil temperatures obtained from the historic network overestimate the reference average by up to 1.5 K and 1.8 K in July and December, respectively (Fig. 1). The historic network also fails to capture the timing of the soil-temperature maxima and minima represented in the reference average. For example, on July 11 and 26, upper soil temperatures from the historic network average do not reflect the warm periods seen in the reference average (Fig. 1). These differences in timing of extremes between the regional averages of the historic network and "reference" occur due to a frontal system passing Siberia. The non-equal distribution of sites of the historic network therefore gets "biased" to the time when the system passes the majority of the sites. In December, the high bias found for the historic network may partly be explained by the fact that the sites of the historic network may not well represent the regional differences in snow cover and/or thickness. The 100-site network also fails to capture the regional soil-temperature averages obtained from the "reference" with 0.8-K bias in July (Fig. 1), while in December, the 100-site network captures the reference average well. Obviously, a randomly distributed 100-site network represents soil conditions in winter well when the soil is partly insulated by snow. However, in summer, convection may lead to spatial differences in soil heating due to shading by clouds and/or heat input by precipitation that a 100-site network cannot capture appropriately. Regional averages of soil temperature obtained from 500-, 400-, and 200-site networks provide acceptable results in comparison to the reference average at all depths in both months. The historic network shows higher biases and RMSEs than all other networks in both months (Fig. 1, Table 1). This means that the historic network introduces some bias into regional averages and any evaluation study therewith.

Higher systematic bias may have occurred due to the difference in landscape and terrain elevations between the regional averages derived from the "reference" and historic network. At 0.2-m depth (0.4 m and 1.6 m), RMSEs for the historic network reach up to 1.5 K (1 K and 1.9 K) and 1.8 K (1.3 K and 1.1 K) in July and December, respectively (Fig. 1). Errors in regional soil-temperature averages based on the historic network are also high for the upper soil layer, and errors decrease at 0.4-m depth and increase again for deeper soil layers in both months. The high diurnal variability close

Table 1. Monthly averages of bias and RMSE for the historic and 200-site networks for upper and deeper soil.

Networks		Historic network		200-site network	
Month	Layer	bias	RMSE	bias	RMSE
July	Upper	0.6	0.7	0.02	0.1
	Deeper	1.7	1.9	0.3	0.3
December	Upper	1	1	0.1	0.2
	Deeper	1.2	1.2	0.2	0.3

to the surface may cause the high errors in the upper soil (Table 1). The increase found for deeper soil layers may be related to the constant lower boundary condition used in WRF. These soil-temperature values are from climatologies which differ notably in space. Thus, the historic network cannot represent the "reference" because the sites are not randomly distributed to capture the regional pattern.

Evaluation of CCSM by gridded data

As reported by PaiMazumder et al. (2007), CCSM captures well the phase of the 30-year average annual soil temperature curves at all depths, but not the amplitude. CCSM overestimates the 0.2-m soil temperature for the majority of the grid cells over Siberia from December to March for the first climatology (1951–1980) (Fig. 2). Similar is true for 0.4-m and 1.6-m depths, but with marginally decreasing frequency with increasing depth, whereas at 0.8 m and 3.2 m, CCSM overestimates soil temperature throughout the year (Fig. 2). In April, soil temperature will be overestimated for most of the grid cells at all depths if soil temperature is below freezing and underestimated otherwise, leading to overall overestimation. In May and June, the general pattern shifts towards underestimation at all depths except 3.2 m (Fig. 2). In July and August, CCSM tends to underestimate soil temperature by up to 1.2 K at 0.2 m, and overestimates them by up to 0.5 K at 0.4-m and 0.8-m depth. At 1.6 m, the tendency to overestimate soil temperature is obvious for the colder (<275 K), but less obvious for the warmer (>285 K) end of the temperature range. In September, soil temperatures are underestimated at 0.2-m and 0.4-m depth by up to 0.6 K and 0.4 K for most grid cells (Fig. 2). At 0.8 m and 1.6 m, CCSM overestimates soil temperatures by up to 0.4 K and 1.1 K, respectively, for most grid cells. In October, the general pattern again shifts towards overestimation by up to 2.5 K (Fig. 2). In November, simulated soil conditions are too warm for soil temperatures below the freezing point at all depths. PaiMazumder et al. (2007) also found that biases and RMSEs decrease with increasing depth because most variability occurs near the surface. RMSEs are higher in winter than in the other seasons for all three climatologies. Mean annual soil temperatures are over-estimated by 2.5 K, on average.

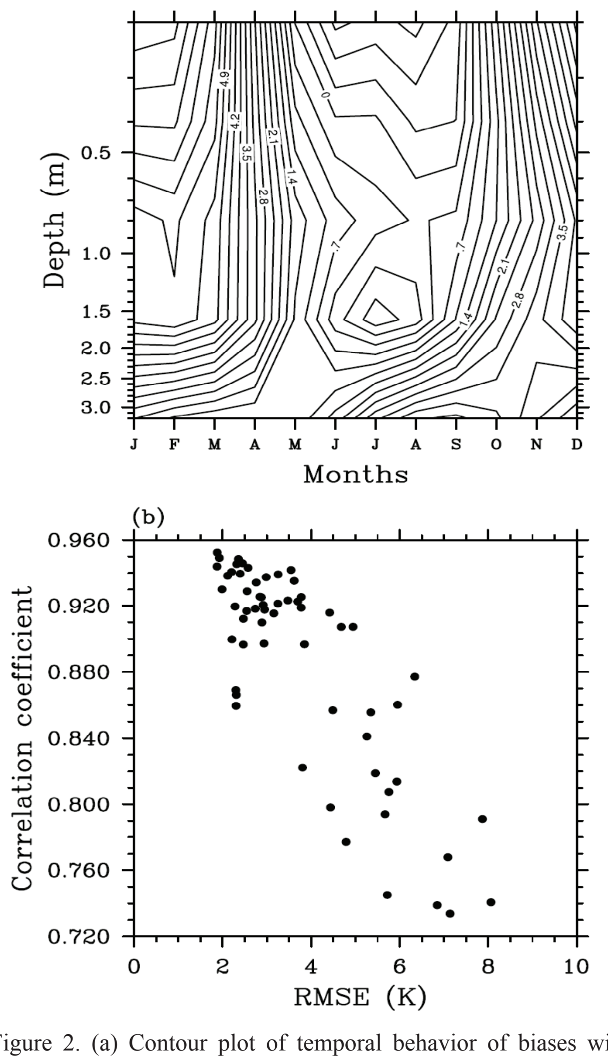

Figure 2. (a) Contour plot of temporal behavior of biases with depths for the first climatology (1951–1980). (b) RMSE vs. correlation coefficient for the first climatology for all 12 months at 0.2-m, 0.4-m, 0.8-m, 1.6-m, and 3.2-m depth.

Overall, CCSM simulates the annual average soil temperature reasonably well, though its performance is better in summer than in winter. Due to acceptable RMSEs and high correlations (cf. Fig. 2), PaiMazumder et al. (2007) concluded that the fully coupled CCSM acceptably simulates soil temperature. As pointed out by these authors, CCSM also has some difficulties in capturing near-surface temperature, cloud fraction, precipitation, and snow depth with biases (RMSEs) -1.0 K (3 K), 0.32% (0.52%), 7.6 mm/month (19.9 mm/month), and 0.04 m (0.09 m), respectively (for further details see Table 1 in PaiMazumder et al. 2007). Hence, the inaccurate simulation of near-surface temperature, cloud fraction, precipitation, and snow depth may contribute to the discrepancies between CCSM-derived and observed soil temperature climatology. Difference in plant functional types between model and real world and decreasing and increasing sand percentage in the model may marginally affect soil temperature. Thus, incorrect assumptions on the mineral soil type cannot explain the discrepancies found. Another source of these discrepancies may be that CCSM only considers mineral soils. However, large areas of Siberia have organic soils at least in the upper soil layers. The thermal and hydraulic properties of mineral and organic soils differ strongly and yield to appreciable differences in soil temperature and soil-water freezing behavior (cf. Mölders & Walsh 2004, Lawrence & Salter 2007). Nicolsky et al. (2007) showed that incorporating organic matter in CLM3 significantly changes the soil temperature simulation. Thus, providing gridded data of organic material distribution and consideration of organic material in CCSM are essential future steps for the scientific community to take.

Discussion and Conclusions

PaiMazumder et al. (2007) found that CCSM tends to overestimate soil temperature in winter and underestimate in summer, with better performance in summer than winter. In spring and fall, simulated and observed climatologies agree the best. Therefore, we performed a case study with WRF for December and July 2005 to further examine reasons for discrepancies in CCSM-derived and observed soil-temperature climatologies. In this case study, we assume the soil temperatures simulated by WRF as a reference dataset from which we determine the "reference" regional averages. These reference averages are compared to the regional averages determined from WRF data at the sites of the network used in PaiMazumder et al. (2007) and to four randomly but spatially even distributed artificial networks to assess exemplarily potential contribution of the historic network to the discrepancies found by these authors.

The high differences (1.8 K) between regional averages of soil temperature obtained from the historic network and "reference" in December suggest that the network design may affect gridded observational averages more in December than in July. This means that the high discrepancies between CCSM-derived and observation-based gridded soil-temperature climatologies can be explained by the network design in winter.

PaiMazumder et al. (2007) also showed that in December, biases between simulated and observed soil temperature reach up to 6 K at 0.2-m depth; about 2.5 K bias may result from incorrect simulation of observed forcing. Our study shows that about 2-K bias may be explained by uncertainties due to network density in winter. This means that about 1.5-K bias may result from measurement errors and/or model deficiencies.

In July, biases caused by the historic network are higher than biases in CCSM found by PaiMazumder et al. (2007). Hence, we have to conclude that in summer, CCSM performs well for simulating soil temperature. On the contrary, in winter, biases in CCSM can only partially be explained by uncertainties due to network density.

Similar results are found for RMSE and SDE in winter, whereas in summer, RMSEs for the historic network are lower than RMSEs in CCSM by 1 K on average. Hence, the discrepancies between CCSM-simulated and observation-based gridded soil-temperature climatologies in winter can be explained by incorrect simulation of atmospheric forcing as well as network design. Thus, improvement of soil-model physics is essential for better winter soil temperature simulation.

From this case study, it can also be concluded that the historic network always fails to capture the "reference" regional soil temperature averages with high biases, RMSEs, and SDEs in both months. On the contrary, the randomly distributed 500-, 400-, and 200-site networks capture the "reference" regional soil-temperature averages well at all layers. These networks also capture well the diurnal variation of soil temperature in the upper soil. Hence, our case study suggests that randomly distributed networks of 200 sites or more reliably reproduce acceptable regional averages of soil temperatures for Siberia. However, maintenance of such networks may be expensive because many of the sites would not be easily accessible in a remote area like Siberia. Future studies should examine the general robustness of the influence of the network density and design.

Abstract

We employed remote sensing techniques in combination with in situ measurements to investigate the presence/absence of permafrost in and around the George Lake area, central Alaska. The complex interrelationship between vegetation, topography, local geology, and permafrost in a discontinuous permafrost setting was examined. We used SPOT multi-spectral data to generate a land cover map for the study area. Eleven land cover classes were mapped including eight vegetation classes in a maximum likelihood classifier. Correlative relationship between surface parameters and permafrost was used to gain a preliminary understanding of permafrost distribution in the study area. In situ measurements in different vegetation and topographic settings disclosed that scattered short black spruce with thick moss layer is a potential indicator of permafrost with shallow active layer depth. Integrated analysis of vegetation map, equivalent latitude values, and field observations suggests that equivalent latitude greater than 63° is permissive of permafrost in the study area.

Keywords: Interior Alaska; mapping; permafrost; remote sensing.

Introduction

This study integrates remotely sensed (SPOT multispectral) data with field data for the area near George Lake, central Alaska, to understand the complex interrelationship between vegetation, topography, local geology, and permafrost in a discontinuous permafrost setting. It is a part of the Alaska Division of Geological & Geophysical Surveys (DGGS) project on the proposed Alaska gas pipeline corridor that aspires to identify the associated geohazards along the Alaska Highway corridor (such as areas underlain by permafrost, areas with highest potential for active faulting, liquefaction, landslides) (Solie & Burns 2007).

In order to make informed decisions regarding alignment and design of future infrastructure development, and assess the impact of climate change, a precise understanding of near-surface permafrost conditions is critical. Direct field investigation of permafrost or detection by indirect geophysical technique is limited to small areas due to the huge extent, extreme climate, and limited fieldwork time, and poor accessibility to most parts of arctic and sub-arctic Alaska. In such a situation, remote sensing techniques can be of great help. Many environmental factors that reflect the permafrost condition and indicate its presence/absence (like vegetation, topography, snow cover) can be mapped fairly from remote sensing data. The correlative relationship between these environmental factors and permafrost is exploited to get indirect information about subsurface permafrost (e.g., Etzelmuller et al. 2001, 2006, Frauenfelder et al. 1998, Jorgenson & Kreig 1988, Leverington & Duguay 1996, 1997, Morrissey et al. 1986, Peddle 1991, Peddle & Franklin 1993). Distribution of permafrost in discontinuous permafrost zones is strongly influenced by local climate, topography (elevation, slope, and aspect), local hydrology, vegetation cover, geology, and seasonal snow cover (e.g., Smith 1975, Goodrich 1982). Vegetation cover is one of the best indicators of spatial distribution of permafrost and relative thickness of active layer in discontinuous permafrost zones (Duguay et al. 2005). Hence, detailed vegetation mapping is critical in mapping near-surface permafrost.

Methods

Fieldwork was carried out during summer 2007 along the Alaska Highway between Lisa Lake and Dot Lake (Fig. 1). We visited different vegetation, topographic, and geologic settings, and collected data on active layer depth, soil type, moss layer thickness, and vegetation type. We sampled a total of 155 locations using a frost probe for active layer depth measurements and a soil auger to reveal the soil profile in the top 1.5 m.

The most widely accepted definition of permafrost is “any ground that remains frozen for at least two consecutive years” (French 2007). However, in this study, we adopted the permafrost definition by Brown (1967) and French (1976) that define “ground remaining frozen (at or below 0°C) throughout at least one summer” as permafrost. We also assume the depth to frozen ground measured using a frost probe in the field as active layer depth.

Absence of ice in well-drained sandy soil makes it impossible to measure active layer depth using a frost probe. In such situations, soil temperature is the only criteria

Table 1. Classification accuracy totals. For a brief description of classes (superscript 1-11), please refer to text.

Class Name	Reference totals	Classified totals	Number correct	Producer's accuracy (%)	Kappa statistics
[1]Thick spruce	15	15	15	100	1.00
[2]Spruce	64	63	62	96.88	0.98

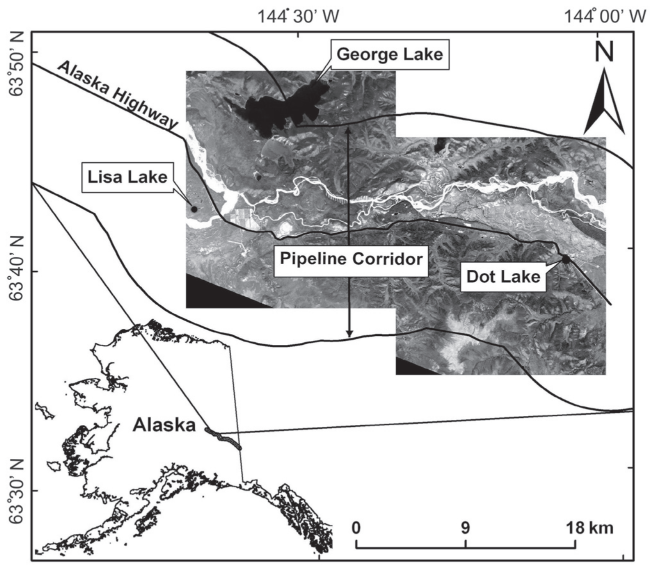

Figure 1. Study area extends from Lisa Lake to Dot Lake along the Alaska Highway. It is a small section of DGGS' proposed gas pipeline corridor study.

to define active layer depth. Hence, we installed Hobo temperature data loggers at 14 selected locations to record soil temperature. The temperature loggers are logging in their first year, and we have not used temperature data in the analysis. These temperature data will be used to estimate thetemperature at any depth and eventually to estimate the active layer depth (Williams & Smith 1989).

We used SPOT 5 multispectral data that has four spectral bands in visible and near infrared (IR) range (Green: 500–590 nm; Red: 610–680 nm; NearIR: 780–890 nm; SWIR: 1580–1750 nm) for land cover classification. Two rectangular scenes covering the study area were clipped from original SPOT scene (acquired on June 30, 2003) that was ortho-rectified and fused with the 2.5 m panchromatic band to improve the spatial resolution of multispectral data (Pohl & Van Genderen 1998). Classification was done using a combination of both unsupervised and supervised signature in a maximum likelihood classifier using ERDAS Imagine, a commercially available image processing software package (Schowengerdt 1983, ERDAS Imagine 2005). We classified the SPOT scenes into eleven land cover classes. These include 1) very dense stands of both black spruce and white spruce; 2) relatively less dense than thick spruce stands; 3) mostly observed in valleys, where spruce is widespread and willows generally grow near small water channel or creek; 4) mix of birch and spruce, generally observed in north facing slope, most prominent forest type in interior Alaska; 5) mix stands of deciduous trees including balsam poplar, willow, alder and birch; 6) stands of aspen vegetation only; 7) small alpine plants (e.g., mountain avens, dryas, sage, etc.); 8) open areas filled with grass; 9) flowing river water with heavy sediment loads; 10) standing water body; and 11) includes different types of bare surfaces (bed rock surfaces, bare surfaces on steep slopes, cut slopes surfaces on foot hills, soils, gravel quarry). Reference totals are the reference pixels selected randomly on the classified image for which actual classes are known. Classified totals are the pixels classified as a particular class by the classification process. Two hundred fifty-two randomly generated points were used to assess the classification accuracy. The superscripts 1–11 in Table 1 refer to the eleven land cover classes described above.

We generated an equivalent latitudes map of the study area from slope and aspect images using 60 m (pixel size) Digital Elevation Model (DEM). Equivalent latitude is an index of long-term potential solar beam irradiation on a surface (Lee 1962). A close relationship exists between equivalent latitude and presence or absence of permafrost, vegetation assemblages, and thaw depth (Dingman 1970, Koutz & Slaughter 1973).

We used the following equation to calculate equivalent latitude (Okanoue 1957):

$$\theta' = \sin^{-1}(\sin k \cdot \cos h \cdot \cos\theta + \cos k \cdot \sin\theta) \tag{1}$$

where k is the slope of the surface, h is the aspect of the surface, θ is the actual latitude of the area, and θ' is the equivalent latitude of the area.

Results and Discussion

The study area is classified into eleven land cover classes, including eight vegetation classes using a combination of both unsupervised and supervised signatures in a maximum likelihood classifier (Fig. 2). For classes 1, 2, 3, 4, 5, and 9, signatures obtained from unsupervised classification were used. For classes 6, 7, 8, 10, and 11, the following numbers of training areas were used in classification 120, 46, 214, 76, and 44, respectively (Table 1). We assessed the classification results using field records, field photographs and in consultation with DGGS scientists. A team of geologists from DGGS did a detailed geologic mapping of the study area as part of the "Alaska Gas Pipeline Corridor" project. Classification results yield an overall accuracy of 89.29% and overall Kappa statistics (Congalton 1991) of 0.87 (Table 1). Classification results of four land cover classes (thick spruce, alpine vegetation, turbid river water, and lake) show 100% accuracy whereas grassland class shows lowest accuracy (62.5%) owing to overlap of spectral signature of grassland and exposed surface classes in visible and near IR bands. Both the grassland and exposed surfaces classes have high digital number (DN) values in all the visible bands. High DN values for exposed surfaces in all the visible bands are obvious, but high DN values for grassland is most likely due to the summer timing of image acquisition (June 30, 2003). During field survey we found that grasslands are mostly dominant in open drained lake beds, and towards the middle of summer lot of grass stems became dry. At the same time the upper soil surface was also very dry. Therefore, the high digital values of grasslands in all the visible bands might be due to the combined effect of dry soil and dry grass stems.

Field sampling in different vegetation settings during summer 2007 revealed that tussocky areas with short, scattered black spruce were characterized by permafrost with shallow active layer depth (less than 50 cm); birch, tall black spruce, and white spruce were found in areas characterized by deeper active layer (greater than 50 cm); and aspen and mixed deciduous vegetation dominated where the upper 1.5 m was unfrozen.

Dividing the classified vegetation map into two elevation units reveals that valleys and floodplain deposits of the low elevation unit (<500 m a.s.l.) are dominated by spruce trees and tussocks. Analysis of the high elevation unit (>500 m a.s.l.) with respect to slope and aspect reveals the dominance of mixed birch and tall spruce on north- and west-facing slopes. Aspen and mixed deciduous trees are generally found in south- and east-facing slopes in well-drained conditions.

On the basis of equivalent latitude values, we classified the study area into three distinct zones. All south-facing slopes have equivalent latitudes less than 60°. Relatively flat floodplain, moraine, and eolian deposits have equivalent latitudes between 63–65°. All north-facing slopes are characterized by equivalent latitudes greater than 65°. The result of integrated analysis of vegetation map, equivalent latitude map and field observation is summarized in Table 2.

Table 2. Interpretation of integrated analysis of vegetation map, equivalent latitude map, and field observations.

Topography	Equivalent latitude (°)	Vegetation	Depth to frozen ground (Summer 2007)
Valleys and flood plain deposits (<500 m asl)	63 – 65	Scattered and/or drunken short black spruce	Less than 50 cm.
North facing slopes (>500 m asl)	Greater than 65	Tall black and white spruce, birch	Greater than 50 cm
South facing slopes (>500 m asl)	Less than 60	Deciduous (aspen, poplar, willow etc.)	None/deeper than 1.5 m

Our findings suggest that equivalent latitude greater than 63° is permissive of permafrost in the study area. This is in close agreement with the findings of Dingman (1970) and Koutz & Slaughter (1973). Dingman (1970) showed that in the elevation range of 256–494 m for Glenn Creek watershed, the permafrost/non-permafrost boundary lay between the 60° and 65° equivalent latitude isopleth lines. Koutz & Slaughter (1973) found a marked correspondence between soils with permafrost and the area above 65° equivalent latitude; and soils without permafrost with equivalent latitude isopleths below 60°.

In the prevailing climatic conditions the high variability of active layer depth

$$(\overline{X} \pm s = 65.61 \pm 19.72 \text{ cm};$$

where $\overline{X}$ is sample mean; s is standard deviation of sample is attributed to difference in soil types, moss layer thickness, and local geology. Thus, even though the equivalent latitude of north-facing slopes is more northerly than that of the valleys and flood plains, the active layer tends to be deeper due to soils which are generally less silt-rich and well drained.

Conclusions

The applied remote sensing technique in combination with *in situ* measurements has considerable potential for use as a tool in regional-scale permafrost mapping. We exploited the correlative relationship between surface parameters and permafrost to gain a preliminary understanding of permafrost distribution in the study area. Tussock land with scattered short black spruce tree and a thick moss layer is a potential indicator of permafrost with shallow active layer depth. At the higher elevation unit (>500 m a.s.l.) birch, tall black spruce and white spruce are dominant in north- and west-facing slopes characterized by a relatively deeper active layer. Broad-leaved, deep rooted deciduous vegetation in south- and east-facing slopes in well-drained soil condition

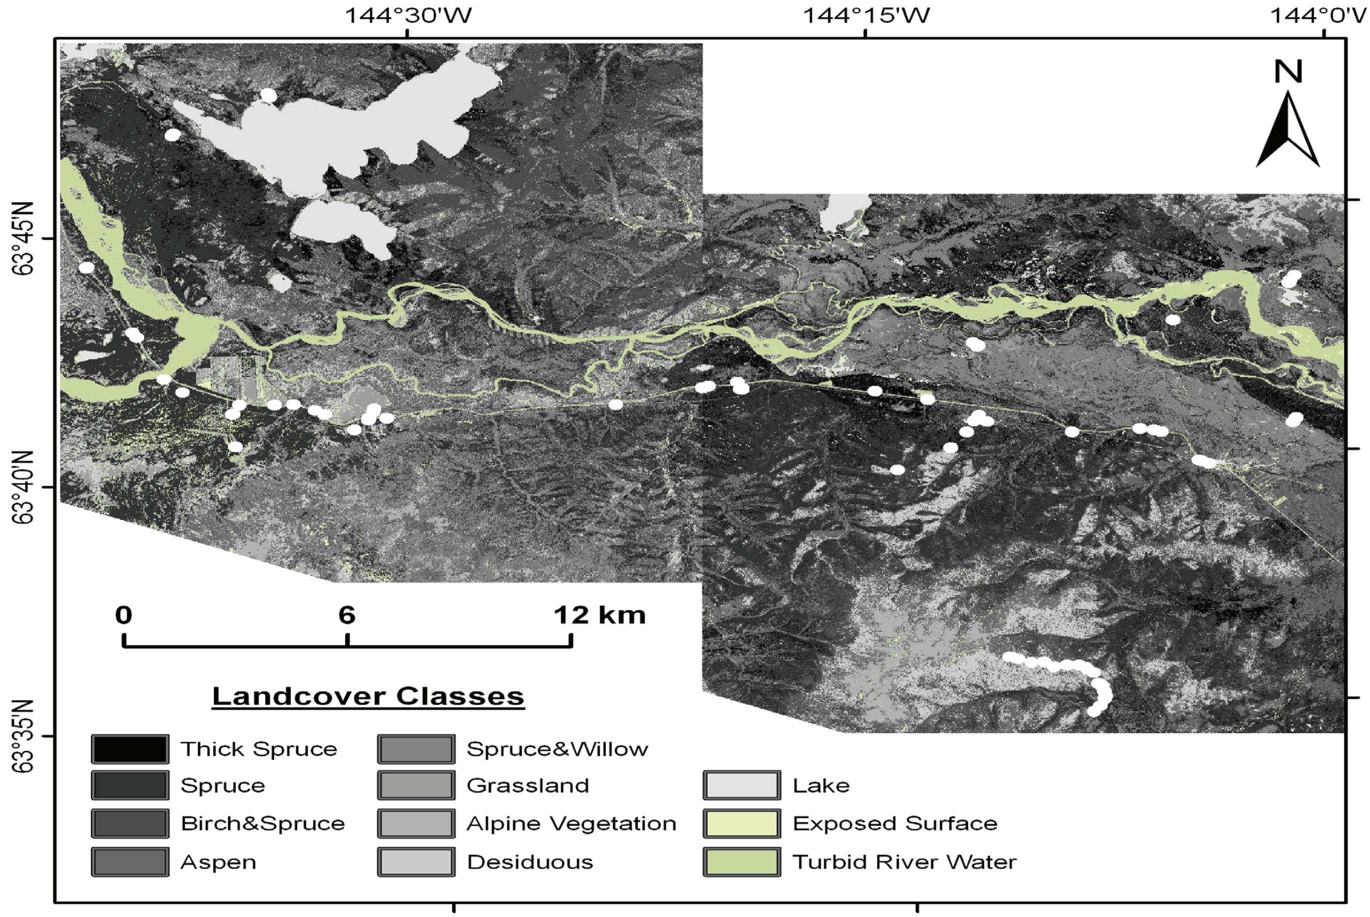

Figure 2. Land cover classification map of George Lake area. Eleven land cover classes including eight vegetation classes were mapped from SPOT multispectral data (acquired on June 30, 2003) in supervised maximum likelihood classifier. White dots represent the sampled locations for permafrost investigations, vegetation distribution, and field data collection.

indicates absence of near-surface permafrost. Equivalent latitude values for the permafrost and non-permafrost portion of the study area also supports the accepted generalization that near-surface permafrost is present under north-facing slopes and absent under south-facing slopes. However, we do not rule out the possibility of deeper permafrost in south-facing slopes. In the prevailing climate conditions, high variance of active layer depth is attributed to different soil types and moss layer thickness.

Acknowledgments

Field support and partial funding for this research was provided through DGGS as part of an on-going project to map bedrock and surficial geology and identify geohazards along the proposed natural gas pipeline corridor from Delta Junction, Alaska, to the Canadian border. We acknowledge additional support from the Alaska Space Grant Program. (ASGP). The authors acknowledge Dr. Richard D. Reger and De Anne Stevens for guidance and help in taking measurements in the field. Special thanks to Dr. Vladimir Romanovsky for advice regarding the various aspects of this study and providing temperature data loggers.

Abstract

A probe containing a series of electrodes spaced at regular intervals was used to monitor electrical potentials developed across the freezing front during permafrost aggradation at depth in the talik of the Illisarvik drained lake bed. Data were collected from 2000 to 2007. The electrode located at the freezing interface showed a peak electrical potential, commonly of tens of mV, when measured with respect to reference electrodes in the unfrozen or the completely frozen region. The location of the freezing front was consistent with temperature measurements using thermistors installed at these depths. This experiment suggests that, with proper electrode probes and frequent measurements, electrical freezing potentials can be used for monitoring the movement of the freezing front in permafrost areas.

Keywords: freezing potential; Illisarvik; permafrost aggradation.

Introduction

The development of electrical freezing potentials across freezing interfaces in aqueous solutions and moist soils has been studied for the past five decades (e.g., Workman & Reynolds 1950). The potentials arise due to charge separation during phase change of water and selective incorporation in the frozen and unfrozen regions of H^+ and OH^- ions in pure water and other cations and anions in solutions and soils. Early measurements of freezing potentials in water and dilute solutions, as well as in soils, have been reviewed by Parameswaran (1982) and Parameswaran et al. (2005). Field measurements of such potentials developed during permafrost aggradation were presented by Parameswaran & Mackay (1983, 1996), during thawing of the active layer by Parameswaran et al. (1985), and during freezing of lake water by Burn et al. (1998).

During freezing, liquid water migrates to the freezing interface, especially in fine-grained silty and clayey soils (Williams & Smith 1989). An electrical field developing at the freezing front will enhance the drift of unfrozen water, leading to accumulation of ice at the freezing interface (Hoekstra & Chamberlain 1963, Nersesova & Tsytovich 1966). Such geo-electrical potentials may also affect the cathodic protection of buried pipelines and other utilities. The purpose of this paper is to present recent measurements of electrical potentials made at depth during freezing of the talik at the Illisarvik drained-lake experiment, near the western Arctic coast of Canada (Figs. 1, 2).

Illisarvik

A field experiment to drain a lake and to study the aggradation of permafrost in a natural arctic environment was conceived by Professor J.R. Mackay in the 1960s

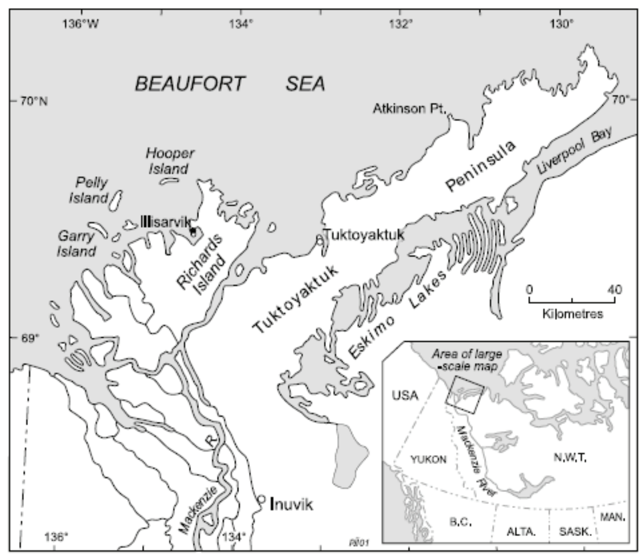

Figure 1. Location of Illisarvik (Mackay & Burn 2002a, Fig. 1, reproduced with permission of NRC Research Press).

(Mackay 1997). Illisarvik Lake, on the west coast of Richards Island, Northwest Territories, was 600 m long and 300 m wide, with a depth mostly between 2 and 3 m, and at the deepest point, over 5 m. Most of the lake bottom remained unfrozen throughout the year, and at the midpoint, the depth of the sublake talik was 32 m (Hunter et al. 1981). The lake was drained on 13 August 1978. After drainage, permafrost started to grow downwards and from the sides of the talik into the lake sediments, and since then, permafrost has been aggrading at the center of the lake by gradual freezing of the ground (Mackay 1997). Field studies have been conducted at the site on a continuing basis into several topics including growth of permafrost, development of ground ice, development of the active layer, pore-water

Figure 2. Aerial view of Illisarvik (Mackay & Burn 2002b, Fig. 2, reproduced with permission of NRC Research Press).

expulsion, electrical freezing potentials developed during permafrost growth, and other geophysical effects (see Burn & Burgess 2000).

By 1995 the talik was at -0.2°C or below, but surface evidence of pore-water expulsion, in the form of an annual ice dome on the residual pond near the center of the lake bed, has indicated that the talik is not frozen (Mackay 1997). The top of the ice dome has been up to about 1 m higher than the surrounding pond ice between 1995 and 2007. Water collected from beneath the ice dome in late winter 2000 may be indicative of the solute concentrations in the groundwater of the unfrozen talik. Measured concentrations of major ions were (mg/L): Na^+ 1000; Cl^- 2000; Ca^{++} 460; Mg^{++} 470; K^+ 51. The total dissolved solids were measured at 6700 mg/L. The conductivity of the water was 6 mS/cm. Similar data are presented by Mackay (1997).

Freezing Potentials at Illisarvik

The deposits in the lake bed consist of 2 to 4 m of fine-grained, organic-rich lake sediments over medium- to fine-grained sand. Permafrost was established in these deposits during the first winter following drainage, and by 1981 the ground had frozen to a depth of about 5.65 m. In June 1981, an electrode probe, about 10 m long, was installed at the center of the lake, with 21 ring electrodes placed around the bottom 3 m of the probe and spaced 150 mm apart. While the freezing front advanced downwards, a small electrical potential (a few hundred mV up to 1 V) developed at each electrode, as the freezing front crossed that location. These measurements, carried out over 15 months, were reported by Parameswaran & Mackay (1983).

The conclusion from this early field measurement, during relatively rapid ground freezing, was that progress of the freezing front could be monitored with suitable electrodes installed at regular intervals. Between March 1981 and August 1982, the freezing front advanced from electrode location 15 down to electrode location 11, about 0.6 m downwards. This was confirmed by temperature measurements near the electrode locations. It is important to note that at this stage of the field experiment, the temperature gradient in the frozen ground was relatively steep, and there was little temperature depression below 0°C within the talik (Mackay 1997). As a result, the freezing front was relatively well-defined in physical terms. The thermo-physical conditions were quite different by 1998 when the investigation reported here began (e.g., Mackay 1997).

Field Methods

Drilling in the center of Illisarvik in August 1998 indicated that the ground was at least partially frozen to a depth of 13.5 m. In August 1999, a hole was drilled by water jet in the center of the drained lake bed, and an electrode probe was inserted to a depth of 16 m. Water-jet drilling does not provide undisturbed samples from the hole, but it is possible to interpret a generalized stratigraphy from the soil materials returned uphole, the behavior of the pipe during drilling, and the resistance of the ground to the drill. A thermistor cable was placed in a second hole, approximately 3 m from the first. The cable was installed in a casing of 1-in steel pipe. We have found that near the ground surface the steel pipe is sufficiently robust to withstand environmental stresses in a field context, while PVC pipes we have installed have lasted only a few years before being damaged.

The stratigraphy at the site comprised the active layer, about 0.8 m thick, lying on top of hard frozen organic lake sediments. Below 4.3 m depth the ground was not as well bonded, and below 13.5 m the ground was unfrozen. Temperature profiles from August 2000 and 2005 for the upper 18 m at the lake center are presented in Figure 3.

Probe Design

Figure 4 presents a schematic diagram of the electrode probe. The top 2 segments of the probe consisted of 1-in steel pipe, each 2 m long. Below that were 6 schedule 80 PVC pipes, each also 2 m long. All the pipes were threaded at both ends to fit joining couplings. Below these 8 lengths was a 1-m long PVC pipe with a conical plug at the bottom.

Ten ring electrodes made of gold-plated copper strips, 12.5 mm wide and about 1 mm thick, were placed around the PVC tubes at various intervals. Most of the electrodes were located in the unfrozen zone below 13.5 m on the PVC pipe #6, but 1 electrode (E1) was located in the hard frozen zone (on PVC pipe #1), and 2 (E2 and E3) were in the partially frozen ground, E2 on PVC pipe #2 and E3 on pipe #4. Electrodes E4 to E10 were on pipe #6 (Fig. 4).

Coaxial cables of sufficient length were soldered to the ring electrodes and fed through the hollow center of the tube assembly. The ends were stored above ground in a pipe nipple connected to the top of the uppermost steel pipe.

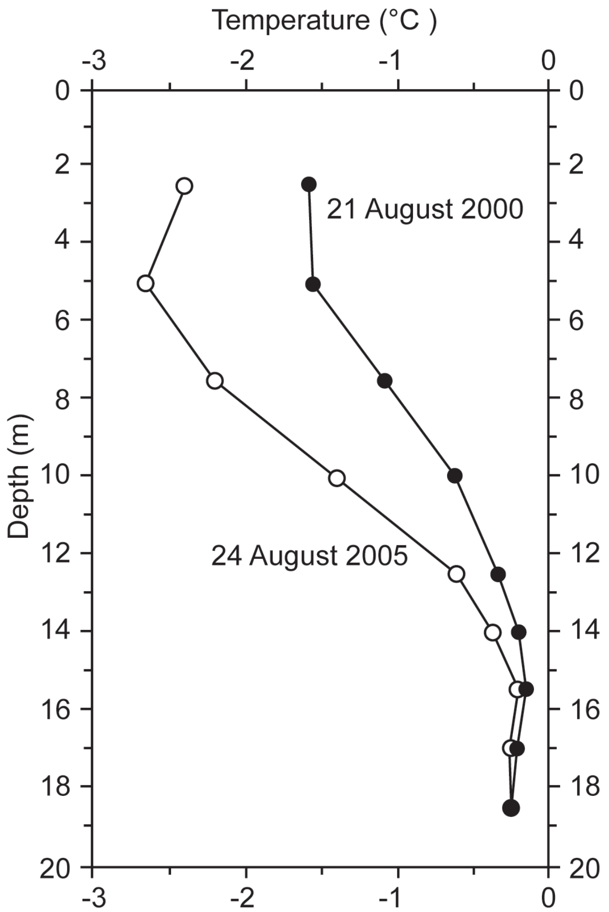

Figure 3. Ground temperature profiles at the center of Illisarvik, 21 August 2000 and 24 August 2005, showing evolution of the ground thermal regime during the study period.

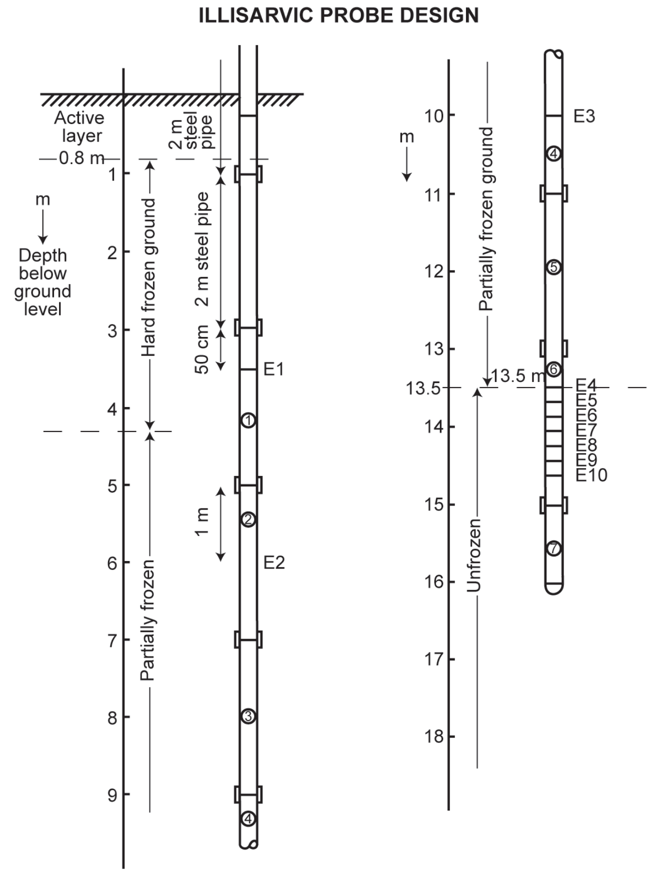

Figure 4. Probe design.

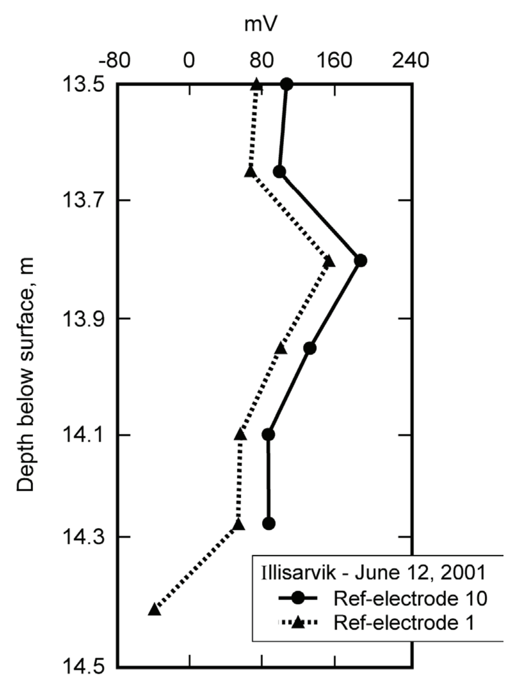

Figure 5. Electrical potential profiles from 12 June 2001.

During field visits throughout the year between 1999 and 2007, the electrical potentials developed at each electrode were measured with respect to the unfrozen ground at electrode E10 as well as the frozen ground at electrode E1. The potentials (in mV) were measured by multimeter with a sensitivity of 0.01 mV.

Results

Data collected up to March 2006 indicated a peak potential within the interval between E4 (13.5 m depth) and E10 (14.4 m depth). After this date, in August 2006 and April, June, and August 2007, the measurements provided no trend with depth, and the potentials at most electrodes tended to 0 mV shortly after connection.

Figure 5 presents data from 12 June 2001, showing a typical set of measurements for E4 to E10. In general, the potential at E1 was positive with respect to E10 throughout the period of measurement. The plot shows the potentials at each electrode as a function of depth.

A peak is observed at electrode E6, at a depth of 13.8 m below the ground surface, indicating the location of the freezing front. Both curves, with reference to E1 or E10, follow the same trend and show the peak at the same location. Figure 6 shows similar measurements from 20 August 2001, when, again, the peak was recorded at electrode E6.

Figure 7 shows the readings taken on 14 April 2003. The peak potential had advanced to electrode E9, at a depth of 14.25 m below the ground surface. This suggests that between June 2001 and April 2003, the locus of electrical potential advanced downwards from 13.8 m to 14.25 m.

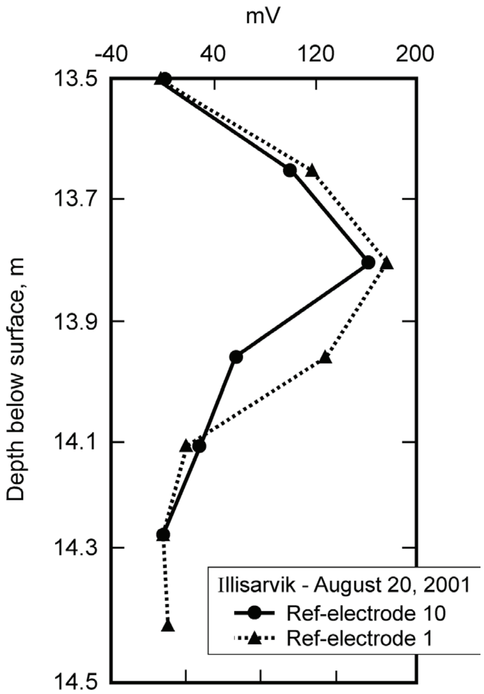

Figure 6. Electrical potential profiles from 20 August 2001.

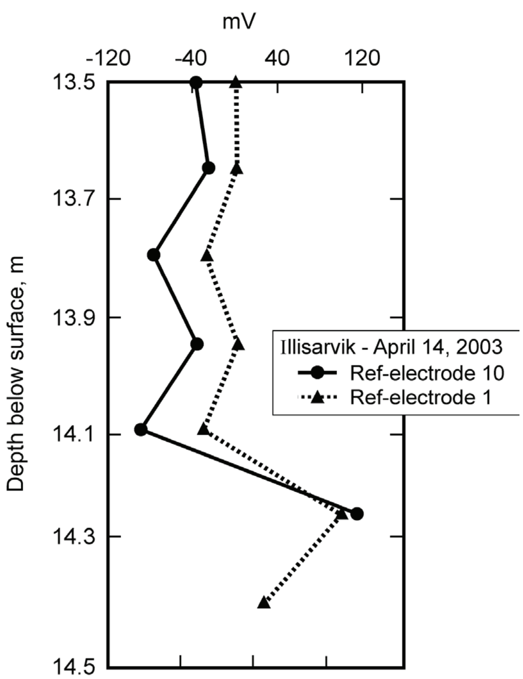

Figure 7. Electrical potential profiles from 14 April 2003.

However, measurements taken on 20 June 2004 showed considerable variation of potentials at the electrodes at different depths (Fig. 8), with the peak occurring at electrode E9 at a depth of 14.25 m below the ground surface. During the period of measurement, data similar to the profile in Figure 8 were collected on several occasions, but normally the profiles presented one distinct peak potential. The peak potential was measured at E8 or E9 between April 2002 and March 2006.

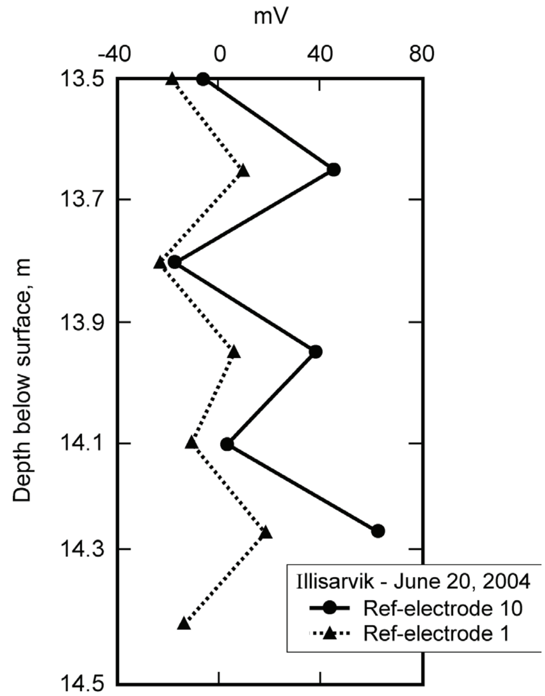

Figure 8. Electrical potential profiles from 20 June 2004.

Figure 9 is a plot of the location of the freezing front with time (as estimated from the peak electrical freezing potentials measured on the electrodes) and the variation of the temperature of the ground between 2000 and 2005. The lower curve shows the temperatures at a depth of 14.0 m and the upper one at 15.5 m. The peak potential in June and August 2001 was at electrode location E6, at a depth of 13.8 m. The temperatures measured by the thermistors installed in this region of the ground were -0.29°C to -0.30°C at a depth of 14 m and -0.20°C to -0.22°C at a depth of 15.5 m. In April 2002, the temperature at 14 m depth was -0.34°C and the peak potentials were observed on electrodes E8 and E9, at depths of 14.1 and 14.25 m, respectively. The temperature at the depth of 15.5 m was -0.18°C, in the unfrozen region of the ground. These data suggest that the peak potential developed at a temperature of about -0.3°C, for the temperature at 14 m, was between -0.3°C and -0.4°C when the peak was measured at depths between 14.1 m and 14.25 m. The pattern illustrated in Figure 8 and the persistence of potentials in the profile lower than the peak value, both above and below the location of the peak, indicate that the freezing front is not a distinct feature at the scale of these measurements (intervals of 15 cm). Instead, there is likely a freezing zone, with some temperature depression, within which the potentials develop. The stratigraphic interpretation from the drilling record indicated partially frozen ground from depths of 4.3 m to 13.5 m (Fig. 4). The measurements presented here suggest that there is a concentration of solutes close to the temperature of ice nucleation in the soil, leading to development of a potential by charge separation. In turn, this suggests that there is a relatively restricted area where solute effects are focused, in comparison with the 9 m of partially frozen ground.

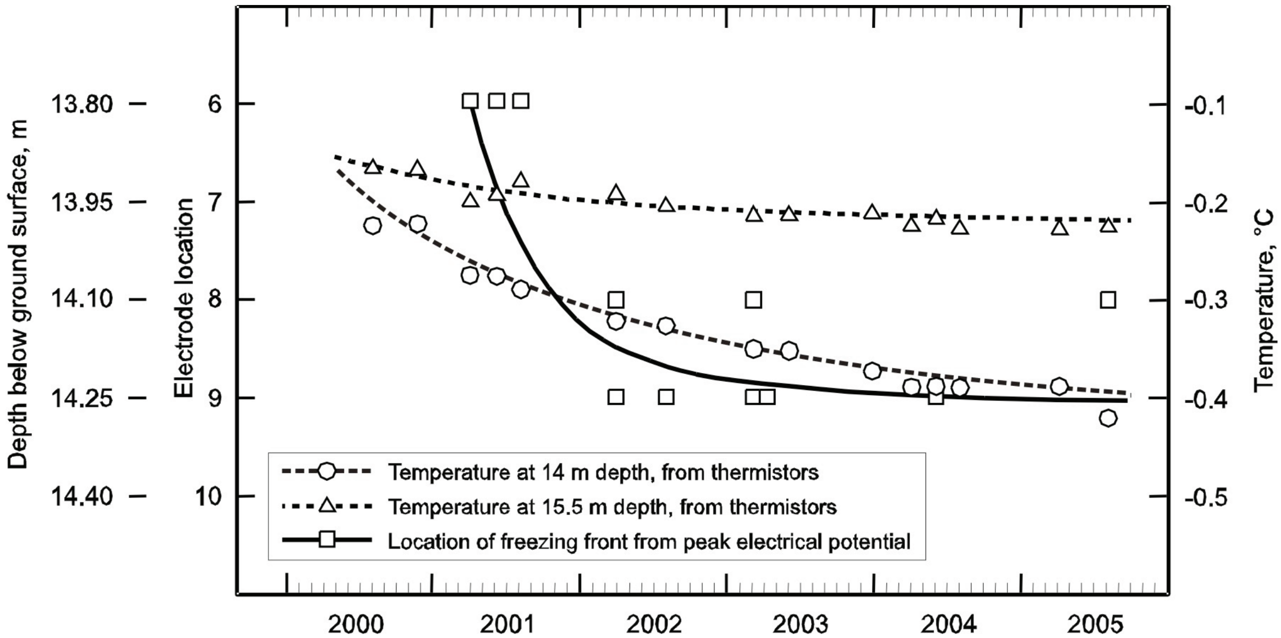

Figure 9. Location of the freezing front interpreted from peak potentials and proximal ground temperatures at depth in the talik at Illisarvik, 2000–2005.

Assuming a freezing point depression of about 0.2°C to 0.25°C due to the solutes present in the groundwater at these depths, we can assume electrode E8 is at the freezing front, and the electrode potential measurements indicate this. By January 2003, the temperature at 14 m depth was less than -0.35°C. The peak freezing potentials were observed on electrode E9, at a depth of 14.25 m. As shown by the upper curve in Figure 9, the temperature at the depth of 15.5 m was still around -0.2°C, the temperature measured after drilling, when it was determined to be unfrozen.

Measurements after March 2006 showed considerable oscillations in the profile, and very low absolute voltages, indicating probably that the freezing front had advanced below the lowest electrode in the assembly. Similar patterns in the measured profile were also observed in the measurements reported by Parameswaran & Mackay (1983), when all the electrodes were embedded in the frozen soil. This could be the effect of shorting the circuit, as the measuring electrode and the reference electrode were both embedded within the same frozen system. Laboratory observations of the shorting potentials were reported by Parameswaran et al. (2005).

Conclusions

Electrical freezing potentials were observed at electrodes positioned at the freezing interface in the talik of the Illisarvik drained lake. The location of the peak electrical potential indicated its development at a temperature of about -0.3°C. The principal results are:

(1) Electrical potentials can be measured during permafrost aggradation. The potential is permafrost positive.
(2) The potential is on the order of tens of mV.
(3) The potential may develop below 0°C, perhaps indicating the nucleation temperature of ice in groundwater.

With proper electrode probes and with more frequent measurements, electrical potential probes can be used for monitoring the movement of the freezing front in permafrost areas.

Acknowledgments

The research has been supported by the Natural Sciences and Engineering Research Council of Canada, the Polar Continental Shelf Project of Natural Resources Canada, and the Aurora Research Institute. We thank Larry Boyle for manufacturing the probe, and A. Burn, D. Riseborough, and J.R. Mackay for assistance during installation. D. Esagok and L. Kutny have provided assistance with measurements throughout the project. We also thank Don Hobbs, Peter Richards, and Michelle Gagnon of the Institute for Research in Construction, National Research Council Canada, for preparation of Figures 3 through 9. The National Research Council of Canada Research Press kindly gave permission to reproduce Figures 1 and 2. This paper is Polar Continental Shelf Project contribution number 00808.

Abstract

The International Permafrost Association (IPA) has a long history of data management. Notable achievements include the establishment of a Global Geocryological Data (GGD) system and the publication of the Circumpolar Active-layer Permafrost System (CAPS) compilations. At the same time, the IPA has struggled to maintain continual stewardship of permafrost and related data with sustained support. Activities as part of the International Polar Year will significantly increase data holdings and will required renewed emphasis on data description, preservation, and integration with other disciplines.

Keywords: data management; frozen ground; GGD; IPA; IPY; permafrost.

Introduction

Permafrost and seasonally frozen ground data and information are critical for fundamental process understanding, environmental change detection, impact assessment, model validation, and engineering applications. The International Permafrost Association (IPA) has long emphasized the importance of these data and has encouraged ongoing data sharing and management through the Global Geocryological Data (GGD) system. The GGD is an internationally distributed system linking investigators and data centers around the world and was proposed by Barry et al. (1995). The World Data Center (WDC) for Glaciology at Boulder has historically acted as central node of the GGD and has published two compendiums of permafrost related data: *Circumpolar Active-Layer Permafrost System* (CAPS) Version 1 and the substantially updated Version 2 (IPA DIWG 1998, IPA SCDIC 2003).

Data advertised through the GGD and published on CAPS include information on borehole parameters, soil temperature, cryosols, and climatology as well as maps, metadata, and bibliographies. Data come from diverse international sources, but data produced by IPA projects have always been prominent in the collections. These products include benchmark maps such as the *Circum-Arctic Map of Permafrost and Ground-Ice Conditions* (Brown et al. 1998) as well as data and metadata from ongoing IPA programs such as the Global Terrestrial Network for Permafrost (GTN-P), the Arctic Coastal Dynamics (ACD) program, and the Antarctic Permafrost and Soils (ANTPAS) project. These IPA programs continue to produce important data with a burst of new activity in the International Polar Year (IPY). Another area of potential data growth is through satellite remote sensing.

While the GGD has succeeded in capturing and describing many important data resources, it has been an ad hoc activity without sustained support for ongoing data collection and stewardship. There is a critical need to sustain data stewardship activities throughout the entire data lifecycle. Note, data stewardship is a broader concept than data management. It can be defined as "all activities that preserve and improve the information content, accessibility, and usability of data and their associated metadata" (NRC 2008). Correspondingly, the concept of a data lifecycle reflects how data are continually evaluated, improved, and maintained for archiving until retired or discarded.

The GGD is linked to the broader IPY Data and Information Service (IPYDIS), which works with the Scientific Committee on Antarctic Research (SCAR) and International Arctic Science Committee (IASC) to establish a lasting polar data infrastructure. The IPA seeks to contribute to this international effort by capturing the burst of permafrost data collection during IPY, and ensuring the preservation of past data in a new CAPS Version 3 compilation. The IPA also seeks to develop a more sustainable data collection and stewardship strategy through linkages to other relevant international programs including the intergovernmental Group on Earth Observations (GEO).

Global Geocryological Data

The need for a consistent and comprehensive permafrost data management has long been recognized. In 1983, the U.S. National Research Council called for greater coordination and a specialized permafrost data clearinghouse (NRC 1983). In 1988, the WDC for Glaciology at Boulder organized a workshop in Trondheim, Norway in conjunction with the Fifth International Conference on Permafrost (Barry & Brennan 1989). This workshop, coupled with a paper presented by Roger Barry (1988), led to the establishment of a Data and Information Working Group within the IPA and established the overall IPA data strategy. The strategy was refined based on an international survey of permafrost data holdings (Barry & Brennan 1993) and culminated in the establishment of the GGD and the first CAPS compilation for the Seventh International Conference on Permafrost, SICOP, in 1998. Furthermore, delegates to the SICOP International Conference recognized the importance of continuity in data and information activities, and the existing Working Group was reestablished as a permanent Standing Committee on Data Information and Communication (SCDIC) during the Twelfth IPA Council Meeting at SICOP in Yellowknife, Canada.

The 1998 CAPS1 included 56 datasets and an additional 89 metadata descriptions for products held elsewhere around the world. In late 2002, the newly established Frozen Ground Data Center (FGDC) at the WDC for Glaciology at Boulder in collaboration with the International Arctic Research Center published the contents of CAPS online at the FGDC web site and began updating and adding to the CAPS collection to create CAPS Version 2. CAPS2 expanded the scope of CAPS by including data and information for seasonally frozen ground regions from in-situ measurements, satellite remote sensing, and model outputs and included data and metadata for more than 200 datasets. More comprehensive data documentation was also written.

Since the publication of CAPS2, the FGDC has published several other datasets. These additions include important historical data (Oberman & Kakunov 2004), maps (Sodnom & Yanshin 1990), and long-term, broad-scale time series of seasonally frozen soil parameters (Zhang et al. 2005). These products are available through the FGDC web site. Data will remain available until the next major media migration or system upgrade at the WDC, at which point the FGDC distribution will need to be retired, unless continued funding can be identified.

In many ways, the history of the GGD parallels the evolution of digital data management in general. Initial bibliographic efforts grew into data compilation and recording efforts. Standard metadata formats were created and implemented. Central catalogs describing distributed data were created. Media and distribution methods evolved.

In some ways the GGD was at the forefront of developments in data management. For example, CAPS1 included specific citations for all datasets and urged investigators to formally cite data use as they would any other publication. This practice is just now gaining wide spread acceptance as is evident in the IPY Data Policy and increasing acceptance of data citations by leading journals.

On the other hand, the GGD has been largely an ad hoc effort punctuated by intense activity around the CAPS compilations. This contrasts with the increasing recognition of the importance of continual data stewardship and full lifecycle data management (USGCRP 1999, NRC 2008). For example, part of the effort of updating CAPS was to try and contact the investigators and institutions holding the 89 GGD products described but not contained on CAPS1. Unfortunately, 45 of the 89 products were not readily accessible and may no longer be available. The potential loss of these data highlights the need for continued support of data management for the permafrost community.

The IPA through its SCDIC needs to evolve its data strategy and the general GGD system to more actively acquire current datasets, rescue data at risk of loss, ensure the planned migration of investigator held data to more permanent archives, and address the growth of data resulting from the burst of IPA activity as part of the IPY.

IPA Programs and the IPY

A summary of the major IPA activities since its formation in 1983 is presented in these proceedings (Brown et al. 2008). In addition to mapping, bibliographic, and terminology projects, the main IPA focus has been on broad, coordinated international field programs. Individual national sponsors fund each program, but the field efforts are unified through IPA coordination of site documentation, data collection methods, and metadata descriptions. Each program has its own data management structure that can be considered a node of the GGD, while metadata should be broadly shared to facilitate discovery across the GGD. IPA programs include:

- The Global Terrestrial Network for Permafrost (GTN-P), which includes both boreholes and active layer sampling protocols.
- The Arctic Coastal Dynamics (ACD) project.
- Northern Circumpolar Soil Carbon Database (NSCD) (Tarnocai et al. 2007).

• Each IPA program is linked to IPY approved and coordinated projects including "Permafrost Observatory Project: A Contribution to the Thermal State of Permafrost" (IPY project #50), "Arctic Circum-Polar Coastal Observatory Network (ACCO-Net)" (IPY 90), "Antarctic and sub-Antarctic Permafrost, Periglacial and Soil Environments" (IPY 33), "Carbon Pools in Permafrost Regions" (IPY 373), and the Russian project, "Response of Arctic and Subarctic soils in a changing Earth: dynamic and frontier studies" (IPY 262).

Global Terrestrial Network for Permafrost

The GTN-P consists of two components: the Thermal State of Permafrost (TSP) and the Circumpolar Active Layer Monitoring Network (CALM) (Burgess et al. 2000). Together they are contributing to the Global Earth Observation System of Systems and the UN Framework Convention on Climate Change through the Global Terrestrial Observing System.

The TSP component of GTN-P consists of a network of boreholes, in which permafrost temperatures are measured. The network currently consists of over 300 boreholes with many new sites to be established during IPY. This network is built on a number of regional networks. Boreholes range in depth from a few meters to greater than 100 m with record lengths of up to three decades. Data collected from this network has provided important information on the change in permafrost temperature over time and are important contributions to major regional and global assessments (ACIA 2004, IPCC 2007, UNEP 2007).

TSP borehole metadata (site descriptions) and summary permafrost temperature data are accessible through the GTN-P web site hosted by the Geological Survey of Canada (GSC). A major goal for IPY is to provide a "snapshot" that describes the thermal state of permafrost for a specific time period. This snapshot can serve as a baseline for the assessment of the rate of change of permafrost conditions and can be used to validate climate model scenarios and to support process research to improve our understanding of permafrost dynamics.

Two national programs within the TSP project illustrate the project scope and its data management challenges. The TSP Norway project plans to establish the North Scandinavia Permafrost Observatory around 70°N, covering a transect from maritime northern Norway into northwestern Sweden and Finland. The Svalbard Nordenskiöld Land Permafrost Observatory around 78°N is already being established. Both observatories deliver borehole temperatures, active layer thickness, meteorological, and periglacial process data from different permafrost landforms. All these data will be organized in the NORPERM database located at the Norwegian Geological Survey. The aim is to also include earlier permafrost and periglacial data from all of Norway and Svalbard in the database. Data from NORPERM shall also be available to others through the GTN-P.

The Canadian Permafrost Monitoring Network coordinated by the GSC consists of over 100 monitoring sites maintained by government agencies and universities. Sites are largely concentrated in the western Arctic (Mackenzie Valley and Delta), northern Quebec, with a few sites in the high Arctic. During IPY, scientists intend to establish new monitoring sites in northern Manitoba, Yukon and Nunavut Territories as part of the TSP project.

The Canadian network maintains a web site that links to the GTN-P web site and provides access to metadata for both active layer and permafrost thermal monitoring sites and summary data. Linkages with the Canadian cryospheric community are through the Canadian Cryospheric Information Network. Canada's contribution to the IPY will be a standardized set of permafrost temperatures collected during IPY that will be compiled into a digital database to be released through the web site and as a CD publication.

The other major component of GTN-P, CALM, monitors active layer thickness and shallow ground temperature, and coordinates field experiments. The CALM network currently consists of more than 150 sites distributed throughout the Arctic and several mountain ranges of the mid-latitudes. Efforts to expand the number and capabilities of sites in the Southern Hemisphere (CALM-S) are underway through ANTPAS. Instrumentation and data-acquisition methods include monitoring the soil thermal and moisture regimes with automatic data loggers, mechanical probing of the seasonally thawed layer at specified spatial and temporal intervals, frost/thaw tubes, and a variety of instruments for measuring frost heave and thaw subsidence.

Data are transferred to the CALM data repository at the University of Delaware for archive and distribution through the CALM web site, which is linked to the GTN-P site and FGDC (Shiklomanov et al. 2008).

Arctic Coastal Dynamics

The ACD project of IASC and the IPA was created in 1999 to improve understanding of circum-Arctic coastal dynamics under the influence of environmental changes and geologic controls. ACD's international and ongoing effort to segment and classify the entire circum-Arctic coastline has resulted in a scalable GIS database of coastal geomorphological characteristics evaluated by regional experts. This detailed evaluation has been compiled into a geographic information system (GIS), which contains data on coastal morphology, composition, dominant processes, ground ice, and environmental forcing parameters such as wind speed, storm counts, melt season, and wave energy.

This information is available for over 1300 segments, covering the coastline of all eight regional seas of the Arctic Ocean. The coasts of the Barents, Kara, Laptev, East Siberian, Chukchi, and Beaufort Seas have been segmented, as has the coastline of Svalbard. The length of individual segments varies (median length is 38 km), but the segmentation format is scalable, allowing the adoption of future digital coastlines and the integration of additional, higher-resolution data. The data are available via an Internet map server and as a downloadable geodatabase at the ACD web site. Others with complementary datasets are encouraged to contribute to this growing data resource. Future development will include the incorporation of remote sensing into the geodatabase.

ACD represents the coastal component of the ongoing international effort to integrate existing and planned Arctic observatories into a coherent Sustained Arctic Observatory Network (SAON). In addition, ACD's IPY activity, ACCO-Net, integrates 17 Arctic coastal observatory projects with 24 ACD key sites into an extended network.

Antarctic Permafrost and Soils

The overall objective of ANTPAS is to develop an internationally coordinated, web-accessible, database and monitoring system on Antarctic permafrost and soils. Specific objectives are to:

1. Develop a web-accessible repository for permafrost and soils data.
2. Prepare thematic maps on Antarctic permafrost and soils.
3. Develop a system of boreholes providing data on permafrost and soils properties, past environmental change, and responses to climate change.
4. Develop a monitoring system recording active layer and periglacial process responses to climate change along selected environmental gradients.

With no centralized funding, ANTPAS progress is restricted to member activity within existing research programs. ANTPAS has developed a web site for publications and links to relevant databases (Objective 1).

Progress has been made on developing soil and permafrost maps (Objective 2), particularly for the Antarctic Peninsula and the Trans-Antarctic Mountain regions. The soil and permafrost data are to be stored, and made available through the web sites of the individual investigators with links to each database from the ANTPAS web site. ANTPAS Objectives 3 and 4 compliment the TSP and CALM projects in the Northern Hemisphere.

Other Geocryological Data

Satellite remote sensing

Satellite remote sensing data are increasingly used for permafrost and seasonally frozen ground studies (Zhang et al. 2004, Duguay et al. 2005). Remote sensing of permafrost terrain and near-surface soil freeze/thaw cycles typically uses a combination of imaging in optical and thermal wavelengths, passive microwave remote sensing, and active microwave remote sensing using scatterometer and Synthetic Aperture Radar (SAR). Consequently, large amounts of valuable data can be generated.

Images and data from the orbiting visible and near-infrared sensors can be used to infer permafrost distribution (e.g., Anderson et al. 1984), active layer thickness, and various periglacial features (Leverington & Duguay 1996). LANDSAT data provide a high-resolution (15 m to 80 m), long (1972–present) time-series, useful to investigate changes in land surface morphology such as in rock glaciers, thaw lakes, and other periglacial phenomena. Land surface temperature is a key parameter for permafrost and seasonally frozen ground studies. The potential application of using land surface temperature products derived from visible and infrared sensors from 1980 to the present can be substantial (Zhang et al. 2004, Duguay et al. 2005). Remotely sensed land surface temperatures can be used to drive numerical models simulating the development of the active layer and thermal regime of permafrost or to estimate thawing index, which can be used to estimate active layer thickness.

SAR data has been used to map bottom fast ice that controls the preservation and development of subsea permafrost (Solomon et al. 2005). Data from passive microwave sensors dating from 1978 can be used to detect near-surface soil freeze-thaw status based on the spectral sensitivity of brightness temperatures to the state of water (liquid or solid) in soils. Zhang and Armstrong (2003) have provided the near-surface (<5 cm) soil freeze/thaw status derived from passive microwave satellite remote sensing data over the Arctic terrestrial drainage basin. Other near-surface soil freeze/thaw data products are also available but have not yet been archived.

Scatterometery can also be used to detect near-surface soil freeze/thaw status with relatively high spatial resolution. Attempts have been made to apply the differential interferometric synthetic aperture radar technique to monitor the surface deformation (frost heave and thaw settlement) due to the annual freeze/thaw cycle of the active layer over permafrost (Wang & Li 1999).

As satellite remote sensing techniques improve, more and better products will continue to be generated. It is essential to archive and distribute such data products.

Periglacial process data

Information on the movement and activity of different periglacial landforms derived from many different techniques including remote sensing, geophysical data such as resistivity and georadar, direct movement measurements, and snow distribution data are increasingly being collected; yet they are lacking coordinated data management arrangements. For example, the TSP Norway project is collecting significant periglacial process data. In another example, the FGDC at WDC for Glaciology at Boulder has received several offers of data on rock glaciers from independent investigators. Because these data are not part of a formal funded program at the WDC, it is difficult for the WDC to acquire the data.

Historical and other data

There are a variety of other important geocryological data sources. Various national programs continue to produce important data outside the bounds of formal IPA programs. While some of these data are well managed and readily available, others need to be better described through formal metadata protocols, converted to digital formats, or migrated to new media. Some data are at risk as investigators retire or research programs end. Some data even need to be "rediscovered", such as those datasets advertised on CAPS that are no longer readily available.

Models are also increasingly important in characterizing and predicting geocryological processes, especially in a changing climate regime (e.g., Marchenko et al. 2008).

Preservation and distribution of significant model outputs will be a growing concern.

Finally, the IPA has often produced specialized bibliographies and these have also been featured on CAPS. The Cold Regions Bibliography Project continues this work with the *Bibliography on Cold Regions Science and Technology* (Tahirkheli 2008).

Future Directions

The increased IPY field data collection, the increased application of remote sensing methods, and the growing need to integrate data across disciplines challenge the ad hoc nature of the GGD. To achieve the IPY goals of greater international collaboration and interdisciplinary research, it is insufficient to simply share basic metadata. Data must be provided in more consistent formats through more interoperable data exchange protocols. Open Geospatial Consortium (OGC) standards and technologies provide one approach to interoperable data sharing. Several information portals such as the Arctic Research Mapping Application and the Arctic Portal build off OGC technologies. Already, within the GGD, the ACD is providing its coastal segment database through an OGC map server, while the WDC for Glaciology provides the *Circum-Arctic Map of Permafrost* and other cryospheric data through several OGC protocols (WMS, WCS, WFS) (Maurer 2007). Users can then use these data and services to prepare their own maps, view regions and variables of interest, and compare data from different sources.

Another goal of IPY is to leave a legacy for future generations. This challenges the SCDIC and the GGD to develop a more continuous and sustainable data stewardship and preservation strategy. This applies not only to publicly available databases, but sufficient resources must also be committed for active data rescue activities. We should also recognize the value of the past CAPS compilations in providing data snapshots at periodic intervals. These snapshots can act as archival records that are, in essence, preserved simply through their broad and public distribution. IPY marks an important milestone for the IPA with a pulse of new data, and much of that data will be presented at the Ninth International Conference on Permafrost. The SCDIC hope to use this opportunity to create a new CAPS3 compilation. An excellent deadline and opportunity for broad distribution of CAPS3 is the large IPY closing conference in Oslo, Norway in June 2010. Table 1 summarizes some of the potential content.

As the SCDIC develops CAPS3, it must consider how CAPS can evolve as a preservation medium, as well as what data and information it will contain. Is it still appropriate to create physical media for public distribution (e.g., DVDs), or are other strategies such as the peer-to-peer based LOCKSS (Lots of Copies Keeps Stuff Safe) Program more appropriate? Documentation on CAPS3 should evolve to comply with the ISO standard Open Archival Information System Reference Model (CCSDS 2002, cf. Duerr et al. 2006). Finally, quality control procedures for the data compiled need to be determined. Historically, quality control was the responsibility of individual investigators and national programs, but CAPS3 compilers will want to ensure data are in suitably preserveable formats with adequate description of data uncertainties. CAPS3 can serve as benchmark in the development of a lasting polar data system.

Table 1. Initial CAPS3 data sources.

Source	Description or Activity
GTN-P TSP	Temperature data from 300 designated boreholes
GTN-P CALM	Active layer data from 150 sites
ACD	1331 coastal segments described in a geodatabase.
ANTPAS and TSP	Maps, thousands of soil profiles, and periglacial process data
NCSCD	Database of thousands of polygons with soil properties and carbon stocks
CAPS1 and CAPS2	Updates to key products Rescue of lost products
National programs	Identification, description, and acquisition of important products
Remote sensing & model output	Identification, description, and acquisition of important products
Other projects and investigators	Historical data and value added products such as maps, graphical presentations, analyses, etc.
Bibliographies	Monthly updates to the Cold Regions Bibliography

Acknowledgments

Work discussed in this paper is supported by the U.S. National Science Foundation Office of Polar Programs, the Canadian IPY programme, and the Norwegian Research Council's IPY programme.

Regional Geocryological Dangers Associated with Contemporary Climate Change

Abstract

Contemporary climate plays an important role both in the evolution of frozen strata and in genesis of the cryogenic processes. The activation of seasonal thawing, thermokarst, and solifluction is specified by the perennial changeability of the climate characteristics during the warm period of the year. The activation of seasonal freezing, cryogenic cracking, frost heave, and partly of icing formation is specified by the winter ensemble of the climate factors. The small-scale map of the geocryological hazards in the north of Russia has been fulfilled. Western Siberia, the Taimyr Peninsula, southern Yakutia and the Trans-Amur territories are among the unstable regions. The most stable conditions have been registered in the European part of the Russian cryolithozone, in northeastern Siberia and on the Chukot. The climate warming has brought about the increase of the mean annual ground temperature, some displacement (towards north) of the boundary of the types of permafrost, and the 15% reduction of the area of the continuous permafrost.

Keywords: climate warming; cryogenic processes; geocryological hazards; permafrost temperature.

Introduction

During the last hundred years, the climate warming has become distinctly apparent and has been widely discussed in scientific literature and in press (Anisimov et al. 1999, Douchkov & Balobaev 2001, Izrael et al. 1999, 2002, Klimenko et al. 2001, Malevsky-Malevich et al. 2001, Obzor 2003, Pavlov & Ananieva 2005, Pavlov et al. 2002, Pavlov 2001, Fotiev 2000, Gavrilova 2005, Nelson et al. 1993, Osterkamp 2003, Zhang & Osterkamp, 1993).

The meteorological data revealed that the global climate warming which had begun in the 1960–1970s was most distinctly registered in subarctic and middle latitudes. For the end of the 20th Century, the rise in air temperature in the north of Russia made up on average 1.1–1.2°C whereas the rise in global temperature was about two times less (0.6°C). The greatest rate of global warming fell in the 1980s. The centers of contemporary warming in Russia were central Yakutia and Transbaikalia, where the air temperature increase amounted to 2–4°C during 1965–2000. In the arctic regions the increase made up not more than 0.5–0.7°C during the same period. Since the second half of the 1990s, the tendency towards the delay in climate warming has exhibited in some northern Russian regions (towns: Turukhansk, Olerkminsk, Aldan, and Yakutsk).

In 2001–2005 the air temperature rise all over the north of Russia has been estimated as very weak (about +0.1°C) (Pavlov et al. 2007). In northwestern Siberia the mean annual air temperature rise of 1/3 part has occurred due to the warm period, whereas in central Yakutia it has been less than of 1/3 part. Only since the middle of the 1990s the contribution of the warm period to the formation of the total climate warming has had a 15–16% increase in central Yakutia.

Methods

The researches are based on the accumulation, classification and analysis of data on the air temperature for more than 80 weather stations with the observation time up to 150–165 years. The data on each weather station have been presented in Excel format in order to make the carrying out of the computerized mode of the statistical assessment of the observation results easy to use. The data smoothing with 3, 5 and 10–year periods has been executed.

The correlation and regression analysis of the observational series have been used (Pavlov et al. 2007). The deviations of the moving mean 10–year air temperature values from climatic norm have been estimated as very weak, weak, moderate and strong. The spatial regularities of the contemporary changes in climate have been revealed by means of the small-scale electronic mapping (Pavlov & Malkova 2005).

The investigations have demonstrated the high performance of the electronic maps' application for regional assessments of the climate changes and for identification of the geocryological dangers under these changes. The electronic version of these maps allows the on-the-fly registration of the necessary refinements when new data are obtained.

Contemporary Increase in the Mean Annual Air Temperature during Warm and Cold Periods

In 2005–2007 the authors of this paper have worked out the maps of the contemporary increase in air temperature during the warm and the cold periods. In order to make the comparative assessment of the air temperature rise in the summer period, the coefficient n_s (relative thawing index) has been inserted. This coefficient is equal to the ratio of the summer air temperature sum in 1991–2000 to the climatic norm.

The regularities of this coefficient's change in the north of Russia are represented as isolines (Pavlov & Malkova 2005). For the most part in northern regions the rise in n_s makes up 1.05÷1.1 (Fig. 1). The north of central and eastern Siberia is remarkable for stable (in the perennial cycle) summer air temperatures (n_s is approximately 1.0). The air temperature rises in summer period are greater only for the Gydansky and Taimyr Peninsulas (1.1÷1.25). On the whole, the map characterizes the potential of seasonal thawing depth increase under the contemporary climate warming. The perennial decrease of n_s has been registered nowhere, and that's why the contemporary climate changes do not promote the thawing depth decrease in the north of Russia.

For the most part of the Russian cryolithozone we predict the weak increase of the ground seasonal thawing depth (up to 5%). The increases of seasonal thawing depth for 5–10% are to be expected only in western Siberia and in the Far East, and the greatest ones (10–20%) on the north of the Gydansky and Taimyr Peninsulas. In these regions, the massive and wedge ground ice beds are widely spread, and therefore the increase of seasonal thawing depth can contribute to activation of the thermokarst, thermodenudation and thermo-abrasion.

Our colleagues (Gravis & Konchenko 2007) also have executed in the short term a forecast of activization of cryogenic processes the nearest years, using other methods. By their estimations, significant activization of cryogenic processes of the Russian cryolithozone is expected on the arctic islands of the Kara Sea and on Taimyr. These researches have confirmed authentically our forecast estimations.

In order to make the comparative assessment of the air temperature change in the winter period, the coefficient n_w (relative freezing index) has been inserted. This coefficient is equal to the ratio of the winter air temperature sum in 1991–2000 to the climatic norm (Pavlov et al. 2007). The regularities of this coefficient's change in the north of Russia are represented as isolines. For the various regions of Russian cryolithozone the change of n_w makes up 0.85÷1.0 (Fig. 2). This fact testifies to the warming in the cold period of the year. According to the meteorological observation data all over the territory, the fall of temperature in the winter period has not been registered during the last decades. Thus, the existing climatic situation does not promote the increase of seasonal freezing and the activation of cryogenic cracking but contributes to the intensification of the cryogenic heave and of the icing formation, and sometimes to the kurum activation. The greatest dynamics of these processes is to be expected in Transbaikalia and in southern Siberia, where recently the East Siberia–Pacific Ocean trunk pipelining has been started.

Elaboration of the Small-Scale Map of the Geocryological Hazards under Contemporary Climate Warming

The elaboration of the map of geocryological hazards under contemporary climate warming is based on the maps of the contemporary air temperature increase during warm and cold periods. For that, the territories with the relative

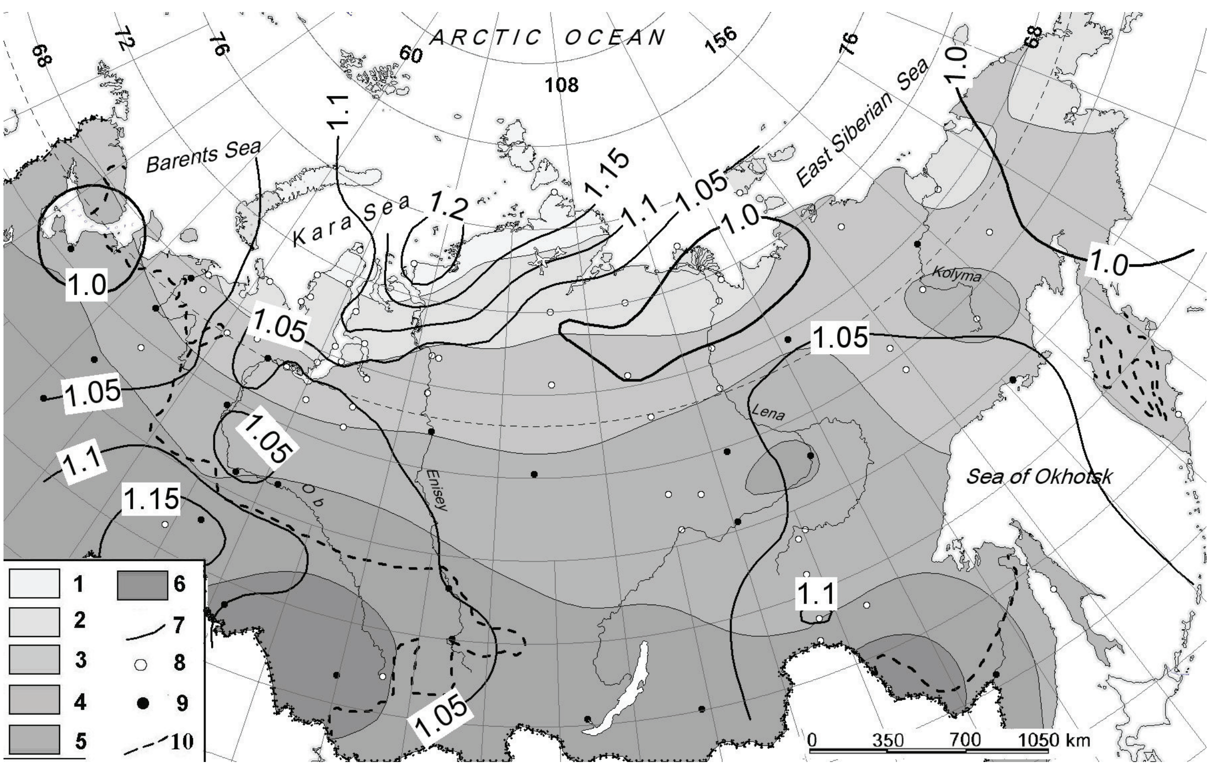

Figure 1. A map of the contemporary increase in air temperature during the warm period. The norm of sums of air temperature in warm season, °C•month: (1) less than 15, (2) 15 to 30, (3) 30 to 45, (4) 45 to 60, (5) 60 to 75, (6) >75, (7) isolines of the relative thawing index, (8) weather stations with observations made for <100 years, (9) weather stations with observations made for >100 years, and (10) the southern limit of permafrost.

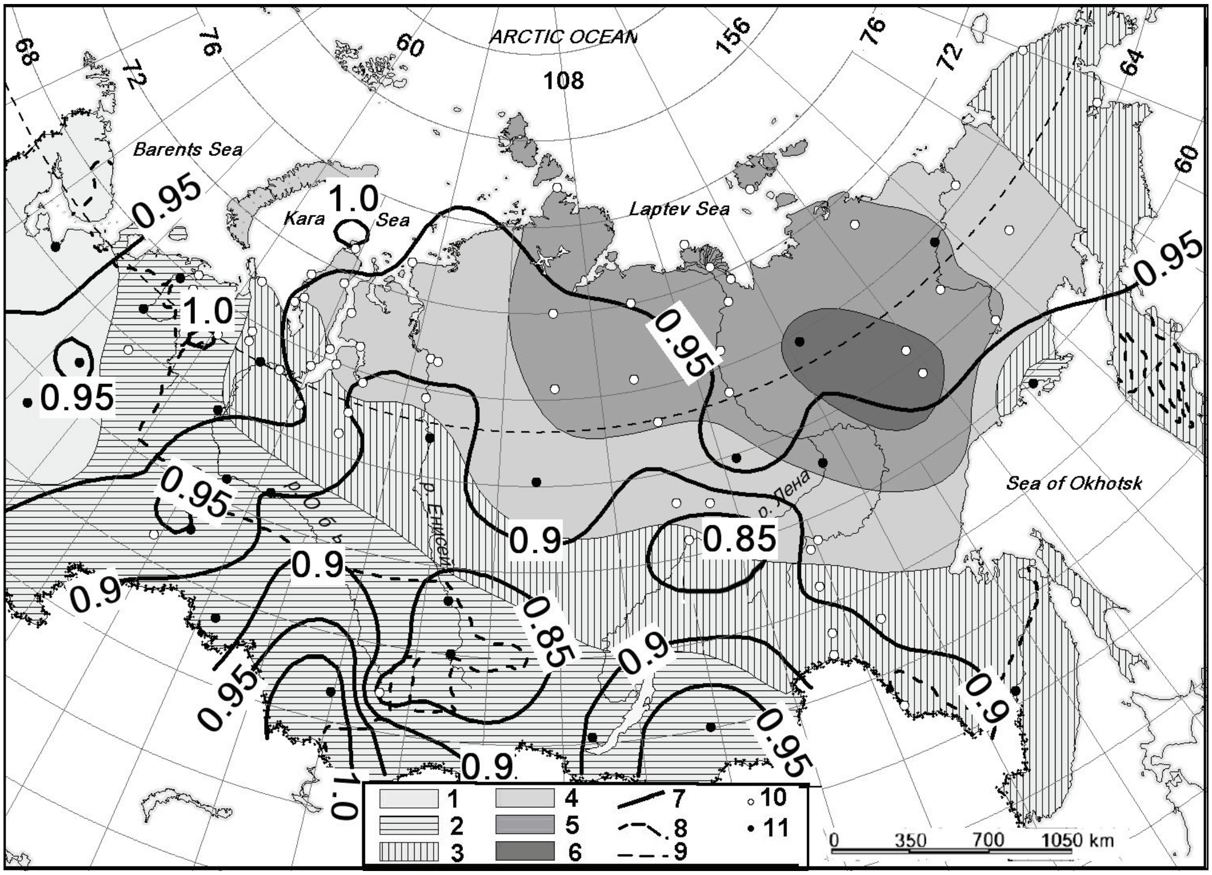

Figure 2. A map of the contemporary increase in air temperature during the cold period. The norm of sums of air temperature in cold season, °C•month: (1) > -60, (2) -60 to -100, (3) -100 to -140, (4) -140 to -180, (5) -180 to -220, (6) < -220, (7) isolines of the relative freezing index, (8) the southern limit of permafrost, (9) Arctic Circle, (10) weather stations with observations made for <100 years, and (11) weather stations with observations made for >100 years.

index n_s more than 1.1, within 1.1 and 1.05, and less 1.05 have been marked out on the map of the relative warming of summer period. The data of the territory are characteristic for strong, moderate and weak degree of the activation of cryogenic processes during summer period, respectively. The territories with the relative index n_w less than 0.9, from 0.9 to 0.95, and more than 1.05 have been marked out on the map of the relative warming of winter period. The singled-out territories characterize the degree of the potential activation of the cryogenic processes (strong, moderate and weak) during the summer period.

The superposition of the two transformed maps makes it possible to make up the map of the geocryological hazards under the climate warming (Fig. 3), depicting on the whole the extreme warming of the summer and winter periods.

The superposition of maps doesn't result in the coincidence of territories with strong activation of the cryogenic processes both in warm and in cold periods simultaneously. But there occurs the combination of strong activation of the processes in the warm period and the moderate one in the winter period (Taimyr Peninsula), as well as the strong activation in the winter period and the moderate one in the warm period (southern Siberia and the Trans-Amur territories). Besides, the intersection of the territories with moderate activation of the cryogenic processes both in warm and in cold periods has been noted (western Siberia, eastern Russia and Transbaikalia). During the perennial cycle the stable geocryological conditions have been registered on the most part of northern Europe, on northeastern Siberia and on the Chukot.

Within the ranges of the Russian cryolithozone, the stable climate conditions and hence the weak manifestation of the geocryological hazards are maintained for 1/4 of the area. The most unfavorable combination of the climate factors, and hence the greatest manifestation of the geocryological hazards, are characteristic for 10% of the territory. The moderate degree of the geocryological hazards is typical for the rest of the area.

Forecast of the Ground Temperature Change and Permafrost Extent

The predictive estimations of the increase of the temperature of the upper horizons of the permafrost on the territory of the Russian cryolithozone have been carried out taking into account the contemporary warming and change of air temperature during summer and winter periods (Malkova 2006). The approximate solutions of the Stephen's problem

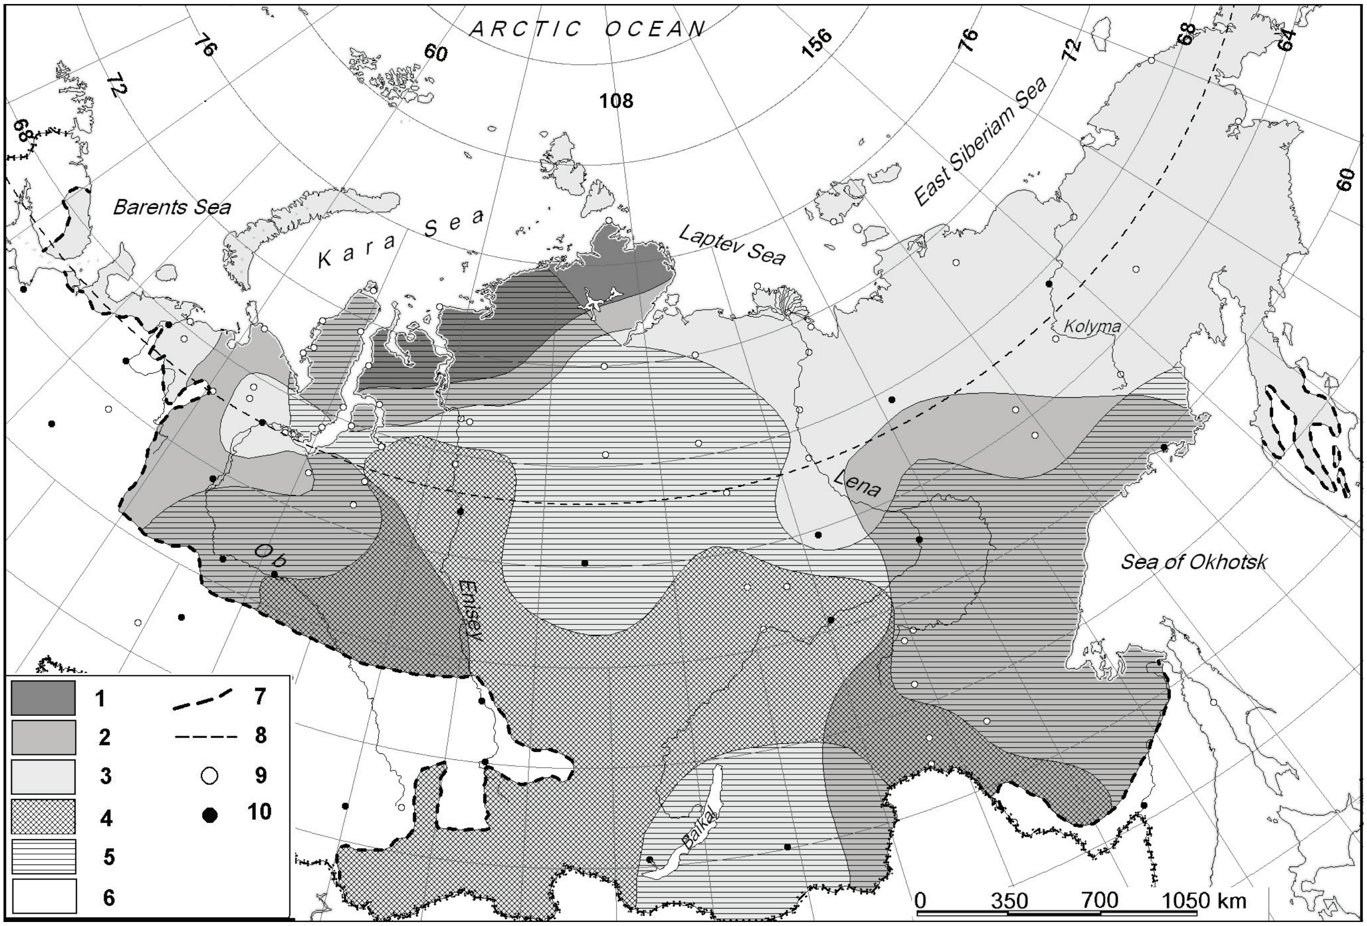

Figure 3. A map of geocryological hazards under the contemporary climate warming in the Russian cryolithozone. Potential activation of the cryogenic processes during the summer period: (1) strong, (2) moderate, (3) weak potential activation of the cryogenic processes during the cold period, (4) strong, (5) moderate, (6) weak, (7) the southern limit of permafrost, (8) Arctic Circle, (9) weather stations with observations made for <100 years, and (10) weather stations with observations made for >100 years.

and the on-line technique of calculation of the mean annual ground temperature have been used for the predictive estimates of the cryolithozone's evolution (*Recommendations*... 1989, *Geocryological forecast*... 1983).

According to the predictive estimates (during the last 30 years) the zone with the transient type of ground temperature (-1 to +1) under the influence of contemporary warming has moved towards north for 100–120 km in western Siberia, for 20–50 km in the European part, for 50–80 km in central Siberia and in eastern Russia. The adduced estimates of the changes of the mean annual temperature of the active layer are well agreed with the field data of the geocryological steady-state stations in the plains of western Siberia and northern Europe but are to be verified in the eastern regions of the country.

In the situation of the contemporary warming, the favorable conditions for permafrost thawing from the top and for replacement of seasonal thawing by seasonal freezing have occurred on the south of the Russian cryolithozone. The data of the recently drilled holes witness that the total thawing of the whole permafrost strata (both contemporary and relict) has not yet taken place. On the whole the area of the island permafrost has been reduced by a factor of 2 (for 1.3 million km^2) throughout Russia. As a result, the continuous and discontinuous permafrost limits have moved towards the north, and the area of the discontinuous permafrost extent has changed insignificantly whereas the area of the continuous permafrost diminished by 15% (for 1 million km^2).

Conclusions

During the last 30–40 years climate warming has been registered all over the territory of north of Russia due to the air temperature rise in summer and winter periods. The greatest increase of the mean annual air temperature is typical for subarctic and adjacent regions. The carried out researches demonstrate the possibility of using meteorological data for the assessment of the development of the dangerous cryogenic processes and the manifestation of the regional geocryological hazards. The conditions for some moving of the permafrost extent limits towards the north have been created due to the peculiarities of the contemporary warming. The tendency toward reduction of the island and continuous permafrost areas has been marked. The researches are proposed to be continued involving the fulfillment of verification of the results on data of the immediate observations on the development of the cryogenic geological processes and ground temperature.

Abstract

Wedge-like structures occur in raised beach gravels near Rio Grande, eastern Tierra Del Fuego (latitude 53°50′S; longitude 67°5′W). They vary in dimension, being approximately 1.0–1.5 m deep and 0.3–0.8 m in apparent width. Some are closely spaced, while others are as much as 5.0–8.0 m apart. The infill is predominantly fine and coarse sand, together with silt, all of local provenance. There is little evidence of secondary infill. It is unclear whether these structures are soil wedges, sand wedges, or composite wedges. Their significance as regards the possible previous occurrence of perennially-frozen ground in the lowlands of Tierra del Fuego has yet to be determined.

Keywords: frozen ground; periglacial; soil wedges; Tierra de Fuego, Argentina.

Introduction

This paper documents the occurrence of wedge-like sedimentary structures in the lowlands of eastern Tierra del Fuego. The morphology of the wedges and the nature of the wedge infill are described.

The critical question is whether these structures are relict permafrost phenomena (i.e., ice wedge casts, sand wedges, or composite wedges), or whether they are simply soil (i.e., "ground") wedges and, as such, merely reflect deeper seasonal frost conditions than today. The recent literature that discusses the significance of these various phenomena includes Ghysels and Heyse (2006), Murton and Bateman (2007), and French (2007, 117–118, 127, 327).

Study Area

Tierra del Fuego is located between 52°40′S and 55°7′S and 65°05′W and 68°40′W. Its Atlantic coastline is about 330 km long and runs from northwest to southeast. The dominant feature is steep cliffs, in part formed on sediments, fronted by wide sedimentary intertidal surfaces developed under paraglacial conditions.

The study area near Cape Peñas (Fig. 1) is located at 53°50′S and 67°35′W. The present climatic conditions are temperate-cold, semi-arid, with a mean annual temperature of 5°C. The mean temperature during the coldest month, June, is 0°C while that of the warmest month, January, is 9°C. Rainfall is distributed throughout the year, diminishing between August and October. Total annual rainfall is 380 mm, and snow is generally scarce. The prevailing winds are westerly and to a lesser extent northwesterly and southwesterly. They reach their maximum intensity during the spring and summer months. The wedge-like sedimentary structures are developed on raised beach deposits and were first described by Coronato et al. (2004).

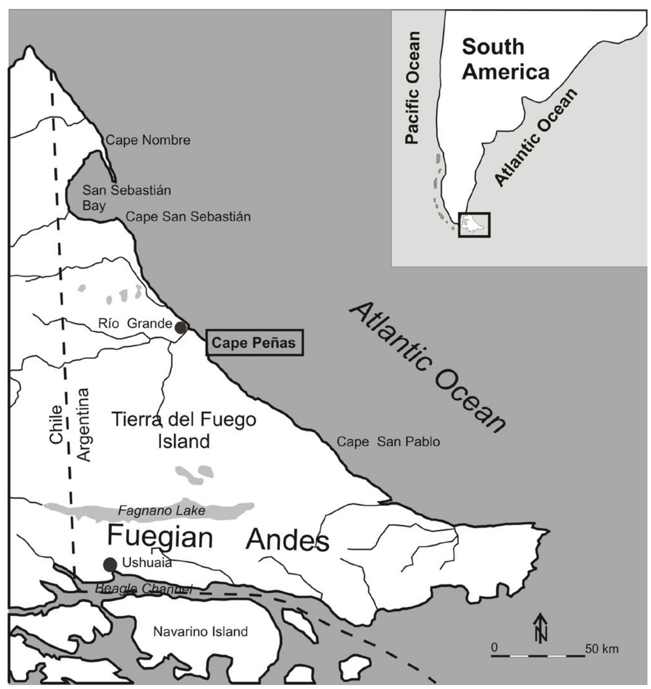

Figure 1. Location of Cape Peñas.

Codignoto (1983, 1984) obtained a radiocarbon age for the beach deposit that was older than 43 ky B.P., and amino-acid racemization on shells of *Pilar rostrata* gave a DL-aspartic acid ration of 0.36 (Rutter et al. 1989). The beach deposits

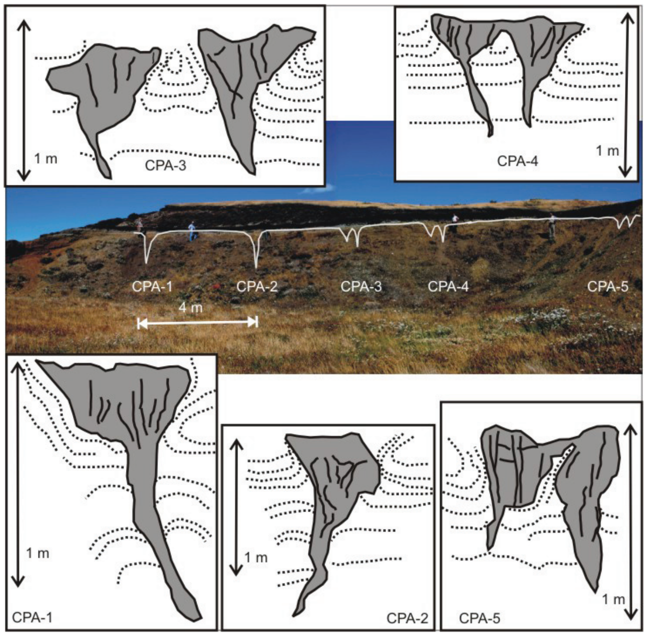

Figure 2. Morphological characterization of sector CPA.

were assigned therefore, to marine oxygen-isotope stage 5e (Meglioli 1992).

The depositional sequence consists from bottom to top of alternating layers about 12 cm in thickness, composed of gravel, pebbles, and sand. The pebbles are rarely more than 8 cm long. Near the coastline there are thick layers of gravels, while further inland there are alternating layers of gravel and sand. The gravel is covered by organic deposits rich in aeolian sand.

Wedge structures attributed to cold-climate conditions have been described previously from southern Argentina (Corte 1968, Auer 1970, Abrahan de Vazquez & Garleff 1984, Grosso & Corte 1989, Vogt & del Valle 1994).

The Permafrost Context

Several authors (e.g., Burn 1990, Murton & Kolstrup 2003, Lemcke & Nelson 2004) refer to the difficulty of determining the type of climatic environment that causes the formation of wedges. Polygonal networks may occur in temperate as well as cold (i.e., periglacial or permafrost) environments. Wedges that occur in non-periglacial environments rarely exceed a few meters in depth. In contrast, those formed in periglacial and permafrost environments are larger and may form polygons 10+ m in diameter. As a rule the polygons that develop in the absence of permafrost are smaller and usually measure between 0.5–2 m in diameter.

There appears to be little difference in the spacing of ice wedge and sand wedge networks. For example, in Siberia and Arctic North America ice and sand wedges are typically separated by distances of between 10–30 m. However, Gozdzik (1986) indicates that in Poland the distance between Pleistocene-age sand-wedge casts is usually much smaller, and the modal size of the dimensions of sand-wedge polygons is about 3.3 m.

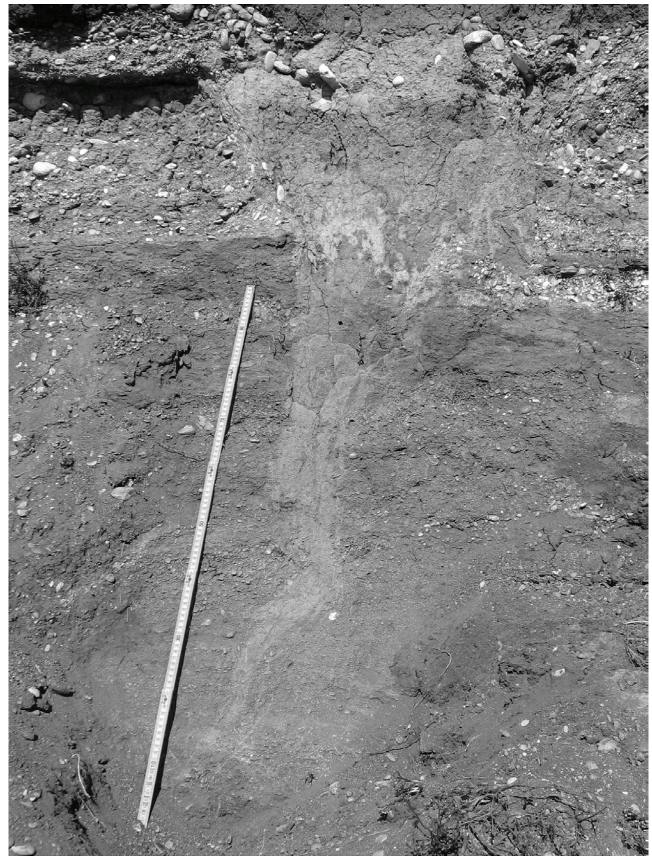

Figure 3. Wedge structure CPA-2.

It is increasingly understood that the mechanism underlying the formation of polygonal structures is related to fast and marked drops of temperature to below -15°C to -20°C. Also, the geometry and size of fissures is related to the type of material affected.

Another consideration is the material infill of the cracks and the thaw-modification that results as the permafrost degrades. Usually there is a slumping of the enclosing sediments and formation of sets of miniature faults. The fissure infill is regarded as secondary. In contrast sand wedges, even when thawed, constitute wedges of primary infill. Thus the resulting sedimentary structures are quite different between the two types of wedges.

The occurrence of cold-climate wedge structures always gives rise to the question of the climatic conditions under which they were formed.

Both sand and ice wedges form under conditions of continuous permafrost. Péwé (1966) indicated that ice wedges only exist where mean annual air temperature (MAAT) is in the -6°C to -8°C range, while Romanovskii (1985) pointed out that, on a substrate of sand or gravel, cracking commonly occurs at MAAT of around -7°C, but in silt the MAAT is slightly higher, -2.5°C.

Wedge Structures

At Cape Penas, a number of wedge structures are exposed in a gravel quarry. The wedges are elongate in shape, reaching up to 1.50 meters in depth and 85cm in width, separated by distances ranging from 1.5 to 9m. One exposure (CPA) is parallel to the coast and nine well-defined forms were identified (Fig. 2).

Wedge structure CPA-1 is slightly inclined seawards and measures 120 cm in depth. The upper section is concave, funnel-shaped, and 85 cm deep and 40 cm wide. The wedge gradually narrows downwards. In the lower section of the wedge layers of sand and gravel dip toward the bottom. In the upper section rounded clasts are turned upwards. The wedge is covered by a level of pebbles and peaty-sandy materials.

CPA-2 (Fig. 3) is located 4m west of CPA-1 and is 140 cm deep. The upper section increases its width from 40 cm to 50 cm. The lower section narrows from 20 cm to 5 cm in width. Upturning of enclosing sediment is evident. CPA-3, located at a distance of 4 m from CPA-2, is smaller and more diffuse in shape. It has an open V-structure for a depth of 92 cm. It has a width of 32 cm in the upper section and 10 cm in the lower part. As in the previous wedge structures, pebbles in adjacent sediments are imbricated or tilted upwards.

CPA-4, located 4 m from CPA-3, shows a double wedge structure with a width of 58 cm and 73 cm. The smaller of the two structures is 47 cm wide at its head, while the bigger one (CPA-4a) is between 46 cm and 73 cm. The first narrows in depth whilst the second shows well differentiated segments: an upper one 25 cm deep and 13 cm wide, and a lower one of scarcely 5 cm.

Wedge structure CPA-4b shows the best example of adjacent pebbly strata being deformed upwards. The pebble layers trace perfect arches with clasts oriented in an upwards direction. Another double structure is found in CPA-5, about 9 m away from CPA-4. It is composed of two fissures measuring 80 cm and 68 cm in depth and 42 cm and 34 cm across their upper sections respectively. They also show evidence of upward deformation of enclosing beds.

CPA-6 is located about 3 m from CPA-5. It measures 70 cm in depth. Its width is 30 cm in the upper section and 19 cm in the middle. CPA-7 is 2.20 m away from CPA-6, and is 130 cm deep, with the top section being 80 cm wide. It also shows signs of upward thrusting of adjacent clasts. CPA-8 is at distance of 2.4 m from CPA-7. It is 140 cm deep and its upper section is 78 cm wide, decreasing to 18 cm in the middle part. The upper section shows some clast upturnings. CPA-9 is about 3.40 m from CPA-8. It is 90 cm long, 46 cm wide at the top, and 24 cm in the middle section. As in the previous cases, the infill is well defined with regard to the surrounding deposit.

Granulometry of Wedge Infill

In an attempt to understand the genesis of the wedge infill, samples of wedge infill material were taken from three wedges: CPA-2, CPA-4, and CPA-5. Samples were extracted from soil horizons that were common to each wedge: A, E, Bg_1, Bg_2, and BCg. Grain-size analysis was applied to the fine fraction (<2 mm) using the pipette method following

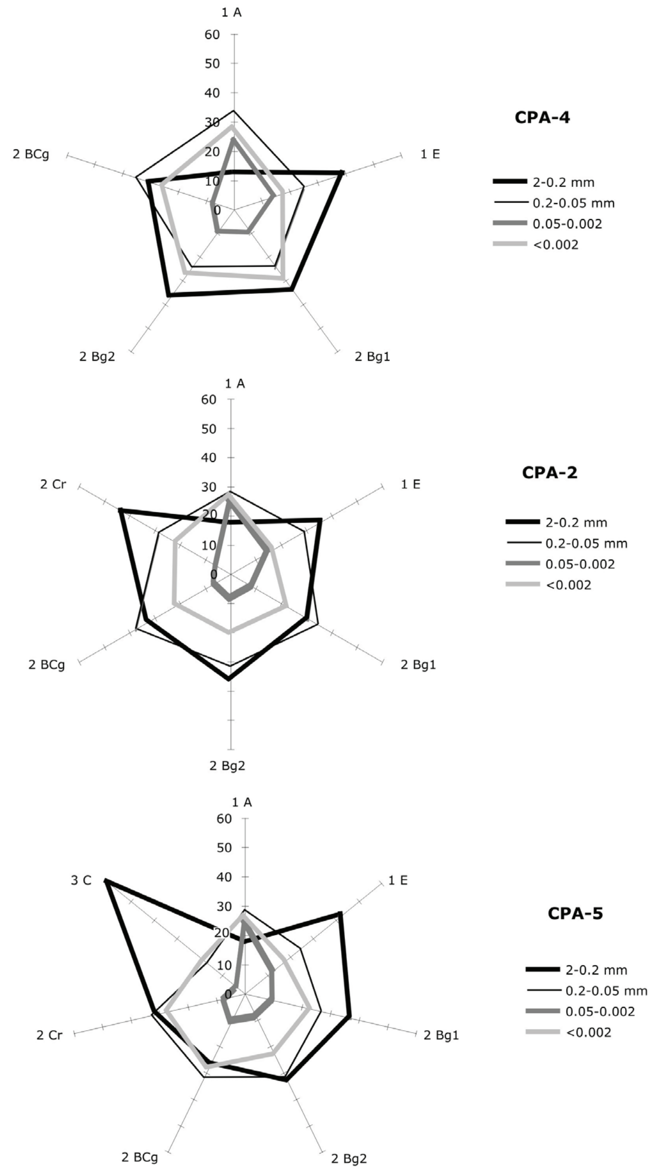

Figure 4. Granulometry of wedge infill.

dispersion with sodium hexametasulphate. The granulometric descriptions of the samples from each horizon are illustrated in Figure 4. The results for all wedges are similar except for the presence or absence of horizons Cr and C, the former being present in wedge CPA-2 and both in CPA-5.

Sand prevails in the three profiles analyzed, with mean values ranging from 46% to 77%. The lowest percentages of sand occur in horizons 1A (46%), while the highest values (between 64% and 77%) appear in 2Cr and 3C. These are in contact with the beach sediments. In horizon 2B, mean percentages ranges from 59% to 70%, increasing towards the lower subhorizon BCg with the exception of wedge CPA-5, which shows a tendency to decrease in this subhorizon.

In the three wedges analyzed there is a size-sorting reflected in the horizons. For example, in the 1A horizons the proportion of fine sands is greater (34% fine sands and 12% coarse in CPA-4), as it is in subhorizon BCg, although the difference is not so marked (37% fine sands, 33% coarse sands in CPA-2). In the remaining 2B subhorizons the values of the fine and coarse fractions are very similar. This tendency changes towards the bottom of the wedges in horizons 2Cr and 3C. For example, the percentage of coarse sands tends to increase (with minimum values of 64% and maximum values of 77% in horizon 3C of CPA-5).

Clay is the second most important fraction. Maximum values occur in horizons A (28% in CPA-4), BCg (29% in CPA-5), and Cr (28% in CPA-5). This fraction decreases in horizons E (17% in CPA-2) and C, the latter at the base of the wedge (18%). The decrease is irregular.

The percentage of silt is never greater than 30%. The highest values are reached in horizon 1A (26%), diminishing progressively until horizon 3C (4%). Fractional analysis reveals a higher content in coarse silt than in fine sediment (9% fine silts as opposed to 17% coarse silts in horizon A of CPA-2).

Mineralogical Analyses

Study of the coarse and fine sand fraction was undertaken for the infill of wedge CPA-2 with the aim of describing the degree of weathering and roundness.

It was found that the mineral fragments are dominated by quartz and by rock fragments in which metamorphic rocks predominate. In general it is possible to classify the mineral fragments into three groups. The first group includes horizons 1A, 1E, and $2Bg_1$; the second group, the horizons $2Bg_2$ and 2BCg; and the third group includes the 2Cr and 3C horizons.

In the first group, rock fragments are predominant in the larger fraction, while monomineral particles prevail in the smaller one. There are rounded rock fragments, some of them spherical, with unpolished surfaces showing impact marks indicative of wind-dominated transportation. The quartz particles on the other hand generally show polished surfaces, with V-shaped impact pits that reveal that they were worked in a marine environment. The clearest marine features appear in the coarse sand, while the fine sand shows aeolian features.

The second group (from horizons $2Bg_2$, 2BCg) shows a smaller number of fragments of both rock and spherical minerals and a progressive increase in the number of sub-rounded and non-spherical fragments. The latter are highly polished and bear impact pits. There are some signs of contact with the upper horizon, evident in the existence of some unpolished, spherical, and rounded fragments in the fine fraction of subhorizon $2Bg_2$. The third group, composed of horizons 2Cr and 3C, reveals a more heterogeneous character. Rock fragments predominate in the coarse sand, and monomineral particles in the fine sand. The quartz particles are polished, ranging from rounded to subrounded, and show impact pits on their surface. There are traces of oxidization on the external faces of all grains, producing a highly characteristic shiny dark-brown patina.

X-ray diffraction analysis of the clay present in the wedge infill revealed the presence of illite and smectite, and the total absence of kaolinite.

Discussion and Conclusions

The origin of these wedge-like structures is not clear. They may or may not reflect cryogenic processes. If they are cold-climate phenomena, it is uncertain whether they formed in seasonally or perennially frozen ground.

Several generalizations can be made. First, it is clear that the wedge structures are not isolated phenomena but occur at regular intervals throughout the section studied. Second, the adjacent enclosing sediments frequently show upward deformation adjacent to the wedge. Third, fine or very fine sand is the predominant infill material, although other size fractions are also present. Fourth, the reworking of the sand-size material suggests an autochthonous contribution. Fifth, the surface characteristics shown by the majority of the sand particles indicate that they were modeled in a marine environment. However, some sand in horizons A, E, Bg_1 possess aeolian features that suggest transport into the wedge by wind.

If the wedges are cryogenic in origin, they appear to have been generated in two phases. In the first phase, thermal-contraction cracking would have occurred in a cold and arid environment marked by an intense temperature drop during the winter months. Such climatic conditions do not exist today on the coast of Tierra del Fuego. In the second phase, more humid conditions would have seen the incorporation of coarse sand and fine gravel into the wedge, presumably during episodes of deep seasonal frost.

The heterogeneous nature of the infill suggests the wedges are of a composite origin However, the possibility that they are soil or ground wedges and formed under conditions of deep seasonal frost rather than permafrost cannot be eliminated. Their age has yet to be determined.

Modeling Interaction Between Filterable Solutions and Frozen Ground

G.Z. Perlshtein

Institute of Environmental Geoscience, Russian Academy of Sciences, Moscow, Russia

Abstract

Research of interactions between filterable solutions and frozen ground are very important for many problems of contemporary basic and applied geocryology. In thaw zones, heat and salt transport by groundwater often proves to be more significant than transport by means of a molecular-diffusion mechanism. For the case of water movement in permeable frozen ground, quantitative description of convective heat and mass transfer is insufficiently devised. The presented model consists of the conventional equations set for convective heat and salt transfer. It is supplemented by an ice melting equation. Phase equilibrium ice-solution is expressed by dependency of the crystallization temperature upon concentration. The heat sink is prescribed in direct proportion to the difference between solution temperature and the eutectic point. Modeling results accord entirely to the modern view on the physical essence of the processes under consideration. The obtained method is planned for practical use, in particular, diamond mining in Yakutia.

Keywords: eutectic point; groundwater flow; ice melting; mathematical modeling; permeable frozen ground.

Introduction

The interaction between salts and frozen ground has increasingly drawn the attention of permafrost scientists and engineers. Salt and heat transfer with groundwater flow plays a significant role in forming the frozen massif structure, thermal regime, and ground characteristics in the cryolithozone. Solution appearance in ice-containing ground changes the phase equilibrium conditions: the temperature derived at the point of contact with the frozen zone corresponds to the eutectic point at a given concentration. For that reason, the temperature field dynamics of saline ground is highly dependent on the solute diffusion.

Understanding the essence and quantitative regularities of the process is very important for solving such problems as contemporary basic and applied geocryology : as an evaluation of salted ground state,; palaeoreconstructions and prediction of coastal and offshore permafrost behavior,; cryopeg dynamics,; thawing frozen ground by the use of salts, etc. A number of works (Ershov 1990, Komarov 2003, Permyakov & Romanov 2000, and others) are devoted to theseis problems. These works consider heat and salt transport only by means of a molecular-diffusive mechanism.

Quantitative research of heat and mass transfer induced by groundwater movement is of great interest. In the case of forced convection, energy and substance fluxes often prove to be much more intensive than those conditioned by molecular-diffusive forces.

It should be noted that the theory of convective diffusion started to develop rapidly about the middle of the last century (Bear 1961, Veriguin 1962, and others). In many respects, it was associated with leaching and other geotechnological method problems. (Kalabin 1981).

Existing quantitative theories of the interaction between groundwater flow and frozen ground have been developed in connection with solving practical problems such as hydraulic thawing of frozen ground and hydraulic engineering in permafrost regions (Bogoslovsky 1959, Goldtman et al. 1970, and others). These works consider movement of fresh water only, in the thaw zone.

However, it is not uncommon in nature that, when pores and fissures of frozen soils and rocks are only partially filled with ice, they keep an essential permeability and can not be considered as aquifuges. The movement of saliferous water in such a medium has some important features. Knowledge of them is important for general theory as well as for solving practical problems of drainage waters burial (in particular, at diamond mining in Yakutiya) and other technological challenges.

Short Review of Existing Models

There are two approaches to quantitative description of interrelated processes of heat and salt transfer: (1) the model of phase change on the mobile interphase surface that is well known as Stefan's problem, and (2) models of phase change in some temperature range. In the case of a classical (front) approach to the problem, diffusion occurs only in a thawed zone. The models with unfrozen water also take into account the salt transport in the frozen zone through the films of unfrozen water. In either case, the equations of heat transfer and diffusion use the dependency of the solution thermodynamic potential from its solute concentration (for instance, functional dependency of solution concentration on eutectic point).

As a rule, both approaches are realized in the frames of one-dimensional calculating schemes.

In equations, a heat-mass transfer with moving water is factored in through an additional item summand that is proportionate to the water flow velocity. The latter is found through solving groundwater dynamics equations.

Methods for calculating thaw rate are well-developed for the cases of water moving in thawed zones along an impermeable boundary with frozen ground. They were used widely, for example, for designing mining works at the permafrost placers of northeastern Russia.

When deriving an equation, the assumption is used that the temperatures of matrix solid material and moving water are equal. Owing to that, the temperature fields of the ground components are described by one common equation.

It should be noted that coarse-grained ground and fissured rocks could have a significant permeability in the frozen state. It is obvious that this assumption noticeably conflicts with studied processes when water moves in permeable frozen ground that has some amount of ice in it. The simplest case of heat transfer during fresh water movement through permeable frozen zone has been analyzed by one of the authors (Perlshtein & Jiltsov 1984) and was distinguished into a special type of convective heat transfer in thawing ground. To date, however, the processes of joint convective transfer of heat and salts in permeable frozen rocks are very poorly explored and studied.

Main Assumptions and Mathematical Statement of the Problem

This paper offers a quantitative description of heat-mass transfer during solution movements, not only in the thaw zone, but also in permeable frozen massif. This model reflects the following features of the process:

1. salt diffusion occurs in the part of a fissured-pored space that is not filled with ice;
2. when solution gets in contact with frozen rocks, the temperature on the contact instantly settles to the crystallization temperature at a given concentration;
3. in every elementary volume of the area of study, moving solution and matrix solid material with ice inclusions can have different temperatures (at least, until the ice completely melts).

The source, brought into equations of convective heat and salt transfer, is defined by heat flux density from solution into solid phase for temperature fields, and by the water influx due to ice melting for concentration fields. The value for this source is included in a boundary condition for ice and matrix solid material temperature fields. In the first approximation, it is assumed that in both solid and liquid phases, the heat fluxes normal to solution flow are negligible in comparison to energy absorption on a melting front, and that right after ice melt-out, temperatures of medium components equalize.

The stated assumptions lead to the following system of heat-mass transfer equations:

$$\rho_w c \frac{\partial T}{\partial t} = \nabla(\lambda \nabla T + c\rho_w T k_f \nabla \varphi) + n\rho_i L \frac{\partial \theta}{\partial t}, \qquad (1)$$

$$\frac{\partial \theta}{\partial t} = W_\theta(T, \theta, M), \qquad (2)$$

$$\frac{\partial M}{\partial t} = \nabla(D\nabla M + Mk_f \nabla \varphi) + W_M(T, \theta, M) \qquad (3)$$

$$\nabla(k_f \nabla \varphi) + nW_\theta = 0 \qquad (4)$$

where $W_\theta(T, \theta, M)$ – rate of ice saturation changes, units:

$$W_\theta(T, \theta, M) = \frac{\beta(V, \theta)}{n}\left(T^*(M) - T\right) \qquad (5)$$

and $W_M(T, \theta, M)$ –rate of dissolution due to ice melting:

$$W_M(T, \theta, M) = \frac{M}{(1-\theta)} W_\theta(T, \theta, M); \qquad (6)$$

T = temperature, K; M = concentration, kg/kg; t = time, s; ρ_w, ρ_i = water and ice density, kg/m^3; c = specific heat, J/(kg ·K); λ= heat conductivity, W/(m ·K); L = specific latent heat of ice melting, J/kg; k_f = hydraulic conductivity, m/s; V = water flow velocity, m/s; D = diffusion coefficient, m^2/s; φ = hydraulic pressure head, m; β = the volumetric coefficient of convective heat transfer, 1/s ·K; T^* = eutectic point, K; θ = ice saturation in pores, m^3/ m^3; n = porosity.

Modeling Results

A modeling objective was to study ice melt-out processes with $CaCl_2$ solution being injected into the layer of permeable highly fissured frozen rocks. Temperature and concentration fields had an axial symmetry. The characteristics of permeable zone and country rocks are given in Table 1.

Surface rock temperature was equal to -4° with 0.01 K/m gradient. The brine injected in the borehole had constant temperature (7°C) and concentration (6 and 20% in two model runs).

Main calculation results are presented on the graphs. It shows that energy and material flow has a high propagation rate around the borehole. It is explained by the very high permeability of rocks that was specially set in calculations for evaluating an extreme impact of convective heat-mass transfer to frozen rocks.

Just as was expected, in the first model run (M_0 = 6%) salt concentration is monotonously increasing in the whole area studied and quickly approaches the concentration of injected solution. In the distance from the borehole, temperatures and concentrations very quickly equalize with eutectics of injected solution.

The temperature pattern of change is somewhat more complicated (Fig.1).

It is interesting to note that, in the second model run, the temperature is even decreasing in the beginning. The reason for it is the fast brine propagation, when the eutectic

Table 1. Characteristic of massif under consideration.

№ of layer	Depth	n	k_f	θ	λ	c
1	0–250	0	0	0	3.0	836
2	250–300	0.1	$3\cdot10^{-5}$	0.5	3.0	836
3	300–1000	0	0	0	3.0	836

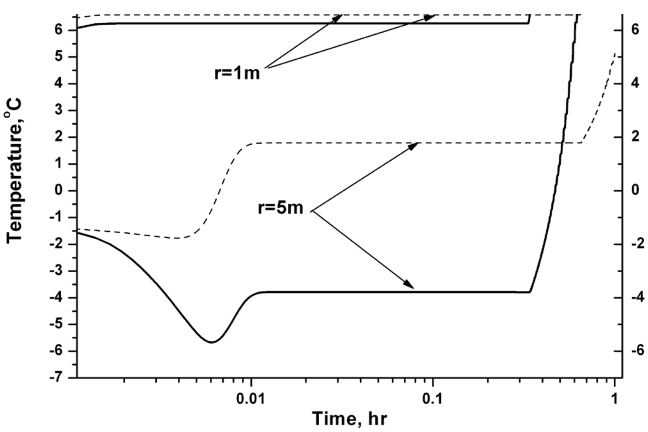

Figure 1. The temperature changes at different distance from borehole with mass transfer (solid line) and with initial concentration (dash line).

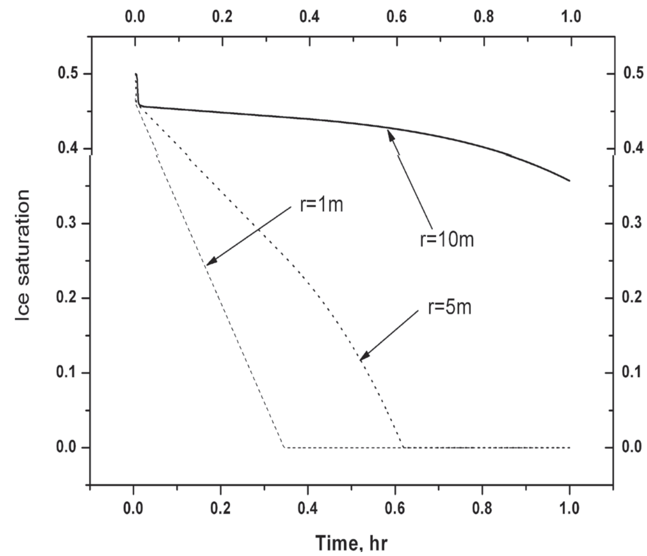

Figure 2. Ice content dynamics at different distances from the borehole.

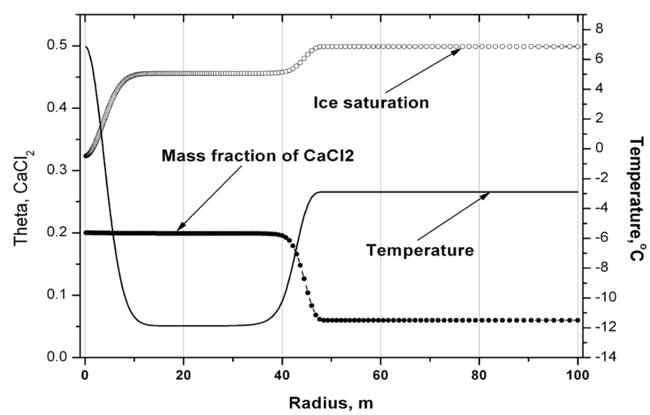

Figure 3. Spatial variation of the ice content, salt mass fraction, and temperature (time: 6 minutes).

point of the brine is lower than the beginning temperature of the area studied. Its growth is obviously suppressed by heat consumption for melting the ice.

Quite interesting are the peculiarities of ice content dynamics in different parts of area studied (Fig.2)

High and constant thawing speed is registered close to the injection well because of a significant solution influx that has practically an initial temperature. A clearly defined jump in an ice-melting rate is traced on some distance from the borehole, and the value of this “step” does not change with the further distance increase. It indicates that thawing at this point happens at the expense of heat released due to rock cooling, provided that the solution temperature does not change much at all. It is to be recalled that the initial temperature in the permeable zone was significantly higher than the eutectic point. After that, the process happens with increasing speed due to the solution temperature that increases in time, arriving at every point.

Spatial variation of studied parameters is presented in Figure 3.

Conclusions

The most interesting of all the obtained results is the pattern of ice content change in space and time. For the first time ever, this paper gives a mathematical statement of a problem for temperature and concentration fields, which is determined by high rates of solution flow in permeable frozen massif. Model calculations are in good agreement with a general concept about the physics of studied processes of convective diffusion and heat transfer. It proves that it is a working model. It seems likely that the described calculation method could be used for solving practical problems associated with burial of drainage brines in permafrost. This is an acute problem for commercial development of diamond mining in Yakutia. The authors see the main object of further research in conducting laboratory and field experiments to verify the model and to develop methodology for experimental determination of volumetric (intra-pore) heat transfer coefficient. This coefficient needs to be determined for rocks of different composition, porosity (fissuring), and level of ice saturation.

Russian Approaches to Permafrost Engineering

Georgy Perlshtein
Institute of Environmental Geoscience, Russian Academy of Sciences, Moscow, Russia

Abstract

The basic goals and problems that permafrost engineers and scientists are facing presently remain almost the same as they were 20 years ago. Nevertheless, the contemporary stage of cold regions development has specific features. One of the most important is permafrost response to global climate changes. In this report, some new technical solutions are described concerning construction, mineral mining, and development of oil and gas fields, environmental protection, surveys, and other related activities. Among them, a foundation on sandy back-filled ground in Yakutsk is exemplified. Most erected buildings here have not undergone any dangerous deformations over a 20-year period of operational experience. The methods of roadbed operation were improved for the railroad lines Obskaya-Bovanenkovo, Chara-Cheena, and others. Some new features of thermokarst, frost heave and other dangerous cryogenic processes have been revealed in connection with pipeline construction. This has induced the development of permafrost monitoring. In any event, the main principle of Russian specialists is to apply such scientific-technical decisions that utilize the site's natural conditions. This helps alleviate the negative influence of permafrost and uses favorable features of the territory

Keywords: discontinuous permafrost; frozen ground; monitoring of cryogenic processes; permafrost engineering; pipeline; oil and gas field development.

Introduction

During long years of exploring and developing the large territories of Siberia, the Far East and the European North, Russians have gained considerable experience on living and working with permafrost conditions. At the end of the last century, the old system of scientific-technical maintenance of the economy proved to be obsolete, and the new one is in the process of being developed. The problems of development within the permafrost regions that engineers and scientists presently face remain the same as they were 20 years ago.

In the last few years, because of some positive shifts in the economic and political atmosphere, the demand for scientific and technical support of human activities in the permafrost zone has increased. New approaches for implementing innovative engineering solutions and improving survey and monitoring systems of permafrost terrains are important in relation to the economy.

Methodological approaches for operating on frozen ground state formed the basis of the natural-technical systems concept (Epishin 1985).

Permafrost response to climate change has received much attention. Research follows such directions as observations at permafrost stations and using specially equipped geothermal wells; improving methods for long-term geocryological forecast and modeling the permafrost thermal regime for different scenarios of climate changes; and comparative analysis of geocryological maps prepared at different times.

In spite of all obvious difficulties in the economic transitional period, the potential of Russian geocryology has remained high. Thus the modern approaches used by Russian specialists for solving permafrost engineering problems are of value.

Construction

Stability of construction in frozen ground is one of the most responsible and important goals in permafrost engineering. Existing federal construction norms and regulations (SNIP 2.02.04-88) specify two construction methods for permafrost territories: 1) preserving the ground in the frozen state, and 2) keeping the ground under foundations in a thawed state. The choice of method and particular technological scheme occurs at the design stage and depends on the engineering-geocryological conditions of a given construction site. However, in the area of continuous permafrost, the first methodology is usually preferred.

For example, in Central Yakutia (Yakutsk, Mirny), pile foundations are used widely, usually with a ventilated crawl space. The preference is for cast-in-place piles. Unfortunately, this method is expensive. Costs related to foundations can amount to 3 to 5 times as much as foundations outside of the permafrost zone and can be 40% of the total cost of building. Such construction does not prevent the subsidence of ground caused by water leakages, departure from recommended maintenance programs, and other factors. In the near future, these problems may increase due to global warming.

In conditions of discontinuous, warm permafrost, construction is usually carried out according to the second method, with the preliminary thawing of frozen ground to a depth no less than the thaw bulb. Most engineering constructions in the Central Transbaikalia, close to the southern limit of the permafrost zone, were built in the 1950s using the first method, and since then have undergone catastrophic deformation. Recommendations for foundation reconstruction have been developed, taking into consideration the fact that the major part of thaw settlement has already occurred. These recommendations suggested

Figure 1. Housing estate erected in Yakutsk on back-filled ground.

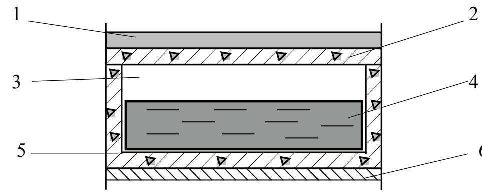

Figure 2. Scheme of foundation equipped with the cold accumulator: 1 – insulation; 2 – ceiling slab; 3 – ventilated channel; 4 – cold accumulator filled with water; 5 – concrete case; 6 – ground surface.

allowing thawing of ground (Recommendations… 1988). The resulting economic impact exceeded 100 million rubles (Institute of Natural Resources, Ecology and Cryology SB RAS).

A particularly interesting form of construction employed in Yakutsk has been to utilize sandy back-filled ground (Fig. 1).

Both permafrost construction methodologies were used in this case. Buildings with pile foundations were erected using the first methodology with ventilated crawl space. Meanwhile, the placement of sandy ground up to the design reference level was carried out after installing bearing posts of 4 m in height. Ground freezing occurred during the preparation of construction, construction itself, and at exploitation stages. The buildings have remained in satisfactory condition except for the kindergarten, which was dangerously deformed because of hot-water leakage under the building. A substantial number of the buildings are constructed on raft foundations without taking any special measures to regulate the foundations' temperature regime. Twenty years of operational experience have shown that none of these buildings has undergone any dangerous deformations, and they have sustained structural stability (Tseeva & Egorov 2005, Polishchuk et al. 2008).

The new method for assessment of foundation reliability is beginning to be applied. It is based upon statistical analysis of meteorological factors that change randomly (Khrustalyov & Pustovoit 1988). A characteristic feature of modern construction on permafrost is increased attention to maintaining a predetermined temperature regime, or ground thermal stabilization. There are active and passive stabilization methods. Active thermal stabilization involves refrigerating ground to a given depth by means of special equipment and technology. The most popular are seasonal refrigerating devices, especially two-phase thermosyphons (Dolgikh et al. 2005). In recent years, devices working year-round have become more and more common. During the summer period, their above-ground condensers are chilled by special devices that work using the Peltier effect (Bayasan et al. 2005).

Building reliability analysis using probabilistic methods brought us to the conclusion that, in many cases, use of thermal stabilizers drastically decreases the influence of chance meteorological factors on ground temperature. This approach gives the opportunity to determine the safety factor correctly, thereby preventing the damages caused by construction breakdown.

The original type of surface foundation on frozen ground deserves attention (Fig. 2). Here, the crawl space is equipped with a special device that acts as zero curtain (Khrustalev 2005).

Heat pump applications in permafrost engineering are important. New research on this subject has been carried out since the late 1980s (Goodrich & Plunkett 1990, Guly & Perlshtein 1998, Instanes 2000). Unfortunately, in Russia, research on the subject did not go beyond purely theoretical studies. Nevertheless techno-economic evaluations were accomplished, assisted by computer modeling for the temperature fields of foundations. They indicate that the cost of installing a heat pump to cool the foundation can be compensated for by using the heat produced by the building itself (Perlshtein et al. 1998). Heat pumps also can be successfully used in other engineering applications in cold regions; for example, in frozen food depots as conceived and constructed by Krylov (1951), which received wide recognition. To increase the storage life of perishables, it is necessary to maintain a low interior storage temperature, which in warm seasons requires artificial cooling. Heat pump cooling may frequently be the most economic way to achieve the necessary thermal regime. The design concept of such refrigerated ice storage, combined with a heated greenhouse, was worked out by the Northeastern Permafrost station for the native company Oyary. The results of this work were reported at the Seventh International Conference on Permafrost (Guly & Perlshtein 1998).

It should be noted that the considered examples do not exhaust all possibilities of heat pump usage in northern engineering. It is of great interest to study combinations such as warm and cold food depots; underground mine and surface domestic complexes; and a tailings impoundment and ore-dressing plant. Heat collection from solar heating in summer is considered to be especially prospective. Heat pump usage combined with the simplest solar collectors (synthetic hose) will allow for the reduction of 90% of hot water cost in the period June through August. Finally, in the global warming context, applying heat pumps is a unique technical solution which may make it possible to prevent catastrophic thawing of ground under foundations, practically without additional expense. Investments are needed to develop further research in this new direction of applied geocryology.

Valuable experience on the design, construction, and management of railroads on permafrost was accumulated in Russia during the twentieth century, and continues to increase. Measures are systematized that include control

Figure 3. Impoundment of the road surroundings, northwestern Siberia.

of the ground surface heat exchange, combined usage of thermosyphons and heat insulation for stabilizing frozen foundations, and roadbed monitoring (Kondratiev 2005).

Rock fills have wide application in roadbed construction (Minailov 1979, Goering 1998). The physical effect consists in ground cooling at the expense of air convection. Rock fills are employed not only for road construction, but also in other branches of industry; for example, in pipeline installation.

The monitoring system of the railway on permafrost soils is based on the allotment of potentially hazardous sections with establishing the control on their deformation (Ashpiz 2005).

The methodology of roadbed operation was developed for projects of the railroad lines Obskaya-Bovanenkovo, Chara-Cheena, and others. Full-scale experiments and theoretical studies (Passek et al. 2005) were conducted on the temperature regime of the road foundations under conditions of flooded lands (Fig. 3). The impoundment depth was found that induces permafrost degradation in different climatic conditions.

A new algorithm and programs for numerical modeling have been developed at St. Petersburg State University of Means of Communication (Kudryavtsev 2004). These allow the calculation of 3-dimensional temperature and moisture fields of the ground in the roadbed base. The procedure for correct assignment of the bottom boundary condition was worked out (Danielyan & Tkachenko 2005).

Oil and Gas Field Development

In the last few decades, oil and gas field development has become more active in northwestern Siberia, especially on the Yamal Peninsula. Yamal is a unique place in regard to its natural wealth of resources and the difficulty of their development, which is caused by the complexity of natural geocryological conditions and by a particular vulnerability of this territory to technogenic pressure. As a result, there was a need to strengthen the geocryological service and organize monitoring of territories under development.

"Nadymgazprom" specialists, in collaboration with leading Russian scientific, design, and exploration organizations, conducted a geoecological evaluation of the territory and obtained several important results from the scientific point of view (Remizov et al. 2001). For the first time, the connection between cryogenic processes, not only related to

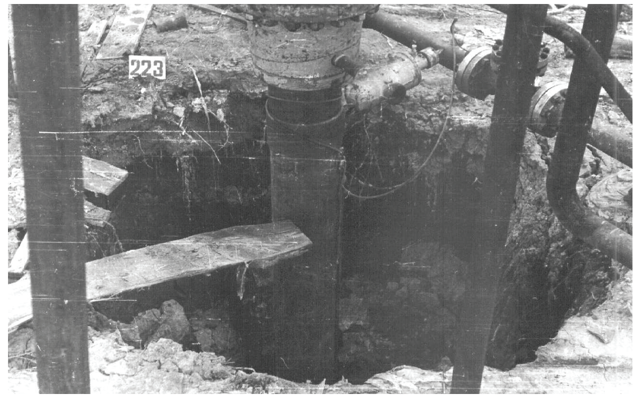

Figure 4. The thermokarst funnel around production wellhead.

climatic changes but also to tectonic sensitivity of the region, was documented. Also, the influence of surface subsidence as a result of hydrocarbon extraction at significant depths has been analyzed. These data are interesting for future statistical analysis of established quantitative characteristics of thermokarst and landslides-earthflow for understanding these cryogenic processes.

Local standards and environmental protection measures have been developed taking into account the prognosis of cryolithozone reaction to modern climate changes.

The stability of producing wells is one of serious technical-ecological difficulty to an oil and gas complex (Fig. 4). Heat exchange in the ground around an operational well has been modeled for the Bovanenkovo field. A new system of preventing "wellhead funnel" formation has been developed on the basis of this model. It includes radially positioned thermosyphons and thermal insulation (Bereznyakov et al. 1997).

The expansion of pipeline construction in the cryolithozone is due to Russia's increasing demands on hydrocarbon fuel for domestic and foreign markets. Unfortunately, an accelerated rate of construction negatively influences the quality of surveying and design solutions. Thermokarst subsidence and frost heave uplift of above-ground pipe foundations are among the common cryogenic processes (Fig. 5). Extremely intensive frost heave uplift of the tube support was recorded during Urengoy pipeline operation—up to 1.5 m in one year (Pazinyak 2001). Quite an attractive option is to install underground pipes; However, for safe operation, a proactive geotechnical monitoring service that can anticipate dangerous situations is a necessity.

Difficulties in the development of Yamal natural resources are induced not only by building and operating industrial structures. Conventional permafrost regions problems are connected with activity of the all local infrastructure.

Institute Fundamentprojekt (Institute of Foundation Design) has devised the main engineering solutions on foundations for the facilities of the Bovanenkovo and Harasavey gas fields (Yamal Peninsula) and also for the gas pipeline from Yamal to the central regions of Russia. These include frozen ground stabilizing with heat shields and thermosyphons, reinforcing ground surface on the slopes with geogrids and geocells (Grechichshev et al. 2005).

Figure 5. Deformations of the pipes due to thermokarst subsidence and frost heave processes.

Figure 6. Fissured rocks of the cryogenic weathering zone (gold-bearing ore deposit Troitskoje, Transbaikalia).

Mineral Mining

In many sites of eastern Siberia and the Far East that are located within the permafrost zone, mining plays an important part in the regional economy.

Open-pit mining of ore deposits has special features in most sites. It is known that the cryogenic weathering zone usually has significant thickness (Slagoda 2005). The fissured rocks of this zone have low ice content (as a rule, no more than 30–50 kg/m^3); however, it predetermines a loss of strength when thawing (Fig. 6).

That is the reason why, in the summer, miners thaw rocks layer by layer using natural heat. This minimizes and sometimes completely avoids the more expensive and dangerous drill-and-blasting operations. The calculation of the open-pit slope takes into account that the warm-season thawing penetrates several meters into rock massif. The placer mining with open-pit method occurs in the warm season, and earth is moved primarily with bulldozers. To make sense of using them, it is necessary to thaw frozen ground. The heat required to melt the ice consumes the main part of the overall energy spent on thawing the ground. Hence, the main goal of an engineering survey is to detect and show the borders of the frozen ground and determine its ice content. As for the ground temperature regime, there is no need to study it carefully.

One of the constant difficulties in placer mining is flushing out frozen sands from open-pit and underground mining. Deposits of the productive horizon, extracted by explosives and deposited in piles at the beginning of the summer, do not have enough time to thaw. And at the end of the flushing season, the ground quickly freezes. This leads to a tremendous loss of metal. This problem, however, is easily solved by using sprinkling thawing. The approximate analytic formulas for it were derived 25 years ago (Perlshtein & Giltsov 1984). The numerical model is described in a paper submitted for this conference.

The simplest methods of thermal melioration of frozen soils are applied to permafrost placers (for example, removal of plant-moss-peat cover). However, under new economic conditions, it is often necessary to use powerful excavators and prolong the season for overburden removal. This brings about hydraulic thawing and deposits drainage. In turn, this requires studying the permeability and other mass transfer properties.

Underground mining of gold placers is used when the burial depth is more than 20 m. It requires breaking gold-bearing deposits during the winter and processing them on the surface during the summer. In this case, the primary goal of the survey is to study permafrost thickness and its temperature. Also sub-permafrost waters must be detected to prevent their ingress into the mine. If the frozen massif temperature is warm (minus 1–2ºC), that predetermines reduced strength of the ground, and mining work is usually conducted in the winter. It is possible to harden the ground significantly at the expense of ventilation with cold air. This should be thoroughly examined in the course of underground-mine planning. Also a hard winter in the permafrost zone allows for the use of ice filling of underground workings. It provides stability when excavating the pillars (bearing blocks).

Hazards and Environmental Protection

For abatement against impact of dangerous cryogenic processes, Russian specialists try to take advantage of the local natural features (severe climate, specific properties of the frozen ground, etc.).

For example, burial of mining toxic waste poses a serious threat to the vulnerable environment. In any tailings disposal method, the seepage-control measures must be designed in such a way to exclude contaminating surface and ground water within the adjacent areas. It is possible to install dams with an impervious frozen core, as used widely in the permafrost zones of Canada, Russia, and Alaska. A new method of tailings management is planned for use at some ore deposits. Its essence consists in dividing the entire area of the tailings disposal facility into several cells. The winter ones (at the periphery of the tailings facility) are filled with successive layers of tailings each of them being permitted to freeze under natural cold conditions prior to the placement of the next layer. The winter regime of slurry discharge must provide for tailings settlement, mill-water return, and complete freezing of sediments. This method makes it possible to turn the inclement climate into a helpful factor for mining in permafrost regions. Storage of the mine wastes in the frozen state reduces the risk of seepage losses of the toxic solutions. As a result, the construction cost of the tailings disposal facility considerably decreases, and the level of the environmental safety rises.

The method of keeping nuclear waste underground in artificially frozen ground was considered (Khrustalev et al. 2004; 2005). A facility for underground water storage also uses impermeability of frozen soils and ice walls (Kuzmin 2005).

Important data was collected by analyzing catastrophic shifts on the Kolka Glacier, where a huge ice block collapsed on September 20, 2002. The resulting giant ice-water-rock stream was 18 km in length and 80–100 m in height, and flowed at a speed of 150 km/hour. Over 120 lives were lost, the Verkhny Kardamon settlement was buried, the Verkhnaya Saniba village was flooded, and all communication systems were destroyed. After studying the consequences of the Kolka Glacier collapse, it has been determined that this catastrophe as a natural event most resembles a snow-rock-ice avalanche. Based on field research and satellite image analysis, the ice volume involved in this catastrophic shift was 80 ±15 million m^3. Part of the glacier could still remain in its bed. New data made it possible to refine the prognosis of how events could develop in the catastrophe zone. In the next 10–20 years, new catastrophic processes in the Kolka Glacier cirque are unlikely to occur. The main part of the ice body in the Karmadonskaya depression will melt in 2–3 years, but its full degradation will take not less than 10 years [include a reference].

Surveying, Mapping, and Monitoring

The Russian school of engineering-geological survey is traditionally based upon complex geosciences assessment of explored territories involving a wide range of information. Heightened attention is given to methods of mapping. Thus Fundamentprojekt has investigated natural conditions for major industrial facilities on the Barentz Sea coast. Maps at different scale and functions have been prepared and reflect frozen-ground properties (temperature, salinity, strength) and also the results of geocryologic prognosis.

The team at the Earth Cryosphere Institute SB RAS (ECI SB RAS) has drawn up a series of medium-scale GIS maps for permafrost territories with intensive economic activity, such as northwestern Siberia, central Yakutia, the northern variant of pipeline eastern Siberia-Pacific Ocean, and others. These maps present the clearest available information on permafrost conditions in these regions (Drozdov et al. 2007).

Geophysical methods of prospecting are widely practiced. The ECI SB RAS has developed an original methodology of high performance seismic prospecting on lateral SH waves.

Figure 7. Deformations of the railroad bed (Chara-Cheena).

Among the most significant practical implementations are surveying for the third traffic-ring road for Moscow, and research on the factory MFFR-R site to utilize weapon-grade plutonium in the Tomsk region, which was conducted in 2004 within the framework of the Intergovernmental Russian-American Agreement.

Monitoring of cryogenic processes was conducted for the Novaya Chara-Cheena Railroad (northern Transbaikalia). It has been determined that anthropogenic impact, along with climate change, in the foothills of the Udokan Ridge has caused thawing massive ice and ice-wedges as well as catastrophic subsidence of the railroad base (Fig. 7). Under the influence of earthquakes and cryogenic destruction, catastrophic landslides and flow slides occurred in the mid-elevation mountain zone. In the areas of rock streams (kurums) development, these processes led to a railroad slide (Institute of Natural Resources, Ecology and Cryology SB RAS).

Data from integrated monitoring was used to study the natural dynamics of vegetation and its changes under the influence of oil and gas development for northwestern Siberia. It is interesting to note that according to a second grading of peat-mineral hummocks, which took place 30 years after laying the pipeline, the surface had undergone subsidence, heave, and stabilization, but had never returned to its original position, remaining 8–80 cm lower. The intensity of subsidence decreases, moving further away from the pipeline (Institute of the Earth Cryosphere SB RAS).

Conclusions

Permafrost influences the development of northern territories (oil and gas production, mining placers and ore deposits, open-pit and underground operations, etc.). Applied technological methods must use advanced scientific-technical solutions according to the natural conditions of the site. This allows alleviation of the negative influence of permafrost and also uses favorable features of the territory. Accordingly, engineering services must determine necessary and sufficient volume of geocryological information to provide for the success of prospecting, design, and operational activities.

Exchange of experience and analysis of design errors are very helpful in solution of such problems. Round-table discussions on permafrost engineering problems take place at the annual Russian permafrost conferences.

I think that, presently, the main tasks for Russian applied geocryology are:

- Arrange monitoring of cryolithozone for the most economically important regions;
- Enhance the theoretical basis and determine unified methods of quantitative geocryological prognosis;
- Develop a complex of quantitative models of permafrost-geological processes on the basis of combining deterministic and probabilistic approaches;
- Develop further explorative-investigational work around the use of nontraditional resources of natural heat and cold of the cryolithozone;
- Actively participate in and closely coordinate research within the framework of the International Polar Year;
- Equip laboratory, stationary and fieldwork with modern control and measurement instrumentation.

Acknowledgments

The author thanks S.E. Grechishchev, L.N. Khrustalev, V.P. Melnikov, M.A. Minkin, L.T.Roman, V.N. Zaitsev and R.V. Zhan for their proposals on selecting initial materials for the report. I appreciate the participation of my colleagues D. Sergueev and M. Tishkova in discussing and preparing this text. Especially I would like to express my thanks to IPA President Dr Jerry Brown, who reviewed and suggested revisions to this paper.

Numerical Modeling of Differential Frost Heave

Rorik A. Peterson
Mechanical Engineering, College of Engineering and Mines, University of Alaska Fairbanks, Fairbanks AK, USA

Abstract

Differential frost heave (DFH) is laterally non-uniform heave. DFH occurs near buried chilled pipelines, leads to roadway and foundation damage, and also causes some types of patterned ground. Several recent advances in numerically modeling multi-dimensional frost heave at two different spatial scales are discussed. Coupled heat and liquid water transport in a partially frozen saturated soil is modeled at the millimeter scale. Individual ice lens formation is shown to occur when the effective interparticle pressure becomes zero at a finite distance below the nearest existing lens. Liquid water velocity is time dependent, and initially increases quickly and then decreases more gradually until subsequent lens initiation. Velocity also appears to be temporally unstable, occurring in pulses balanced by heat flux. DFH is also spatially unstable on the meter-scale and strongly dependent on the frozen soil mechanical properties. A three dimensional model on the meter-scale shows pattern ground development that depends on soil modulus.

Keywords: frost heave; ice lens; numerical modeling; patterned ground.

Introduction

Differential frost heave (DFH) is laterally non-uniform (i.e., multi-dimensional) heave. The spatial irregularity of DFH causes out-of-plane stresses that result in bending, compaction, dilation, and failure of both the frozen and unfrozen soil. DFH occurs at buried chilled pipelines, leads to roadway and foundation damage, and also causes some types of patterned ground. Analytic and numerical frost heave modeling has progressed significantly as our fundamental understanding of its origins has improved and computational techniques and resources continue to advance. The problem remains complex, however, due to the wide range of length scales from micron-scale unfrozen water films, to the millimeter-scale frozen fringe, to meter-scale soil deformation.

Some of the early numerical models of frost heave that attempted to account for individual ice lens formation are due to O'Neill and Miller (1985) and Gilpin (1980). These models were one-dimensional, which made them both more numerically tractable at the time and also directly applicable to laboratory frost heave experiments. Over the next few decade several numerical variations were developed for the one-dimensional solution, but the underlying physics remained essentially the same.

More recently, Rempel (2007) has shown that an assumption in the previous models concerning local ice pressure is unnecessary and probably incorrect, and provided both an analytical and numerical solution to the one-dimensional frost heave problem. Quantitatively, this solution is not drastically different than those previous when reproducing laboratory frost heave scale experiments. However, it may have more profound implications when describing frost heave with greater overburden pressure as would occur below glaciers and ice sheets.

Multi-dimensional solutions of frost heave are less prevalent, perhaps due to the complicating factor of describing the unfrozen and frozen soil deformation that one-dimensional solutions need not address. Michalowski and Zhu (2006) have recently addressed this issue numerically by introducing a "porosity rate function". The effect of frozen soil elastic modulus on the spontaneous initiation of DFH has been demonstrated analytically by Peterson and Krantz (2003) using a linear stability analysis.

Several recent advances in numerically modeling DFH at two different spatial scales are discussed here. The formation of discrete ice lenses occurs on a roughly millimeter scale in a region of partially frozen soil. The coupled heat and liquid water transport is modeled in two dimensions. The formation of a new ice lens at a discrete location below the nearest existing lens is shown, and its dependence on a spatially variable overburden pressure is demonstrated. The flux of liquid water to the growing ice lens is shown to vary in time. Flux initially increases rapidly as the frost heave pressure increases, but then quickly subsides due to decreasing permeability as pore ice increases. Additionally, the velocity appears to be temporally unstable when the heat flux from the lens is held constant. Pulses of water on an approximately one-second scale occur, and are balanced by the constant heat flux and slowing decreasing temperature at the lens boundary.

During freeze up of a natural soil such as the active layer in permafrost regions, hundreds of individual ice lens can form, and modeling at the millimeter scale rapidly becomes complex due to discontinuities in water flux as each new lens forms and the liquid water pressure adjusts nearly instantaneously. Scaling analysis (Fowler & Krantz 1994) indicates that the process can be recast into a more continuous problem by applying jump boundary conditions at the frozen fringe. This reduced model still accounts for discrete lens formation but does not directly solve for the temporally evolving temperature, pressure and liquid water profile within the frozen fringe. Analytic solutions to this reduced model are currently known only in one dimension. A multi-dimensional numerical solution can be used to investigate the effects of surface variability in temperature

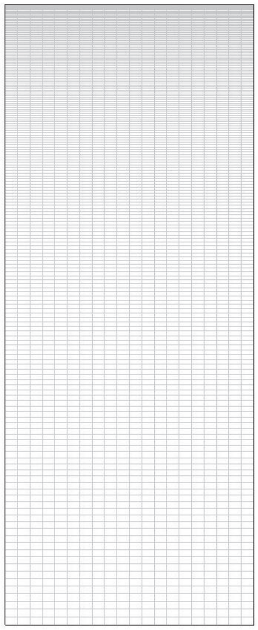

Figure 1. The finite element grid with a logarithmic vertical element size distribution.

and pressure, due to ground vegetation cover or engineering infrastructure, for example.

Here a three-dimensional solution demonstrates that patterned ground can form due to a positive feedback mechanism when small perturbations in the ground surface are randomly distributed as an initial condition. The elastic modulus of the frozen soil provides a stabilizing mechanism once perturbations reach a moderate size, resulting in larger patterns in more stiff soils. This may have implications for changes in natural patterned ground size when soil properties and/or ice content are spatially variable. The soil elastic modulus is only one of several properties than may be spatially and temporally variable, and conclusive model predictions will likely have to consider the combined effect of them all.

Model Description

The two-dimensional model of the partially frozen, saturated soil beneath an ice lens includes transient heat and liquid water transport. The transient energy balance equation is

$$\rho_{eff} C_{eff} \frac{\partial T}{\partial t} = \nabla \bullet \left(k_{eff} \nabla T \right) \tag{1}$$

where T is temperature, C is heat capacity, ρ is density, and k is thermal conductivity. The subscript *eff* denotes effective properties that are volume averages of the three phases: liquid water, ice, and soil. The soil volume fraction is assumed constant. The water transport equation is Darcy's Law for a saturated soil

$$\nabla \bullet \left(\frac{\rho_w \kappa}{\eta} \nabla p_w \right) = 0 \tag{2}$$

where κ is permeability, η is viscosity, and p_w is water pressure. The permeability is a non-linear function of the ice content, W, which is also a non-linear function of the temperature

$$\kappa = \kappa_0 W^{\gamma} \tag{3}$$

where the exponent γ=8 and κ_0 is the unfrozen permeability. Here an exponential function is also used to describe the unfrozen water content.

$$W = \exp[\alpha T] \tag{4}$$

where α = 5 and T is in °C. The exponent depends on the soil type and is usually in the range of 2–10. The results discussed here are general for any value of the exponent, although the exact numerical values will vary.

A two-dimensional finite element mesh consisting of quadrilateral elements was created in a 1-cm wide by 2.5 cm tall domain. The third dimension is not modeled a this scale. The temperature, pressure, and their dependent properties are highly non-linear just below the top boundary. Therefore, element size follows a log space distribution in the vertical direction with evenly spaced elements in the horizontal. The resulting 20 by 200 element grid is shown in Figure 1. The smallest element at top is 2.9 microns by 0.5 millimeters.

Frost susceptible soils are usually silty clays, with relatively wide particle size distributions spanning 1.0 to several hundred microns. This model makes a continuum assumption that material properties are continuous throughout each numerical element, and therefore mass transport can be modeled using Darcy's flow equation. Although the smallest elements in this analysis are of the order of some particle dimensions, it is assumed that micron-scale heterogeneities will average out and the continuum assumption is valid. An attractive alternative would be to use a Discrete Element (DEM) or Material Point Method (MPM), but they are not investigated here.

Initial and Boundary Conditions

The initial conditions are 0°C for temperature and zero gage pressure throughout the domain. The pressure boundary conditions are zero gage pressure at the bottom and $P_{load}(x)$ at the top. Gravitational effects on the pressure distribution are negligible at this scale compared to flow resistance and thermomolecular pressure. The functional form of P_{load} is discussed below. The thermal boundary conditions are 0°C at the bottom and constant heat flux at the top; the flux value is discussed below. The side boundaries have a no-energy-flux condition for the thermal problem, and no mass flux for pressure.

The numerical problem is solved using Comsol Multiphysics version 3.2, a commercial finite element package that is tailored to coupled physical problems. The non-linear solver uses an adjustable time step based on the temporal dynamics of the transient solution.

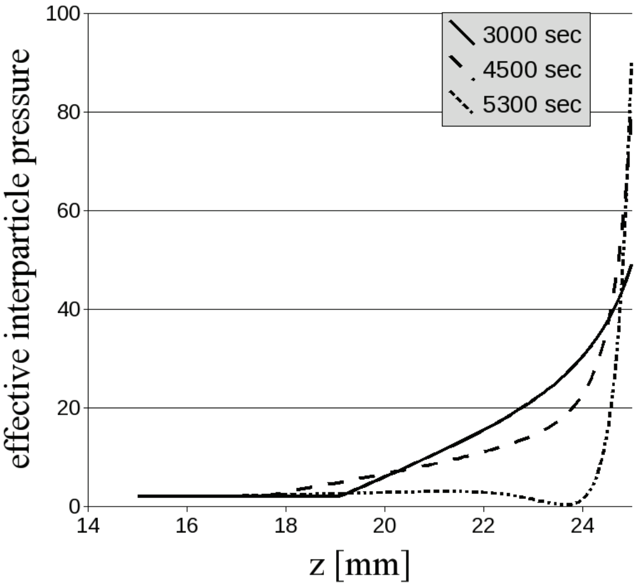

Figure 2. Interparticle pressure in kPa as a function of the vertical location below the existing ice lens.

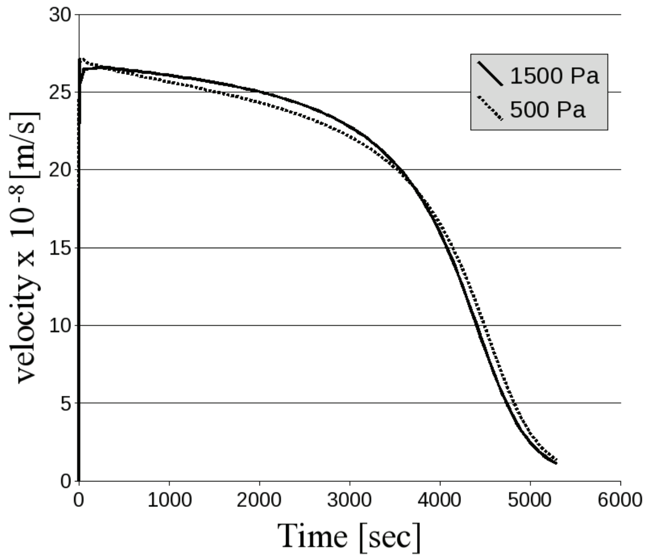

Figure 3. Water flux to the upper boundary for two extremes of the overburden pressure. Len initiation occurs at about 5300 seconds.

Small-Scale Fringe Behavior

All results discussed here used a constant heat flux from the top surface of 100 watts (W) per square meter. During natural soil freezing in autumn when snow depth is relatively thin, the rate of heat flux would be on the order of 10-–100 W/m^2. This estimate assumes a snow thermal conductivity of 0.1 W/m·K (Sturm et al., 2002) a snow depth of 1-–10 cm, and an air temperature of negative 10°C. The higher range of this flux estimate is used to expedite the numerical solution, and a preliminary sensitivity investigation indicates that the overall trends discussed here are general for the entire range of heat flux values.

The energy flux is balanced by thermal conduction to the boundary and latent heat of fusion for the water flux advecting to the boundary and freezing. The interparticle effective pressure is calculated at each time step within the domain and initiation of a new lens begins whenever this function reaches zero. Using a sinusoidal varying surface pressure on the top boundary, p_{load}=1000+500[cos(πx/0.01] Pa, the effective pressure is less on the right hand side and a new lens will initiate on that side first. Figure 2 shows the computed interparticle effective pressure at three different times on the right-hand side of the domain.

The *x*-axis of Figure 2 only shows the upper 1 cm of the domain where the effective pressure is changing most dramatically. Note that the major pressure variation is occurring on the scale of 1 mm, which is one to two orders of magnitude larger than the smallest particle dimensions, and lends support to the continuum assumption when using the Darcy flow equation. Initially the effective pressure increases from the base value because of cryostatic suction. In an unconsolidated soil, compaction may occur during this time with a loss of porosity. These effects are not considered at this point and the porosity is held constant. The suction region extends further downward as time progresses and the ice content increases.

As time nears 5300 seconds, the effective pressure begins to decrease below its base value as the thermomolecular force increases and begins to accommodate a larger fraction of the overburden pressure. As the ice content increases at a particular depth, the unfrozen water film thickness decreases and the dispersion force will increase. Eventually, this force is great enough to push between the soil particles and the effective pressure becomes zero. At this point, a new ice lens will form at this location. This is shown in Figure 2 at about 1-mm below the previous ice lens.

The flux of liquid water to the top boundary freezes and causes the existing ice lens to thicken. The velocity is a function of the cryostatic suction and is therefore spatially varying due to the pressure boundary condition at the top surface. The velocity as a function of time is shown in Figure 3 at the left and right sides of the domain where the pressure is largest and smallest, respectively. The *y*-axis is shown in m/s and scaled by 10^{-8}, so the maximum velocity is 0.25 microns per second. There is an initial rapid rise in the velocity followed by a more gradual decrease until subsequent lens initiation. The initial rise occurs as the ice content initially becomes non-zero and the thermomolecular force is greater than the overburden pressure. The decline is due to increasing ice content that decreases the permeability. The magnitude of velocity throughout the domain is similar, and the two curves span the entire range. From about 200 to 3700 seconds, the larger overburden results in greater water flux by about 3%. At times greater than 2700 seconds, the lower pressure results in a greater velocity. This can be seen where the lines cross in Figure 3 near 3700 seconds. The total increase in lens thickness is spatially varying, and can be determined by integrating the velocity with time and is equal to the area underneath the curves. For the data shown

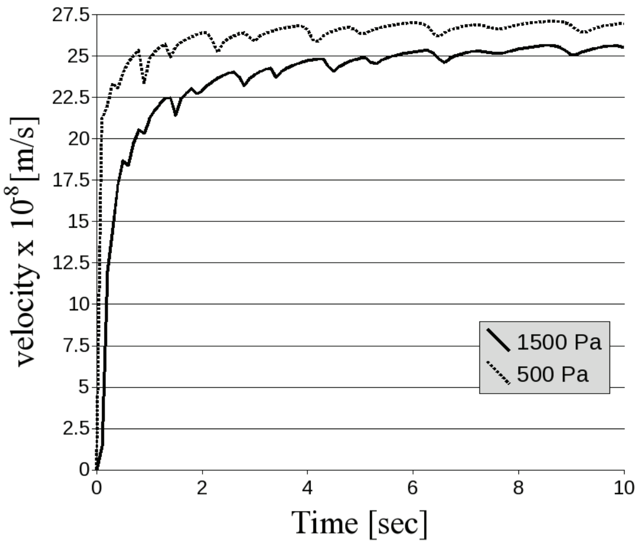

Figure 4. Water flux to the upper boundary during the initial 10 seconds. Pulses occur on a scale of one second.

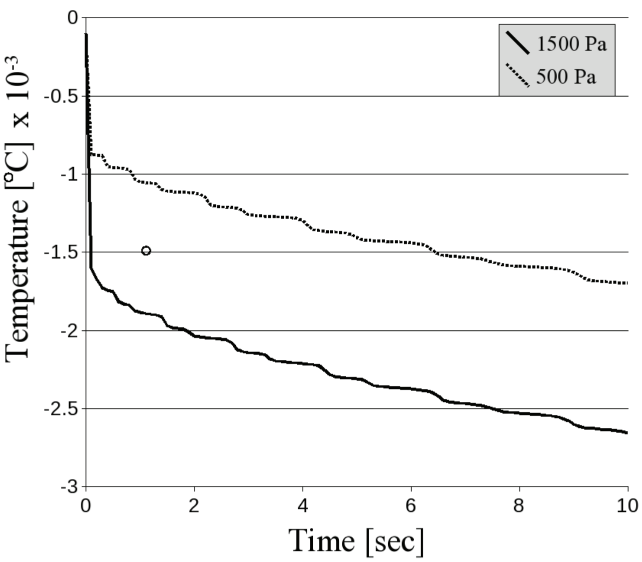

Figure 5. Temperature of the upper lens boundary during the initial 10 seconds. Fluctuations correspond to pulses in the liquid water velocity.

in Figure 3, this results in a thickness of 1.047 mm when P=1500 Pa, and 1.043 mm when P=500 Pa.

The rapid increase in velocity occurs during the first 10 seconds and is shown in Figure 4. There is a slight delay for the greater pressure on the left-hand side because it takes longer for the thermomolecular pressure to balance the greater overburden. A larger ice content is required for water flux to begin and is controlled by the finite energy flux at the top surface. Because the overburden pressures in this simulation are relatively small at only 0.5–1.5 kPa, the delay is less than 1 second. The velocity reaches its maximum value by 5 seconds, and already begins to decline around 10 seconds.

There are obvious fluctuations in the velocity that occur with a periodicity on the order of 1 second. These fluctuations are not due to numerical time stepping and are reproducible with changes in the time stepping protocol. For the results shown in Figure 4, the time step was adaptive and on the order of 0.001 seconds during the first 10 seconds. The fluctuations appear to be due to a temporal instability where a small increase in water flux temporarily slows the rate of ice formation below. Because the heat flux from the top boundary is fixed at 100 W/m^2, it is balanced by the combination of thermal conduction and latent heat of fusion for the liquid water. An increase in velocity means that more lens ice is formed, and therefore less pore ice is formed below the lens. It is the increase in pore ice that eventually slows the liquid water flux. There is a corresponding negative feedback when the water flux decreases slightly. The combination of these two effects results in pulses of water reaching the growing ice lens.

The temperature at the top boundary also shows fluctuations on the 1-second time scale, corresponding to these pulses of liquid water. Figure 5 shows the temperature at the upper boundary for the high and low pressure sides. Overall, the temperature slowly decreases, but there are periods of quick decline that correspond directly with when the liquid water flux is at a minimum. During these short periods more pore ice is formed. When the temperature decline is nearly flat, the corresponding water flux is at a maximum and lens ice formation is at a maximum. These short-term fluctuations become damped as time progresses, and are not readily apparent at times greater than a few hundred seconds.

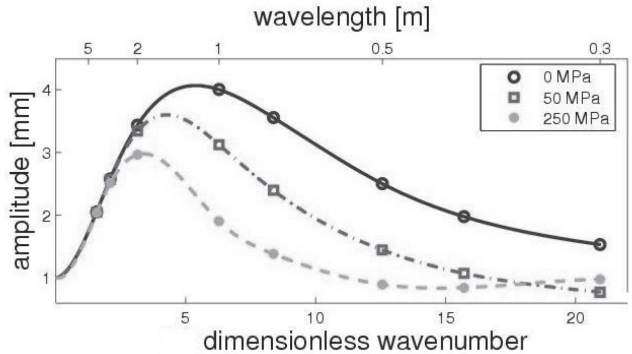

Figure 6. Amplitude of the surface perturbations after one freeze cycle to a depth of 1 meter.

Large-Scale Pattern Formation

The larger scale frost heave problem is solved using the generalized model equations of Fowler and Krantz (1994). An additional description of how the frozen soil deforms must be added to their model, and here it is assumed to behave as a thin plate with Young's Modulus E. The bending of a thin plate of thickness h can be described by

$$P_b = \frac{Eh^3}{12\left(1-\nu^2\right)} w \tag{5}$$

where P_b is the additional pressure (force per area) required (or resulting from) the bending on the plate, w is the deflection of the plate mid-plane, and ν is Poisson's ratio. A

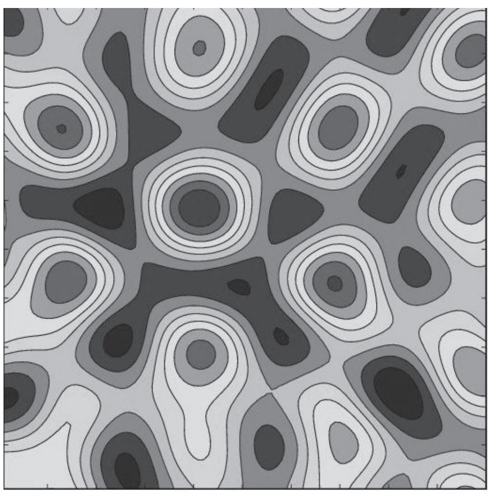

Figure 8. Final ground surface topography after 16 freeze cycles to one meter. Young's Modulus is zero.

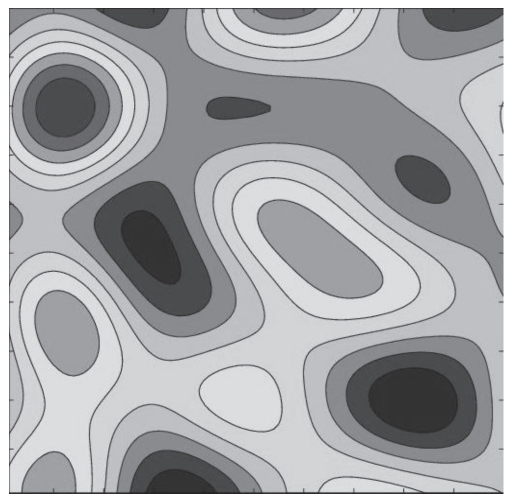

Figure 10. Final ground surface topography after 16 freeze cycles to one meter. Young's modulus is 250 MPa.

two dimensional model for freezing with a constant surface temperature of -10°C was solved using small, sinusoidal varying ground surface perturbations of 1-millimeter amplitude. Because of a singularity when the thickness of frozen soil is zero, an initial frozen thickness of 10 cm was used. The model was run until the depth of freezing reached 100 cm, which is typical of the active layer in permafrost regions.

The final amplitude of the surface perturbations is shown in Figure 6. The top *x*-axis shows the dimensional wavelength of the perturbations, and each curve represents three different values of the Young's Modulus. The symbols show the numerical results of different simulations and the curves are a cubic spline fit to the results. There is a maximum in each curve which indicates the wavelength pattern that is most likely to evolve in the long term from an otherwise homogeneous system that experiences only random perturbations. Even when the modulus is zero, short wavelength patterns do not tend to grow significantly.

Each of the simulations that generated the results shown in Figure 6 involved a perturbation with only a single wavelength. The development of a pattern with a characteristic wavelength can be demonstrated by solving the frost heave model in three dimensions. Random perturbations are once again imposed on the top surface with maximum amplitude of 1 millimeter. In order to approximate the "white noise" of naturally occurring perturbations in nature, a linear superposition of 25 randomly chosen three-dimensional patterns with varying frequencies and spatial offsets was generated. A contour plot of this initial condition is shown in Figure 7, where eight equally-spaced contours represent the range from 0 to 1 millimeter.

Using the same initial conditions, the three-dimensional model was solved for 16 sequential freeze cycles. At the end of each freeze cycle, the final surface topography was used as the initial surface topology for the subsequent year. In this way, the thaw process is not explicitly modeled, and it is assumed that any topography changes due to differential ice formation are maintained. This likely leads to an overestimation of the final pattern amplitude, and probably favors patterns of a shorter wavelength that would otherwise be mitigated by solifluction or other melt-related processes.

Figures 8, 9, and 10 show contour plots of the final surface topology when the modulus is 0 MPa, 50 MPa, and 250 MPa, respectively. Eight equally-spaced contours are shown, and the lateral dimension is $2\pi = 6.28$ meters. Because of the simplifying assumptions concerning the thaw process, the final magnitude of the pattern is of less consequence than the spatial characteristics. It is readily apparent that when the modulus of the frozen soil increases (Figs. 8–10), the dominant pattern that evolves has a characteristically larger size. All other conditions are identical including the initially perturbed surface. This general conclusion has been postulated before based on linear stability analysis (Peterson & Krantz 1994) and a numerical model for stone circle development (Kessler et al. 2001). However, this model solves for the time-dependent evolution of the pattern, and also explicitly accounts for differential soil movement that depends on the mechanical properties of the frozen soil.

Conclusions

Differential frost heave is a complicated process to model due to important processes that occur over a wide range of spatial scales, ranging from micron-scale liquid water films, to millimeter-scale partially frozen fringe, and to meter-scale soil deformation. Results from numerical modeling of differential frost heave in multiple dimensions at the two larger spatial scales have been discussed. Discrete ice lens formation is predicted to occur on the scale of 1-millimeter below an existing lens, which is in agreement with laboratory measurements and field observations of freezing soils under similar conditions. Spatial variability in the time and location of new ice lens formation is shown by solving for when the interparticle effective pressure becomes zero.

The velocity of liquid water to a thickening ice lens is shown to vary in time, with an initially rapid increase followed by a more gradual decrease as the pore ice content increases. The total amount of lens ice that forms is the time integral of this velocity, and is shown to spatially vary with variations in the overburden pressure. Similar behavior would be expected with a spatially varying surface temperature or thermal flux due to variations in surface ground cover. The liquid water velocity also appears to be temporally unstable, resulting in pulses on a scale of one second. The lens temperature also fluctuates on a similar scale because the total heat flux is balanced by the rate of heat conduction from below and the latent heat of fusion of liquid water. These fluctuations eventually dampen long after the liquid water velocity has reached a maximum and are not apparent at the time of subsequent lens initiation.

The larger scale frost heave problem is solved to demonstrate pattern growth that is dependent on the frozen soil mechanical properties. Patterns of a different characteristic wavelength will develop depending on the elastic modulus, with more still soils resulting in patterns of a larger size. The characteristic pattern size is on the order of 1–2 meters, which is in the range of naturally occurring patterns. A more complete model of pattern generation and evolution must more properly account for the dynamics of thawing soil, which will likely lead to favoring of larger patterns.

Abstract

This paper examines two hypotheses that apply to the energy balance of shallow subarctic lakes. These are other factors remaining constant, evaporation and sensible heat fluxes will increase with increasing air temperature, and the influence of mesoscale advection on latent and sensible heat fluxes decreases with increasing wind directional frequency. The data used to examine these hypotheses are derived from a shallow subarctic lake in the Hudson Bay Lowland coastal area near Churchill, Manitoba. They represent two separate years with differing weather and wind directional frequencies. Directional frequencies are divided into onshore (from Hudson Bay) and offshore (from the continental interior). For the former, the air masses are generally cool and moist, and for the latter, they are relatively warm and dry. Analysis of these data indicates that both hypotheses are valid within the framework of this study.

Keywords: advective persistence; Hudson Bay.

Introduction

There are a plethora of small, shallow freshwater lakes and ponds in the North American subarctic. Rouse (1973) estimates that small lakes cover ~3% of the Hudson Bay Lowlands in Ontario, while Dredge (1986) estimates lakes to cover 50% of the Hudson Bay Lowlands in Manitoba. These subarctic freshwater systems, which are dominated by low energy environments and cold region processes, play important hydrological and biogeochemical roles (Pienitz 1995). Hydrologically, these lakes are an important link between the regional hydrology and climate via their evaporative processes, while biogeochemically they can be significant from a nutrient cycling and biological perspective (Schertzer et al. 2003, Nagarajan et al. 2004, Boudreau & Rouse 1995, Macrae et al. 2004). Thus, lakes are an important component of the landscape in this environment and are worthy of consideration in hydrologic and climatologic studies. However, the pronounced warming predicted by global climate models may alter the surface energy balance of these lakes, thereby directly and indirectly altering their hydrological and/or biogeochemical function. Thus, an understanding of the energy regimes of these lakes, and how they are influenced by their regional climate, is required. The goal of this paper is to compare the surface energy fluxes of a shallow tundra lake between a normal wet and warm wet year to gain a better understanding of the potential interactions of these systems with their surrounding environments.

Shallow water bodies have been shown to be especially sensitive to warmer temperatures depending on the amount and timing of regional precipitation (Hondzo & Stefan 1991, Smol et al. 1991, Hondzo & Stefan 1993, Douglas et al. 1994, Nagarajan et al. 2004, Binyamin et al. 2006). Due to their distinctively small size, northern lakes are generally thoroughly mixed with a uniform temperature distribution and may become ephemeral (Bello & Smith 1990). Thus, if global climate models are accurate in their predictions of pronounced warming in high latitudes, the susceptibility of these lakes to ephemeral behaviour, or complete disappearance, is increased. The surface energy fluxes of these shallow tundra lakes have also been shown to be very responsive to advective effects, especially in the Churchill, Manitoba region, where Hudson Bay is seen to have a strong influence on the surface energy balance of the adjacent land up to 65 km inland (Rouse & Bello 1985). In order to investigate this influence on the region's abundant lakes, measurements were taken during the snow free period over Golf Lake, located east of the town of Churchill, Manitoba.

Churchill, a high subarctic wetland region in northern Manitoba, is an area that has been studied in detail. Many shallow lakes and ponds are dispersed throughout this region, most of which are less than 0.5 m deep, and less than 200 m in diameter (Bello & Smith 1990). The smaller ponds are generally poorly defined, very shallow, and frequently flood and dry up. Like most lakes in the subarctic tundra, Golf Lake is shallow (average depth of ~0.88 m) promoting thorough mixing and a uniform temperature distribution >95% of the time (Stewart & Rouse 1976, Binyamin et al. 2006).

The specific objectives of this paper are to study the atmospheric influence on Golf Lake from the surrounding land and adjacent bay, and to examine how the partitioning of the lake energy balance responds to changing mesoscale climatic conditions.

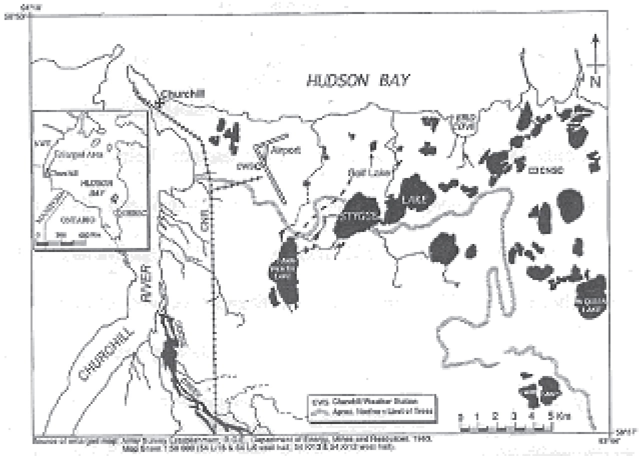

Figure 1. Study map illustrating the location of the town of Churchill, Manitoba and position of Golf Lake relative to the town and Hudson Bay.

Methods

Study area

Golf Lake is located in a wetland-dominated area, 11 km east of Churchill, Manitoba (58°46′N, 94°09′W) (Fig. 1). This region is classified as a high subarctic wetland region (N.W.W.G., Wetland Regions of Canada 1987). Hudson Bay exerts a strong influence on the climate of the area, causing Churchill to have high subarctic conditions, such as long, cold winters, short, cool summers, and low annual precipitation. This strong regional influence of Hudson Bay has been shown to extend at least 65 km inland, enhancing the flux of sensible heat and suppressing the fluxes of both latent and ground heating when winds originate offshore over Hudson Bay (Rouse 1991). This suppression of temperatures by the bay in the Churchill region causes the treeline and region of continuous permafrost to extend relatively far south in the Hudson Bay Lowland when compared to the rest of northern Canada.

Golf Lake is oval in shape with its long axis oriented approximately northeast–southwest (Fig. 1). The lake is approximately 550 m long by 350 m wide, 0.88 m deep on average, and is 1.2 m at its deepest point (Boudreau & Rouse 1995). The lake is surrounded by treeless upland heath to the east and sedge fens to the south, north, and west, with only a few larch (*Larix larcina*) and white spruce trees (*Picea glauca*) two to three meters in height. The immediate perimeter of the lake is dominated by various *Carex* species.

Measurements

An instrumented meteorological tower was located in the centre of the lake in 1.2 m of water. Air temperature, vapor pressure, and wind speed were measured at heights of 0.55, 1.05 and 1.55 m above the water surface. Lake temperatures were taken at the water surface, and at seven depths within the water column, with the bottom two sensors located within the loose organic bottom sediment. The heat flux through the bottom of the lake was measured using a Middleton heat flux plate.

Measurements yielded all components of the lake's energy balance via,

$$Q^* = Q_W + Q_E + Q_H \qquad (1)$$

where Q^* (W m^{-2}) is the net radiation, Q_W is the lake heat storage and Q_E and Q_H are the fluxes of latent and sensible heat, respectively.

The partitioning of the available energy between the sensible and latent heat fluxes is described by the Bowen ratio (β),

$$\beta = \frac{Q_H}{Q_E} \qquad (2)$$

Substitution of the flux equations for sensible and latent heat into equation (2) yields the following expression for the Bowen ratio,

$$\beta = \gamma \frac{\Delta T}{\Delta e} \qquad (3)$$

where γ is the psychrometric constant (0.0662 kPa °C^{-1}), ΔT is the vertical change in air temperature, and e is the vertical change in vapor pressure (kPa). β is a useful term to examine the relative importance of the sensible and latent heat fluxes, and the importance of cold air advection.

The heat storage within the lake (Q_W) is calculated from the sum of the series of lake layers, using the mean temperature and thickness of each layer giving,

$$Q_W = \sum C_W \left(\frac{\Delta T_W}{\Delta t} \right) \Delta z \tag{4}$$

where C_W is the volumetric heat capacity, $(\Delta T_W / \Delta t)$ is the water temperature change over time, and Δz is the depth increment of the volume of water in question, usually from the surface to the lake bottom.

The latent heat flux Q_E is derived using the energy balance approach in which,

$$Q_E = \frac{(Q^* - Q_W)}{1 + \gamma \dfrac{\Delta T_a}{\Delta e}} \tag{5}$$

where $\gamma(\Delta T_a/\Delta e)$ is the Bowen ratio. After determining Q_E, the sensible heat flux Q_H is derived as a residual in equation (1). Measurements are then grouped according to wind direction (with 360° representing true north) according to the following criteria: 315°–45° are referred to as *Onshore winds* (originating over Hudson Bay); 225°–315°and 45°–135° are referred to as *Along shore winds*, and 135°–225° are referred to as *Offshore winds* (originating over the interior tundra). The surface energy balance terms are then normalized as a ratio of the net radiation.

Results and Discussion

The two study seasons differed significantly in their seasonal weather. 1991 was on average about 5°C warmer than 1995, and was wetter and sunnier (Table 1). The air temperature and precipitation for 1991 and 1995 were greater than the observed normals for the region (9.7°C and 112 mm, respectively, Rouse et al. 1987), with 1991 being notably warmer and wetter than normal. The impact of differences in the summer weather on the energy balance of Golf Lake for these two seasons was substantial (Fig. 2). In both years, Q_H followed the same trend as Q*, reaching maximum in late June or early July and decreasing subsequently. Q_E reached maximum values around the first week of July, but remaining high through the measurement periods. There was little lake net heat storage (Q_w) in either year.

Lake and air temperature trends help to understand observed trends in the surface energy balance. In both years, onshore winds were associated with cooler temperatures and offshore winds with warmer temperatures (Table 2). In 1991, onshore winds were less frequent, and also less frequently associated with increased precipitation than in 1995. Inversion periods with negative sensible heat flux were frequent in 1991 (Fig. 2). In contrast, 1995 experienced lapse conditions (air temperature less than lake temperature) for the bulk of the season, with a resulting enhanced sensible heat flux (Table 2). Onshore winds always corresponded with lapse conditions in both years. $\beta = Q_H/Q_E$ generally showed large fluctuations from day to day, but over the season averaged out near zero (Table 3). β was higher for onshore than for offshore winds in both years.

Since the surface fluxes are strongly coupled with the net

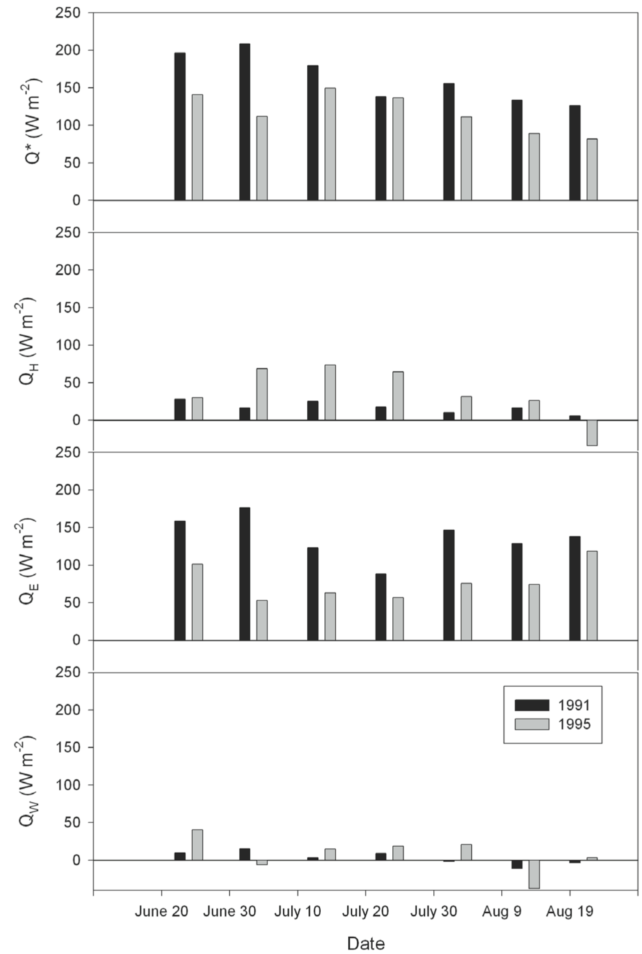

Figure 2. Surface energy balance for Golf Lake, Churchill, Manitoba, 1991 and 1995. Net radiation (Q*), sensible heat flux (Q_H), latent heat flux (Q_E) and lake heat storage (Q_W) data are expressed as 10-day running averages.

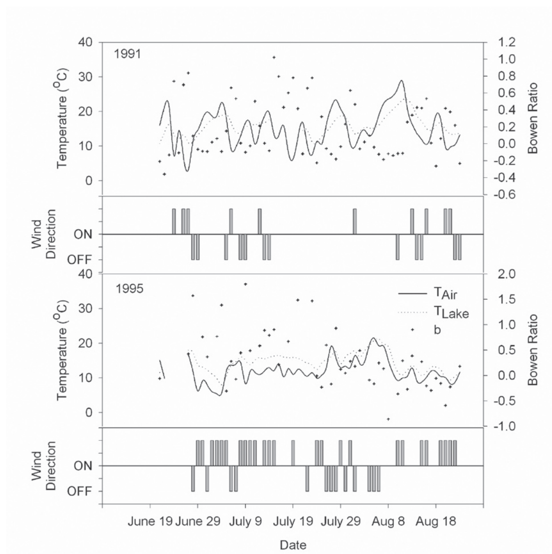

Figure 3. Air and lake temperatures (T_a and T_W, respectively), and Bowen ratio (β) for onshore and offshore winds, Golf Lake, Churchill, Manitoba, 1991 and 1995. All variables are expressed as daily averages.

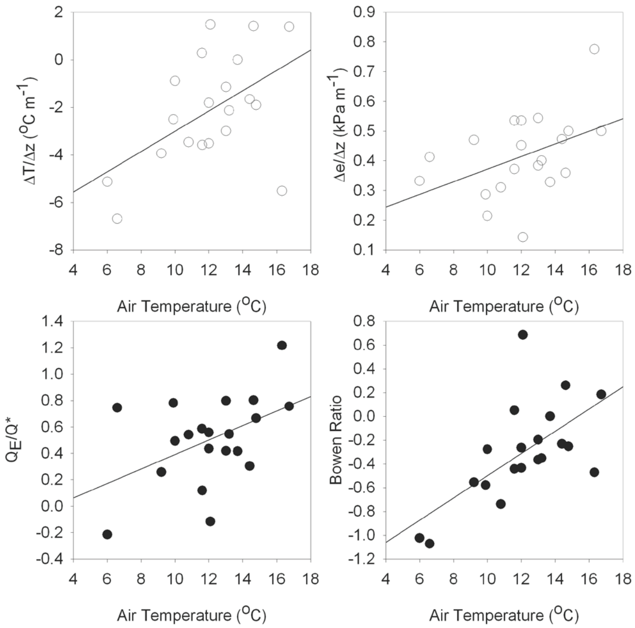

Figure 4. Relationship of vertical temperature ($\Delta T/\Delta z$) and vapour ($\Delta e/\Delta z$) gradients, relative latent heat (Q_E/Q^*) flux, and Bowen ratio (β) to air temperature. Data are plotted for both On and Offshore winds for both 1991 and 1995, for $Q^* = 200 \pm 40$ W m^{-2}. The lines are best-fit regression lines.

Table 3. Seasonal averages of the relative sensible (Q_H/Q^*) and latent heat (Q_E/Q^*) fluxes, relative lake heat storage (Q_W/Q^*), lake (T_W) and air (T_a) temperatures, and air temperature gradient (dT/dz). Golf Lake, Churchill, Manitoba, Canada, 1991 and 1995. Values are for Onshore and Offshore winds and standardized for $Q^* = 200 \pm 40$ Wm^{-2}.

		Q_H/Q^*	Q_E/Q^*	Q_W/Q^*	T_a (°C)	T_w (°C)	dT/dz (°C/m)
1991	ON	0.35	0.85	-0.30	11.5	15.8	2.2
	OFF	0.03	0.75	0.23	16.9	16.1	0.4
1995	ON	0.29	0.63	0.10	9.9	13.5	-1.8
	OFF	0.42	0.79	0.01	15.3	16.2	-0.4

radiation, to better understand their dynamics, it is useful to normalize them as a ratio of the net radiation, to give relative latent and sensible heat fluxes (Table 3). This brings out yearly contrasts. In 1995, all offshore flows produced large relative evaporation, and most onshore flows produced large relative sensible heat fluxes (Table 3). In 1991, onshore winds frequently resulted in larger relative evaporation than offshore winds (Table 3). By eliminating Q* as a variable, it is evident that $\Delta T/\Delta z$, $\Delta e/\Delta z$, Q_E/Q^* and β all increase with increasing atmospheric temperatures (Fig. 4). The rapid increase in β with increasing Ta arises because the rate of increase in Q_H substantially exceeds that in Q_E.

Many of the differences seen in the 1991 and 1995 data are due to differences in the directional persistence of winds. These have a substantial impact on $\Delta T/\Delta z$ and $\Delta e/\Delta z$. $\Delta e/\Delta z$ over the lake resulting from the differing response of lake and air temperatures. Even a shallow lake's response to changing atmospheric conditions requires periods of time

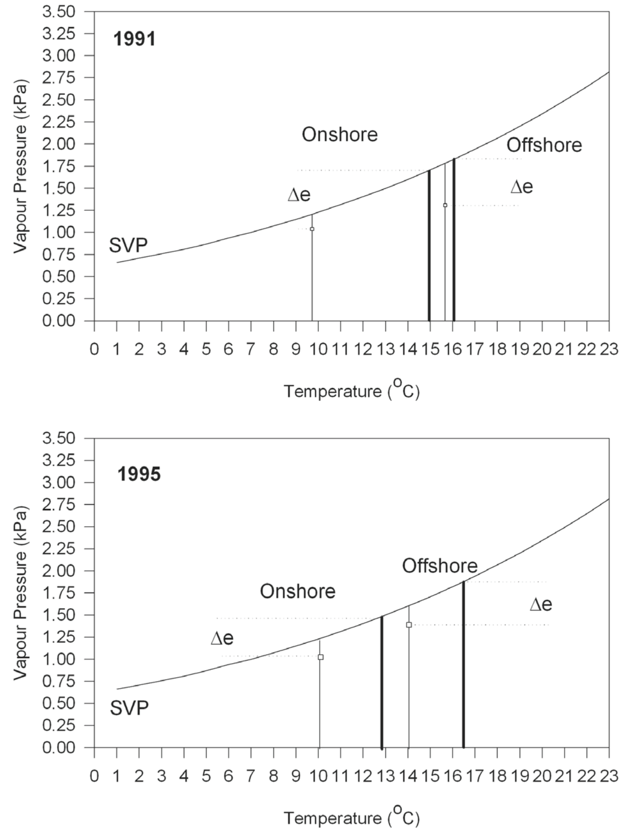

Figure 5. Vapour pressure-temperature relationships, during On and Offshore conditions, Golf Lake, Churchill, Manitoba, 1991 and 1995. Squares represent seasonal vapour pressures; thick lines represent seasonal lake temperatures; and fine lines represent seasonal air temperatures.

ranging from several hours to days, due to its relatively large heat capacity compared with the atmosphere. The large increases in $\Delta e/\Delta z$ and Q_E for onshore conditions in 1991 were due both to the increased temperatures and lesser persistence of onshore winds, which never persisted for longer than two days. (Fig. 3, Table 3). In 1995, there was substantially greater persistence in wind direction (Fig. 3). In 1991, lake temperatures were very close for both onshore and offshore winds, due to the much lower frequency and persistence of onshore winds compared with 1995 (Fig. 3). During offshore winds, larger differences between air and lake temperature generated large vapor pressure gradients. The relationship became stronger as lake temperature increased, due to physical principles dictated by the slope of the saturated vapor pressure-mean temperature curve (Fig. 5). The warmer conditions in 1991 stimulated greater vapor pressure gradients over the lake (Fig. 4), which resulted in greater Q_E. This is similar to the results in Rouse et al. (1987) who reported on a similar increase in evaporation with increasing air temperature for a sedge fen in the Churchill region. The enhancement of the latent heat flux for warmer conditions could also be due to the greater suppression of the sensible heat flux during the frequent inversion conditions of 1991 (Strub & Powell 1987).

Conclusions

Within the context of this study, our evidence indicates that both hypotheses appear valid. With a control on interacting variables, the vertical temperature and vapor pressure gradients increase with increasing air temperatures which, in turn, results in increased sensible and latent heat fluxes. With increasing atmospheric temperatures, sensible heat fluxes increase more rapidly than latent heat fluxes. Thus, shallow lakes respond fairly rapidly to atmospheric temperature changes, especially in the direct heating of the atmosphere. However, this response in advective situations depends on wind directional frequencies. Where wind directions change frequently, the response is greater than when they change less frequently.

Abstract

Mine waste-rock material is often a highly porous medium and it is an ideal environment to analyze the effect of natural and forced air convections on the waste-rock pile temperatures in permafrost regions. Two-dimensional finite element method is utilized to examine the behavior of different waste-rock piles. Forced convection as a function of air velocity is solved by applying the Navier-Stokes momentum equation and the continuity equation. Coupled thermal and air flow modeling of waste-rock piles is carried out for a period of 10 years. The cooling effect of the closed waste-rock piles mainly relies on gravity driven natural convection within the porous waste-rock layer, which is controlled by the thermal boundary condition. The cooling effect of the open waste-rock piles, on the other hand, is controlled by the cold temperature air flow that penetrates the pile. Preliminary results indicate that the center of the waste-rock piles will form a frozen core and an active layer of about 5 meters in approximately 2.2 years.

Keywords: convective heat transfer; natural convection; numerical simulation; waste-rock piles.

Introduction

Natural convection in fluid saturated porous media plays a key role in a wide range of technical applications, such as fluid flow in geothermal reservoirs, insulations, dispersion of chemical contaminants and migration of moisture in grain storage system. A comprehensive literature survey focusing on this subject is given by Nield & Bejan (1998).

Research on natural convection in permafrost regions has seen increasing attention by many researchers. Goering & Kumar (1996) investigated the characteristics of natural convection in porous rock embankments and showed significantly enhanced cooling effects in winter beneath these porous rock embankments. A large number of numerical models showed that natural convection during winter time can lower the foundation soil temperature by as much as 5°C on an annual average basis in comparison with standard sand or gravel embankments. In addition, researchers at the State Key Laboratory of Frozen Soil Engineering at the Chinese Academy of Sciences in Lanzhou have performed numerical and experimental studies on natural convection for the railway project on the Qinghai-Tibetan Plateau. Yu et al. (2003) investigated the cooling effect of coarse rock layers and fine rock layers under open-top and windy boundary in a laboratory investigation. Lai et. al. (2003) proposed the ripped-rock embankment structure on the Qinghai-Tibet railway under climatic warming by numerical simulation. Arenson et al. (2007) presented the results of numerical simulation of natural convection of waste-rock material, where the temperature at the base decreased from -4°C (conduction only) to -6°C due to convection.

In this work, numerical simulation of convection in waste-rock pile will be performed to evaluate the parameters that affect the convective heat transfer in coarse materials, namely wind, snow cover (boundary conditions), and internal intrinsic permeability of the waste-rock.

Governing Equations and Material Properties

Governing equations

Consider a fluid-saturated porous media with constant physical properties except for the density in the buoyancy force term, which is satisfied by the Boussinesq's approximation, thermal conductivity and volumetric heat capacity which are variation with temperature. Local thermal equilibrium is taken into consideration; e.g., the temperature of the fluid phase is equal to the temperature of the solid phase. The porous media is homogenous and isotropic. The flow of fluid within the porous media is governed by Darcy's law and the flow of fluid over the waste-rock pile is controlled by Navier-Stockes law with a Darcy term account

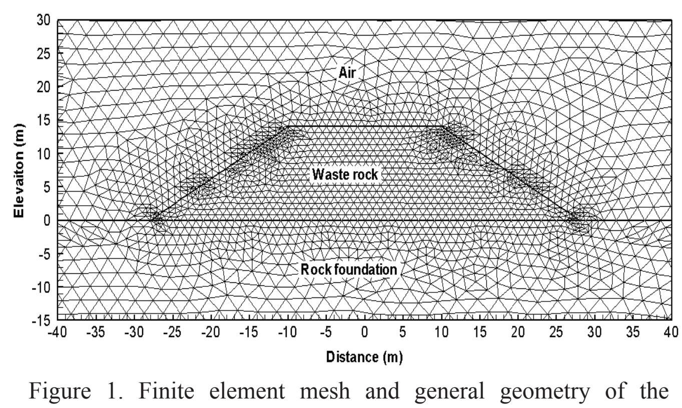

Figure 1. Finite element mesh and general geometry of the simulation.

for the effects of forced convection into the pile. Figure 1 shows the computational domain and mesh.

Conservation of mass:

$$\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}=0 \tag{1}$$

Conservation of momentum

- Fluid in porous media

Darcy's law

$$u=-\frac{K}{\mu}\frac{\partial P}{\partial x} \tag{2a}$$

$$v=-\frac{K}{\mu}\left[\frac{\partial P}{\partial y}-\rho_o g\beta(T-T_o)\right] \tag{2b}$$

- Free fluid flow

Navier-Stokes equation with Darcy's term

$$\rho\left(u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}\right)=-\frac{\partial P}{\partial x}+\mu\left(\frac{\partial^2 u}{\partial x^2}+\frac{\partial^2 u}{\partial y^2}\right)-\frac{\mu}{K}u \tag{3a}$$

$$\rho\left(u\frac{\partial v}{\partial x}+v\frac{\partial v}{\partial y}\right)=-\frac{\partial P}{\partial y}+\mu\left(\frac{\partial^2 v}{\partial x^2}+\frac{\partial^2 v}{\partial y^2}\right)-\frac{\mu}{K}v+\rho g\beta(T-T_o) \tag{3b}$$

Conservation of energy

$$\left(C_S+L\frac{\partial W_u}{\partial T}\right)\frac{\partial T}{\partial t}+C_a\left(u\frac{\partial T}{\partial x}+v\frac{\partial T}{\partial y}\right)= =\frac{\partial}{\partial x}\left(\lambda_x\frac{\partial T}{\partial x}\right)+\frac{\partial}{\partial y}\left(\lambda_y\frac{\partial T}{\partial y}\right) \tag{4}$$

where u and v are velocity in x, y direction; K is the intrinsic permeability; μ: dynamic viscosity; P: air pressure; ρ_O: air density; C_S: volumetric heat capacity of the waste-rock; C_a: volumetric heat capacity of air; L: latent heat of water; W_u: unfrozen water content; λ_x, λ_y: thermal conductivity in x, y direction; β: thermal expansion of air; T is temperature of solid and fluid.

We introduce the stream function ψ, expressed as:

$$u=\frac{\partial\psi}{\partial y} \tag{5a}$$

$$v=-\frac{\partial\psi}{\partial x} \tag{5b}$$

By substituting Equations (5a, 5b) into Equations (2a, 2b), and eliminating the pressure term, we obtain:

$$\frac{\partial}{\partial x}\left(\frac{\mu}{K}\frac{\partial\psi}{\partial x}\right)+\frac{\partial}{\partial y}\left(\frac{\mu}{K}\frac{\partial\psi}{\partial y}\right)=\rho_o\beta g\frac{\partial T}{\partial x} \tag{6}$$

By introducing the stream function, the conservation of mass in the porous media is automatically satisfied.

One of common methods to solve Equations (3a, 3b) is to eliminate the pressure terms through the penalty parameter γ. The method is called the penalty finite element method (Reddy & Gartling 2000).

$$P=-\gamma\left(\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}\right) \tag{7}$$

where $\gamma = 10^4 Re$ to $10^{12} Re$; Re is the Reynolds number.

To determine the effects of heat transfer, the local Nusselt number and Rayleigh number are defined as following:

The local Nusselt number on the base of the waste-rock

$$Nu_b=\frac{1}{L_b}\int_0^{L_b}\frac{\partial T}{\partial y}dx \tag{8}$$

The Rayleigh number of waste-rock

$$Ra=\frac{\rho_o g\beta C_a KH\Delta T}{\mu\lambda} \tag{9}$$

where L_b is the length of the base of the waste-rock pile; H is the height of the waste-rock pile.

The average Nusselt number on the base is defined as.

$$\overline{Nu}=\frac{\left(\frac{1}{L_b}\int_0^{L_b}\frac{\partial T}{\partial y}dx\right)_{convection}}{\left(\frac{1}{L_b}\int_0^{L_b}\frac{\partial T}{\partial y}dx\right)_{conduction}} \tag{10}$$

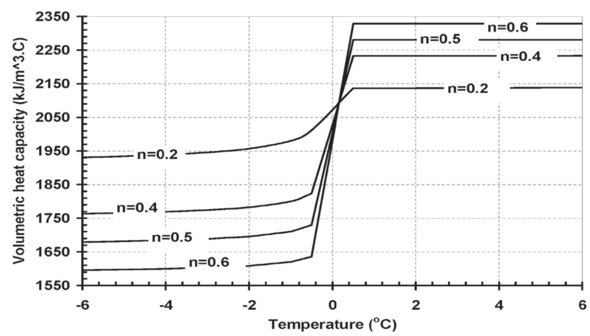

Figure 2. Relation between volumetric heat capacity and temperature with degree of saturation S = 0.6 and porosity n of the waste-rock material at the Diavik mine.

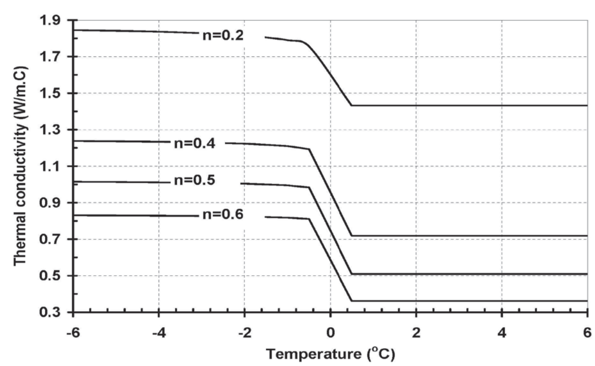

Figure 3. Relation between thermal conductivity and temperature with degree of the saturation S = 0.6 and porosity n of waste-rock material at the Diavik mine.

Material properties

The intrinsic permeability of the waste-rock material varies from 10^{-8} to $3x10^{-7}m^2$, based on calculation from grain size distribution resulting porosity between 0.3 and 0.5 and the degree of saturation is 0.6. A porosity n = 0.4 was chosen for this study.

Figure 2 shows a sharp change in volumetric heat capacity around the freezing point due to phase change of pore water. Similarly, the thermal conductivity changes with temperature as shown in Figure 3.

Additional parameters used are air density ρ_o = 1.293kg/m^3, dynamic viscosity μ = 1.49kg/mday, thermal expansion of air $\beta = 3.6710^{-3}$(C^{-1}), and volumetric heat capacity of air C_a = 1.3 kJ/m^{3}C.

Temperature variation with time is governed by the following equation with a mean average surface temperature of -4.8°C.

Ground temperature:

$$T = -4.8 + 17\sin\left(\frac{-2\pi t}{365} + \frac{17\pi}{180}\right) \tag{11}$$

Air temperature:

$$T = -9.5 + 28\sin\left(\frac{-2\pi t}{365} + \frac{17\pi}{180}\right) \tag{12}$$

Figure 4 shows that the wind velocity varies from 3m/s to 10m/s. Thus, this range was used to analyze the influence of forced convection on heat transfer in the waste-rock piles.

Numerical Results and Discussions

The strength and pattern of the convective heat transfer within a waste-rock depends mainly on geometry, intrinsic permeability of the waste-rock and the ambient temperature on the ground surfaces (Nield & Bejan 1999).

With impermeable surfaces (snow cover during winter), the influence of wind velocity is negligible and the motion of air is governed by natural convection.

With permeable surfaces during summer, the magnitude of the air velocity inside a waste-rock due to wind blow (forced convection) is mainly controlled by the intrinsic permeability of the waste material.

Table 1 and 2 show how the air velocity at the center axis of a waste-rock pile is strongly influenced by the intrinsic permeability based on the modeling in this study.

Results for impermeable surfaces of waste-rock piles

Figure 5a, b, c, and d show temperature distributions 10 years after construction. Figure 5a and b give similar temperature contours and the lowest temperature is -5.5°C. This can be explained by the fact that, under small intrinsic permeabilities ($1x10^{-8}$ and $3x10^{-8}$), heat transfer in waste-rock material is dominated by conduction; e.g., only dependent on the thermal conductivity of the material with small Rayleigh and Nusselt number. Furthermore, a 5-m active layer is formed normal to surface of the waste-rock and ground. In Figure 5c, temperatures at the base of the waste-rock pile are colder than in Figure 5a and 5b. This indicates an increase in the Rayleigh numbers and heat transfer via convection is developing. Figure 5d shows a significant change in temperature at the base in comparison with those shown in Figure 5a, b, and c. Temperatures drop from -5.5°C down to -8°C. This results from the increasing permeability. Furthermore, the unfrozen zone at the toe of the waste-rock decreases substantially.

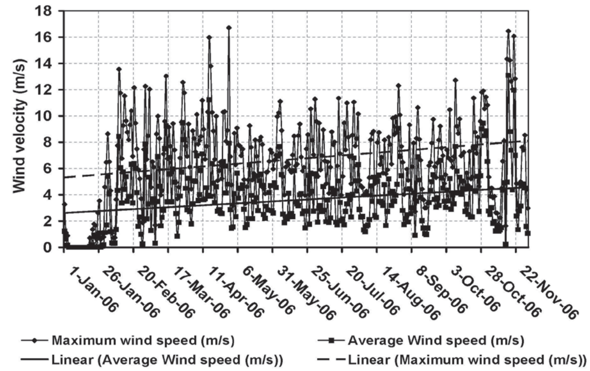

Figure 4. Wind velocity measured at the Diavik mine site.

Table 1. Air velocity inside waste-rock with $K = 1x10^{-8}m^2$.

Wind velocity (m/s)	Range of air velocity (m/s)
4	$3.13x10^{-5}$ – $3.59x10^{-5}$
5	$3.88x10^{-5}$ – $4.40x10^{-5}$
6	$4.51x10^{-5}$ – $5.21x10^{-5}$
8	$6.25x10^{-5}$ – $6.94x10^{-5}$
10	$7.75x10^{-5}$ – $8.68x10^{-5}$

Table 2. Air velocity inside waste-rock with $K = 3x10^{-7}m^2$.

Wind velocity (m/s)	Range of air velocity (m/s)
4	$9.38x10^{-4}$ – $1.05x10^{-3}$
5	$1.16x10^{-3}$ – $1.31x10^{-3}$
6	$1.40x10^{-3}$ – $1.57x10^{-3}$
8	$1.88x10^{-3}$ – $2.11x10^{-3}$
10	$2.31x10^{-3}$ – $2.60x10^{-3}$

Figure 6a, b, c, and d indicate the variation in temperature with time for selected points within the pile. Those points are used to determine when a 5-m active layer forms.

With $K = 1x10^{-8}$ and $3x10^{-8}$, there is no difference in time as conduction dominates the heat transfer and this process is controlled by thermal conductivity. A frozen core forms after 800 *days* following construction as shown in Figure 6a and b. In addition, heat transfer approaches nearly steady state after around 2000 *days*.

In Figure 6c, the time required to form a frozen core is about 780 *days;* i.e., 20 *days* earlier than shown in Figure 6a, 6b. These 20 *days* reduction are due to convective heat transfer, however, conduction still dominates the heat transfer in the waste-rock with $K = 1x10^{-7}$.

Four hundred and fifty *days* is the time required to form this frozen core as with $K = 3x10^{-7}m^2$ (Fig. 6d). Note that the temperature at the base drops rapidly, and after about 200 *days*, it is below the freezing point (0°C). Convective heat transfer dominates with high Rayleigh and Nusselt numbers.

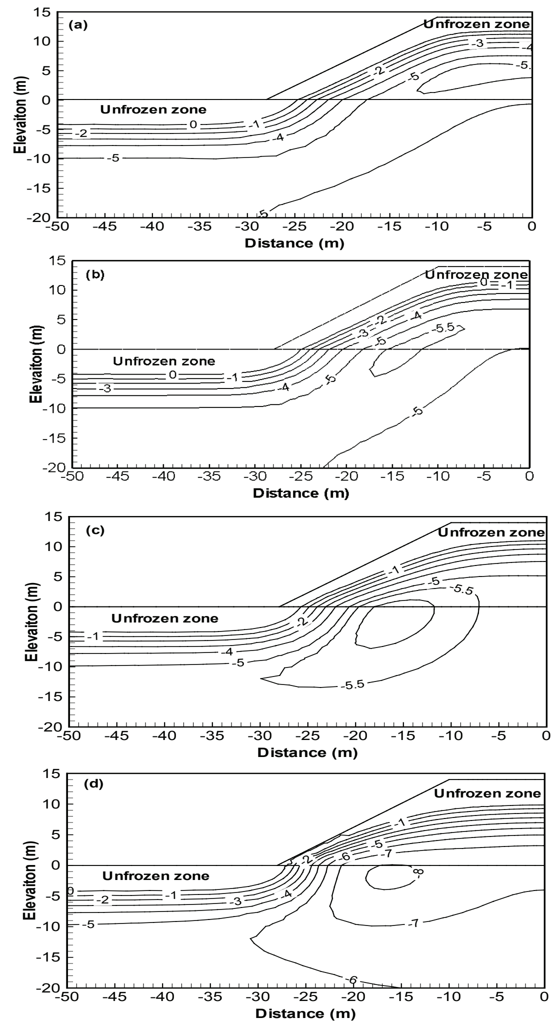

Figure 5. Temperature distribution after 10 *years*, impermeable boundary surfaces with (a) K = 1x10^{-8}, (b) K = 3x10^{-8}, (c) K = 1x10^{-7}, (d) K = 3x10^{-7}.

Just a small change in permeability K = 1x10^{-7} to 3x10^{-7} changes the temperature at point H from -4°C to -6°C after 1.5 *years* (Fig. 7). This establishes the importance of the Rayleigh being greater than a critical value; the convective heat transfer accelerates changing the temperatures. In Figure 7, measured temperatures from the Diavik mine site match the temperature for K = 3x10^{-7}.

The measured temperature from the site shows that the heat transfer in the waste-rock is dominated by convection and the selected intrinsic permeability, thermal conductivity and volumetric capacity are close to the in situ values. However, long-term measurements at the base and inside of the waste-rock pile are needed to confirm these.

They are small at low values of K = 1x10^{-8} – 3x10^{-8}, thus conduction dominates the heat transfer (Fig. 8). The amount of heat extracted from the base is small, and temperatures at the base change slowly. There is a "jump" in the Nusselt number by changing K from 1x10^{-7} to 3x10^{-7}. Therefore, it can be concluded that a small variation in K, assuming the corresponding Rayleigh number is larger than a critical value, will produce significant changes in Nusselt number which controls the heat transfer rate.

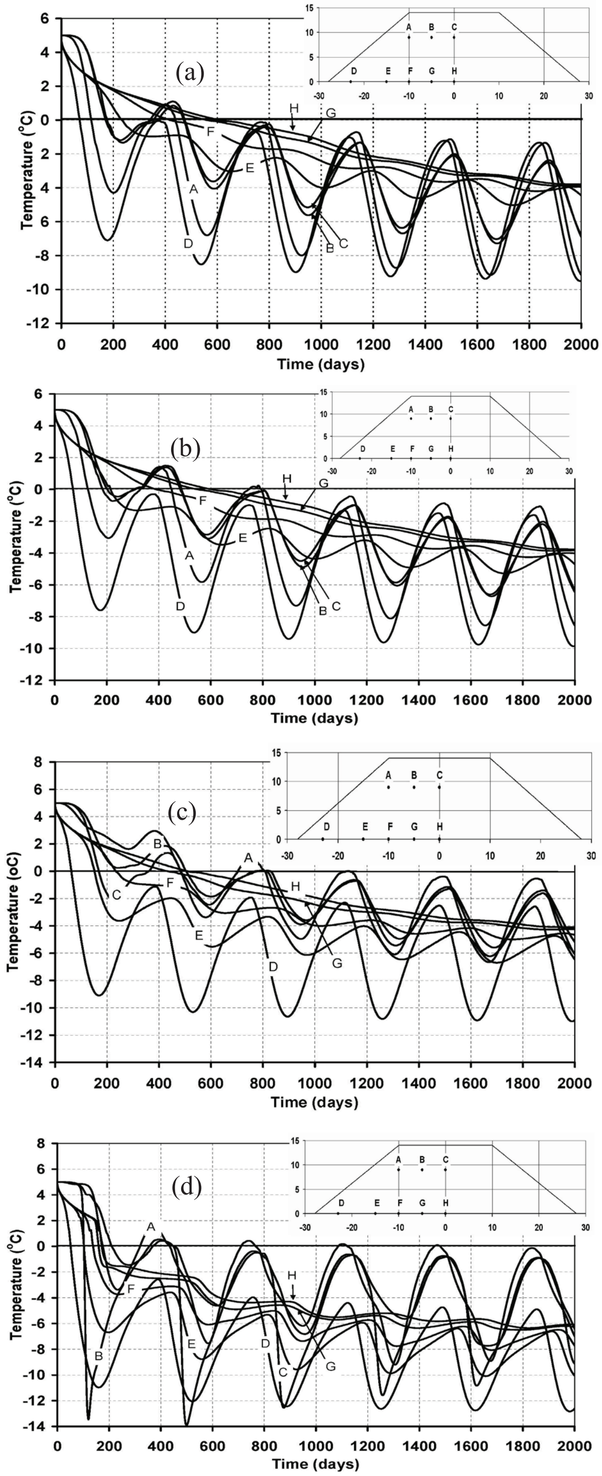

Figure 6. Temperature with time at particular points for K = 1x10^{-8} (a), 3x10^{-8} (b), 1x10^{-7} (c), 3x10^{-7} (c), respectively.

There is a significant change in Rayleigh number when K varies from 1x10^{-7} to 3x10^{-7} and thus the heat transfer rate as indicated in Figure 9. However, there is no significant change in Rayleigh numbers when K changes from 1x10^{-8} to 3x10^{-8} because these values produce a Rayleigh number smaller than the critical value. Zero values of Rayleigh number with K = 1x10^{-7} and 3x10^{-7}m^2 happen during summer when conduction dominates. Critical Rayleigh number is

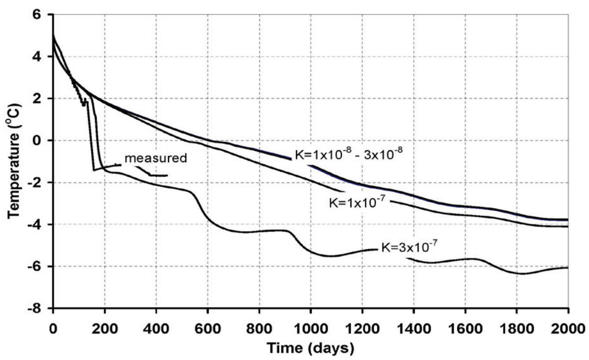

Figure 7. Temperature variation at point H (central point waste-rock pile).

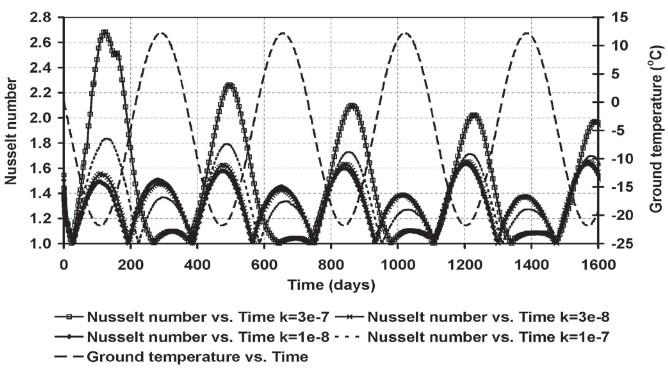

Figure 8. Variation of local Nusselt number (Eq. 8) versus time with K = 1x10^{-8}, 3x10^{-8}, 1x10^{-7} and 3x10^{-7}.

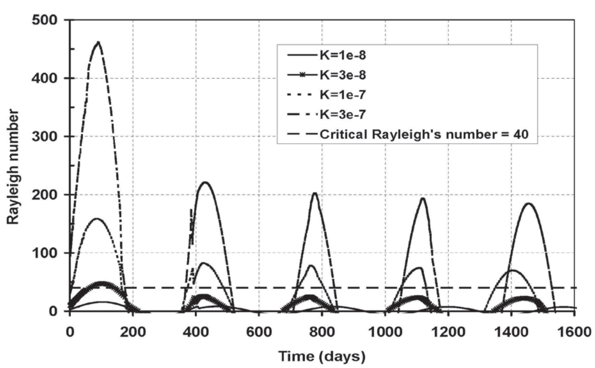

Figure 9. Variation of Rayleigh number with time.

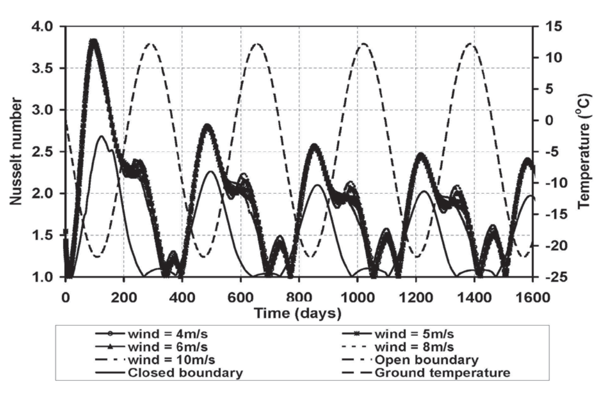

Figure 10. Variation of local Nusselt number with time in the case of open boundary with K = 3x10^{-7}.

defined as $Ra_{cr} = 4p^2$ when the conduction state is unstable or an average Nusselt number larger than 1 (Nield & Bejan 1999).

Results for permeable surfaces of waste-rock pile

With permeable surfaces, the heat transfer rate, which is represented by the Nusselt number, does not change for wind velocity up to 10m/s with K = 3x10^{-7}m^2 (Fig. 10). However, there is a large change in the Nusselt number when moving from a closed to an open boundary. Thus, with open surfaces, heat transfer rate into the waste-rock pile does not change due to change in wind velocity of the environment with K up to 3x10^{-7}.

With a small value of K = 1x10^{-8}m^2, there is only a very small change in the local Nusselt number when the wind velocity changes up to 10 m/s in the case of an open boundary condition or a closed boundary condition. Because with small values of K, the air velocity due to forced convection and natural convection is very small, and thus, convective heat transfer is not significant compared to conductive heat transfer.

Conclusions

Heat transfers in the waste-rock pile are investigated using numerical modeling for two-dimensional momentum, continuity, and energy equations. The results are compared to measured temperatures at the Diavik mine site.

The following conclusions can be drawn from the analysis presented:

- The value of intrinsic permeability has a large impact on the heat transfer in waste-rock materials with Rayleigh's number larger than a critical value. However, with small Rayleigh numbers (conduction dominates), heat transfer does not depend on the intrinsic permeability. With K = 3x10^{-7}m^2 (convection dominates), temperature at the base of a 14-m-high waste-rock pile is about -6°C instead of -4°C for K below 1x10^{-8} to 1x10^{-7}m^2.
- When the Rayleigh number is larger than a critical value, a small increase in K results in a significant increase in the Nusselt and Rayleigh number and thus, heat transfer rates due to convection also increase rapidly.
- Heat transfer becomes steady after 6 years for these studies independent on K. A frozen core with a 5-m active layer is formed after 800 days with K = 1x10^{-8} to 1x10^{-7}m^2 and 450 *days* with K = 3x10^{-7}m^2.
- The influence of the wind velocity on the heat transfer in waste-rock piles with open boundary conditions is not significant when the value of K is below 3x10^{-7} m^2. However, there is a rapid change in the heat transfer due to the conditions of the surface of a waste-rock pile (open or closed boundary) at high values of K.
- A comparison with measurements from the Diavik mine site confirmed the convection within the waste-rock pile, and good agreement was achieved by using an intrinsic permeability of 3x10-7 m^2. However, more data are required to confirm this initial comparison.

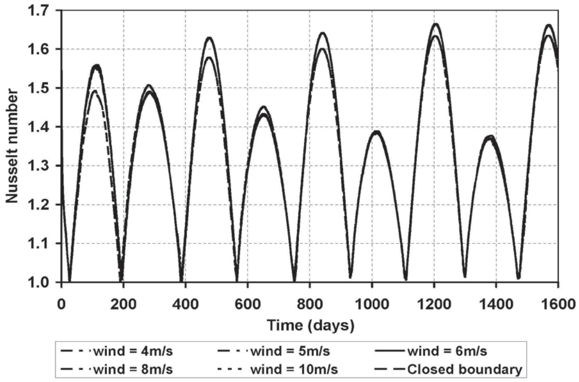

Figure 11. Variation of local Nusselt number with time in the case of open boundary with $K = 1x10^{-8}$.

The results presented clearly confirm reports on convective heat transfer made for arctic waste-rock piles, where temperatures measured within these coarse piles cannot be explained by conduction alone. Numerical modeling showed that once a critical Rayleigh number is reached, significant cooling at the base occurs. However, additional modeling and field data are required to study the combination in parameters and boundary conditions necessary to further convection in waste-rock piles.

Acknowledgments

This research is made possible through funding provided by Diavik Diamond Mines Inc. (DDMI), the Canada Foundation for Innovation (CFI), the Natural Science and Engineering Research Council of Canada (NSERC), the International Network for Acid Prevention (INAP), and the Mine Environment Neutral Drainage (MEND) program. In-kind support provided by Environment Canada is greatly appreciated. We thank Carol Ptacek (Environment Canada), and FDA Engineering for their technical support and patience during the construction phase.

Effects of Ground Temperature and Slope Deformation on the Service Life of Snow-Supporting Structures in Mountain Permafrost: Wisse Schijen, Randa, Swiss Alps

Marcia Phillips
Swiss Federal Institute for Snow and Avalanche Research WSL-SLF
Stefan Margreth
Swiss Federal Institute for Snow and Avalanche Research WSL-SLF

Abstract

Modifications of ground temperature are of special interest in alpine permafrost regions, as the thermal properties of the permafrost influence the geotechnical characteristics of the ground and thus the stability and service life of mountain infrastructure. Air temperatures have been particularly warm in the past decade in the Swiss Alps, leading to various occurrences of slope and structure instability. The case of snow-supporting structures (snow nets) located on a steep slope in alpine permafrost is presented. Some of the structures have undergone such strong deformation that they must be replaced after only 17 years, as opposed to a service life of ~80 years under normal conditions. Borehole temperature and deformation measurements and surveys of the positions of the snow nets show that creep is particularly pronounced during hot summers in steep slope sectors. Technical solutions include the use of floating foundations and of construction techniques specially adapted to permafrost conditions.

Keywords: creep; floating foundations; mountain permafrost; service life; snow nets; technical solutions.

Introduction

Modifications of permafrost conditions and in particular warming and thawing of near-surface ground ice and active layer thickening can have devastating effects on the stability and service life of infrastructure in mountain permafrost regions (Haeberli 1992, Harris et al. 2001). Thaw subsidence, differential settlement, or heave and enhanced creep rates are particularly problematic for alpine infrastructure that is partly or completely anchored in sediments or bedrock containing ice (Phillips et al. 2007), especially in steep terrain. Alpine infrastructure typically includes structures such as cable-car stations, pylons, water pipes, shelters, and snow-supporting structures—many with high safety requirements. The service life of snow-supporting structures in creeping permafrost is the focus of this paper.

The past decade was characterized by a number of abnormal climatic events in the Swiss Alps. Seven of the last 10 years were among the 10 warmest registered since 1900. The warming was generally more pronounced in summer than in winter. The most extreme event was summer 2003, which was 4–5.5°C warmer than average and was the hottest measured since 1753 (MeteoSchweiz (annual reports), North et al. 2007). Mean annual snow depths varied strongly, with some very snow-rich winters (e.g., 1998/1999, 2000/2001) or winters with very little snow (e.g., 2001/2002, 2004/2005). It is not yet possible to determine trends in snow depth at altitudes where permafrost occurs (Marty et al. 2007).

In parallel to observations of slope and rock wall instability (Gruber et al. 2004, Gruber & Haeberli 2007, Springman et al. 2003), reports of structure instability in permafrost in the Alps during this warm decade have increased (e.g., Personal communications P. Feuz, C. Danioth, M. Walser, H.-R. Keusen). Alongside direct monitoring of the structures themselves (Phillips et al. 2003, Steiner et al. 1996, Vonder Mühll & Keusen 1995), the long-term monitoring of ground temperatures and deformation rates is essential to understand the current and future nature of these developments and the influence of factors such as climate fluctuations, construction activity, or the very presence of infrastructure. Improvements of design and service life are consequently the aim of such observations.

This paper presents borehole data (temperatures and deformation) and displacement data for snow-supporting structures (snow nets) that have undergone such strong creep-induced deformation that partial reconstruction is planned for 2008, only 17 years after their construction.

Site Description

The study site Wisse Schijen is a steep east-northeast-oriented slope located between 3010 and 3140 m a.s.l. in the Mattertal, above Randa (Canton Valais, Switzerland). Permafrost occurs in almost the entire slope (Keller 1995, Phillips et al. 2003). Slope angles range between 37 and 42°. The blocky scree is 2.5 m thick (gneiss, quartzite and marble), underlain by approximately 0.5 m of ice-rich sediments and finally by bedrock. There are narrow bands of bedrock visible in places and these are subject to flexular toppling, causing rockfall.

Wisse Schijen is an avalanche-starting zone, equipped with snow nets to protect Randa. There are several rows of snow bridges (rigid avalanche defense structures) below the area protected with snow nets, which would be destroyed if the latter were damaged or removed, and consequently, avalanches would break loose (Fig. 1).

Eight horizontal rows of snow nets between 24.5 and 45.5 m long and with a structure height of 4.0 m were built at Wisse Schijen in 1990 (upper rows 1–4) and 1991 (lower rows 5–8). The snow nets consist of triangular wire rope

Figure 1. The study site Wisse Schijen with 8 rows of snow nets is located in the upper part of the slope (outlined). Row 2 is shown inset. Several rows of snow bridges are visible in the slope sector below.

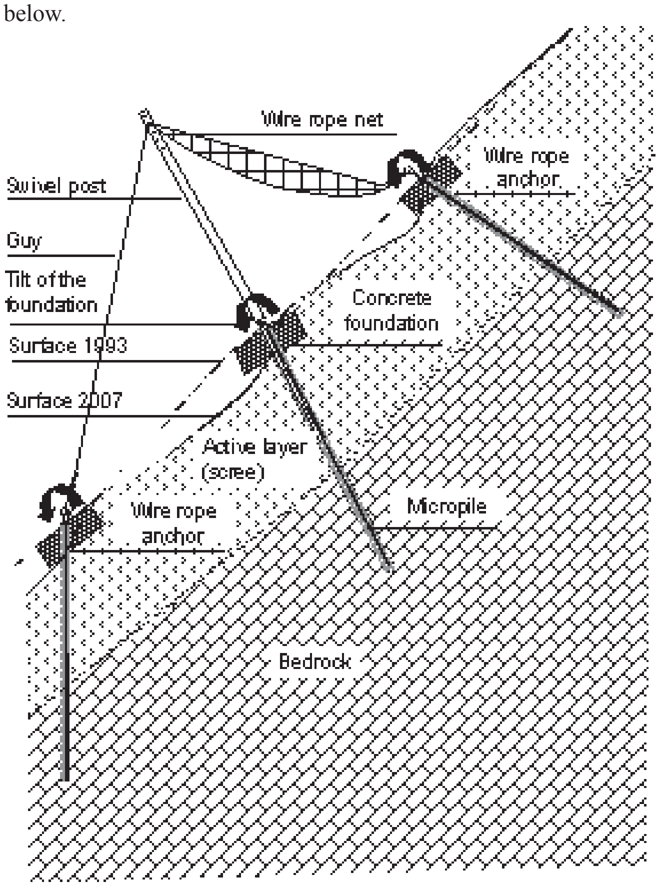

Figure 2 Configuration of the snow nets used. The location of the ground surface in 1993 and 2007 and the direction of tilt of the foundations are shown.

nets, which are attached to swivel supports with a ball joint at the contact to the base plate (Fig. 2).

The support and anchor spacing distance is 3.5 m. The structures are anchored with micropiles consisting of steel tubes (Ø 76 mm, length 1.5 m) and anchor bars (Ø 32 mm) under the supports and with wire rope anchors for the up- and downslope anchors. Concrete foundations were built to facilitate drilling and to stabilize the anchor heads. The anchor boreholes (Ø 100 mm) were drilled through these foundations rather than directly into the unstable scree.

Anchor lengths are 5 m and the anchors penetrate the bedrock. Large amounts of anchor grout were used (up to 30 kg m^{-1} (Personal communication, R. Bumann)) due to the large voids in the scree.

Snow nets were chosen for this sector of the slope (as opposed to snow bridges) because they are better adapted to rockfall. No specific construction methods were applied for permafrost conditions (e.g., the preheating of anchor grout to prevent freezing during the curing process as recommended by Margreth (2007)) or creep.

Two boreholes (B1 and B2) were drilled in 1998 when it became obvious that there were permafrost-related stability problems on the site. B1 is between net rows 5 and 6 (3046 m a.s.l.), B2 is between rows 7 and 8 (3019 m). A third, B3 is located between the top two rows of snow bridges (2953 m a.s.l.), where there is no occurrence of permafrost. All three boreholes are equipped with inclinometer tubes and borehole temperatures are measured in B1 and B2. The boreholes are shallow (6 m) due to various technical problems that arose during drilling.

Methods

Air temperatures and snow depth

Air temperatures and snow depth were measured by an automatic weather station (STN 2, Oberer Stelligletscher) located at 2910 m a.s.l., above St. Niklaus, 8 km away from the study site, on the same side of the valley. There is no weather station on the site itself. The snow data in particular therefore only gives a rough indication of the conditions in the area (e.g., if a winter was snow-rich or not).

Ground temperatures

Universal Temperature Loggers (UTL/Hobo) were used to measure borehole temperatures at five depths (0.5, 1, 2, 3, 4 m) in B1 and B2 (precision 0.25°C). Measurements were carried out hourly and were started in 2001.

Borehole deformations

The boreholes are equipped with inclinometer tubes, and measurements are effected using a Sinco Digitilt inclinometer (precision ±0.15 mm m^{-1}). The measurements were made at 1-m intervals and were carried out once a year (summer 1999–2007), which implies that data covers the second half of the previous summer period and the first half of the current one. Permanent borehole deformation measurements effected at a similar site in the eastern Swiss Alps (Rist 2007, in press) have shown that no deformation whatsoever occurs in winter; all movement ceases when the active layer freezes and only recommences when the latter thaws due to snowmelt infiltration in spring.

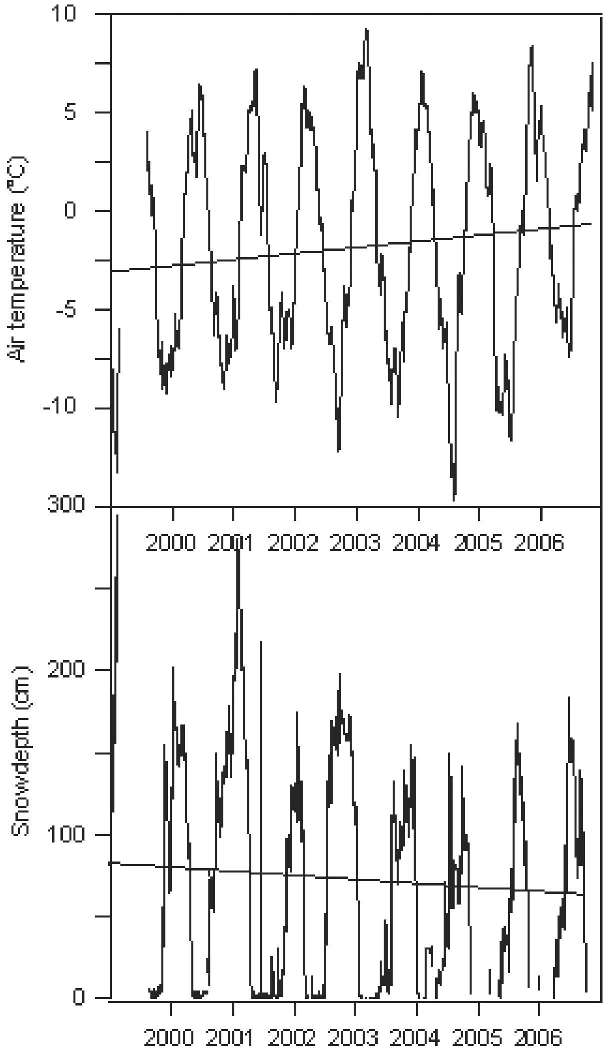

Figure 3. Air temperature (30-day running means) (top) and snow depth measured (bottom) by the automatic weather station STN2 (Stelligletscher, 2910 m, 1999–2007). Trends are shown.

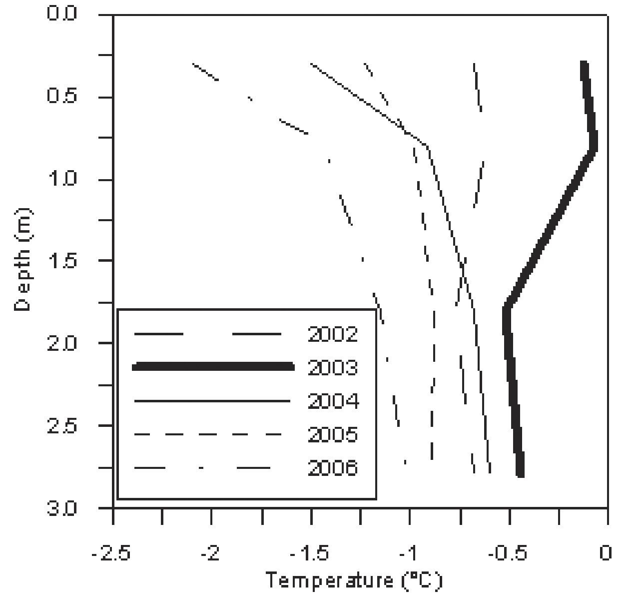

Figure 4a. Mean annual vertical temperature distribution in borehole B1.

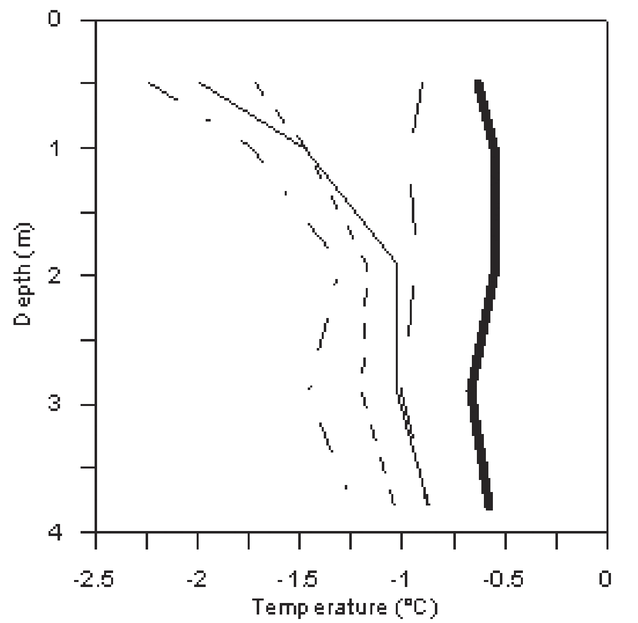

Figure 4b. Mean annual vertical temperature distribution in borehole B2 (same legend as Fig. 4a).

Structure stability

The position of 48 anchor heads was surveyed (1999–2007) using a Wild TC 1610 theodolite (precision ±2 mm). Both horizontal and vertical displacements were measured. The measurements were carried out once a year (summer), which implies that data covers the second half of the previous summer period and the first half of the current one and that the influence of the previous winter (e.g., particularly large snow loads on snow nets, meltwater in spring) must be taken into account.

Visual inspection

The 8 rows of nets were systematically inspected and photographed every summer, and problems recorded and reported. The visual observations include the inspection of row geometry, of the state of the foundations and of the superstructure. Any damage induced by differential creep or settlement, rockfall and surface erosion is assessed according to Margreth (2007).

Results

Air temperature and snow depth

Mean annual air temperature measured by the automatic weather station STN2 during the period 1999–2006 was -1.9°C. Figure 3 (top) shows the 30-day running means for air temperature. Summers 2003 and 2006 were particularly warm, with high thawing degree-days during the snow-free period (744 and 654, respectively, as opposed to a mean of 428 for all other years, see Fig. 5).

Mean snow depth during the period 1999–2006 was 70 cm. Winter 2000–2001 was snow-rich, with snow depths up to 270 cm. In contrast, shallow snow covers characterized winters 2004–2005 and 2005–2006 (Fig. 3, bottom).

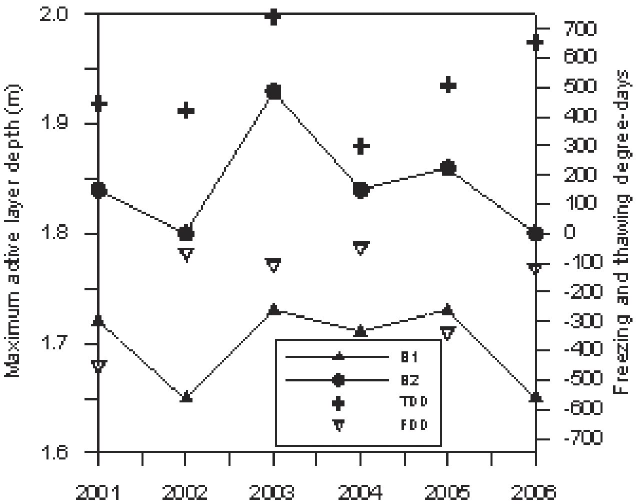

Figure 5. Maximum annual active layer depths measured in B1 and B2 (2001–2006) and thawing- (TDD) and freezing degree-days (FDD) during the annual snow-free period (right y axis).

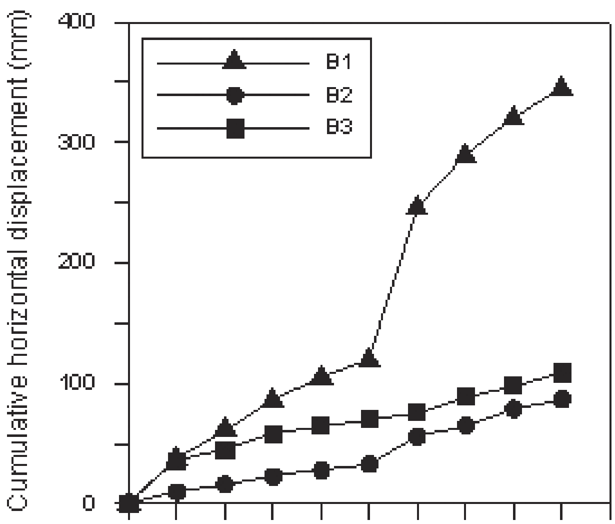

Figure 6. Cumulative displacement (mm) at 1 m depth in boreholes B1, B2, and B3 (1998–2007).

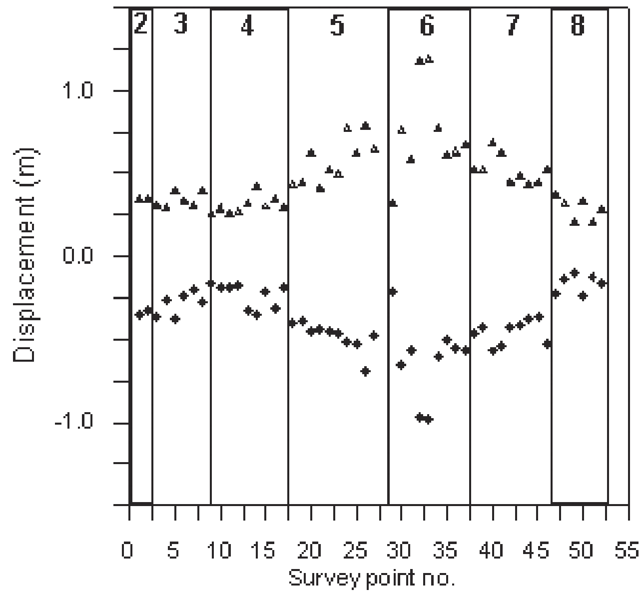

Figure 7. Mean horizontal (triangles) and vertical (diamonds) displacements of 52 anchor heads between 1999 and 2007. The snow net row numbers are indicated in bold.

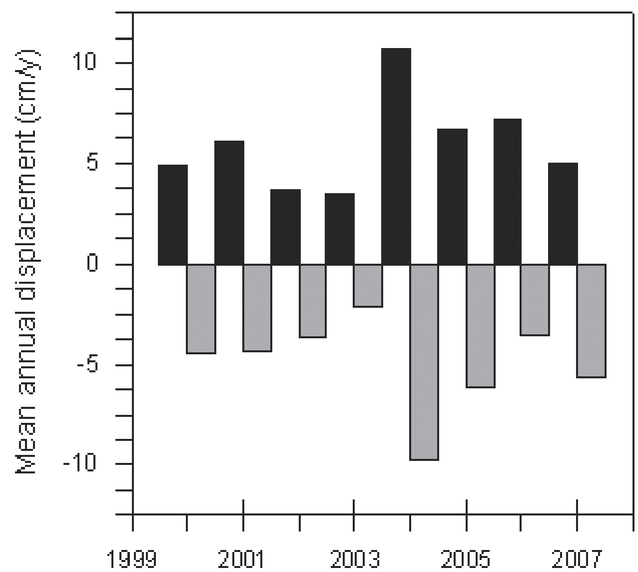

Figure 8. Mean annual horizontal (black) and vertical (grey) displacement of the anchor heads.

Ground temperatures

Borehole temperatures measured in B1 and B2 indicate that B1 is slightly warmer, despite being at a higher altitude. The mean annual temperature was warmest in 2003 in both boreholes (Figs. 4a, b). Shallow snow covers probably cause the slight cooling trend after 2003.

Maximum annual active layer depths are shown in Figure 5. The base of the active layer is defined here as being the depth of maximum seasonal penetration of the 0°C isotherm into the ground (Burn 1998). Mean active layer depth in B1 is 1.70 m and 1.85 m in B2. Active layer depths remained fairly constant throughout the measurement period, with a slight deepening in B2 (9 cm deeper than average) in summer 2003.

Borehole deformations

The cumulative horizontal displacements measured at 1 m depth (Fig. 6) indicate that the yearly displacements were quite regular, with the exception of the measurement period 2003–2004, during which a pronounced deformation of 126 mm occurred in B1 and a slight increase is also visible in B2. It should be noted that B1 is located between the damaged snow net rows 5 and 6. From 2005 onwards, it was no longer possible to measure deeper than 1.8 m in B1, as the inclinometer tube was too strongly deformed.

Structure stability

During the measurement period 1999–2007, the horizontal displacements of the anchor heads varied between 0.2 and 1.2 m (average 0.47 m) and the vertical displacements between -0.1 and -0.97 m (average -0.38 m). Displacements exceeding 0.5 m occurred in the net rows 5, 6 and 7 (Fig. 7). Mean

Figure 9a. Dislocated swivel support (left). Fig. 9b. Tipped concrete foundation (right) in the damaged snow net rows 5 and 6.

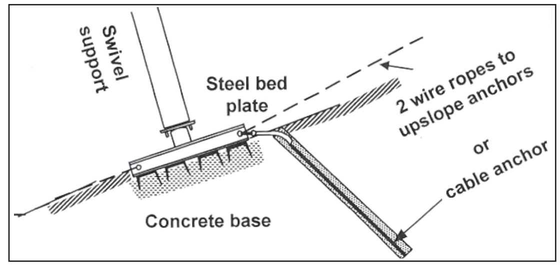

Figure 10. Floating foundation for snow nets in creeping permafrost conditions: steel bed plate on a base of lean concrete.

annual displacement velocities of the anchor heads varied from year to year. In the measurement period 2003–2004, they were particularly pronounced with mean displacements of 10.7 cm and -9.7 cm, respectively (Fig. 8).

Visual inspection

The problems observed at the study site include:

- Disturbed geometry of entire rows of nets, which can lead to uneven snow loading and to elevated constraints in the superstructure.
- Tipping of the base plates, leading to a blockage of the ball joint and to dislocation of swivel supports (Fig. 9a).
- Downslope tipping of the concrete foundations (Fig. 9b).
- Surface erosion and settlement of several decimeters causing anchor tendon exposure, which can lead to buckling or failure.
- Rockfall into the nets.

It is not known whether the anchor tendons are deformed or have undergone failure.

The assessment of the state of the snow nets has shown that all rows with the exception of rows 5 and 6 are in Condition Class 2 ("Damaged"). This implies that repairs are moderately urgent (within 1–3 years), and there is no immediate impairment for the serviceability of the structures. Rows 5 and 6 are, however, in Condition Class 3 ("Poor") (Margreth 2007) and repairs are very urgent, as there is a danger of collapse and their supporting function is no longer warranted.

Discussion

State of the permafrost, slope, and structure stability

As the deformation and displacement measurements occur in mid-summer, it is difficult to attribute movements to a particular cause. However, borehole deformations (in B1) and structure movements were significantly higher in the measurement period 2003–2004. They cannot be attributed to a significant deepening of the active layer or to a snow-rich winter. The mean annual borehole temperatures (January 1 to December 31) show that 2003 was the warmest year at all depths (Figs. 4a, b), and this seems to have influenced the creep rates. Creep rates remained constant in B3 where creep is not temperature-dependant (non-permafrost).

Not only the thickness of the active layer can vary, but also its position relative to the underlying stratigraphy (e.g., downward extension of the active layer into finer, ice-rich sediments due to warming or to settlement), which can augment the potential for slope instability (Rist 2007, in press). The degree of exposure of the micropiles and foundations (up to 0.4 m) indicates that settlement has occurred in places due to loss of permafrost ice. The exact amount and rate of settlement is difficult to quantify however, because scree is constantly eroded and replaced from upslope.

The presence of 300 foundations in the slope may have a slight stabilizing effect at a very local scale, as is shown by the accumulation of material directly above the foundations. However, this may be countered by the fact that there is more snowmelt water in spring due to the artificial retention of snow on the slope. The slope, therefore, cannot be characterized as being more stable due to the presence of the snow nets.

Technical solutions

The anchor heads have undergone substantial displacement from the start—in the first year after construction-isolated damages were visible (Stoffel 1995). Two rows of snow nets (5 and 6, located in the steepest sector) have now been subjected to such intense creep-induced deformation that their replacement is planned for 2008.

Under normal conditions snow nets have an expected service life of 80 years. The mid- and long-term service life of the structures are however not assured with creep rates exceeding 5 cm/year (Margreth 2007). The data presented above helps to explain the remarkably short service life of the snow nets at the study site. Whereas various problems are visible in the superstructure, the current state of the anchors is unknown. It is possible that deformation or failure of the micropiles and wire rope anchors has occurred in places and that collapse may be imminent. In order to ensure protection against avalanches, it is therefore necessary to replace the most badly damaged rows of nets (5 and 6) as soon as possible and to monitor the remaining rows carefully.

In order to improve the service life of the new structures in this highly unstable terrain, floating foundations will be used under the swivel posts, rather than fixed ones (Fig. 10). Steel bed plates on a base of lean concrete have been tested in similar terrain and proved to be well-adapted (Phillips 2006). If necessary, they can be readjusted relatively easily, whereas the replacement of fixed anchors is hardly possible. In addition, specially adapted construction techniques will be used, as recommended for permafrost terrain (Margreth 2007).

As a result of the experience gained with the snow nets in the Wisse Schijen sector, the neighboring avalanche slopes are triggered artificially. Special reinforcement measures against snow avalanches will be met for potentially affected infrastructure in the valley.

Conclusions

Wisse Schijen is a site with particularly difficult conditions for snow-supporting structures. The creep rates in the steep permafrost slope can exceed 5 cm/year, particularly in hot summers, implying that mid- and long-term service life is not ensured. In such cases the construction of snow-supporting structures is only advisable if no alternatives are available (Margreth 2007). In this particular case, it is not possible to build an avalanche retention dam to protect the village due to lack of space at the base of the avalanche slope. In addition, there are snow bridges below that must be protected. It is necessary, therefore, to replace the most strongly damaged structures (rows 5 and 6) as soon as possible and to use floating foundations rather than fixed ones under the supports. In addition, permafrost-specific construction methods must be used (Margreth 2007). It is advisable to continue monitoring ground temperature, slope deformation and the position of the snow nets in order to determine the effects of short- and long-term climate fluctuations on the stability and service life of the structures. The state of the snow nets on the study site is surprisingly good in view of the difficult conditions; rigid steel snow bridges would probably have had much more severe damages and an even shorter service life.

Acknowledgments

The authors would like to thank the Swiss Canton Valais for the financial support of the project and in particular Charly Wuilloud, Head of Natural Hazards in Valais and Leo Jörger, mayor of Randa. Klaus Aufdenblatten and his team carried out the surveys of the snow nets, and Herman Rovina and Damian Gitz carried out the borehole inclinometer measurements—all under difficult terrain conditions, for which they are sincerely thanked. Christian Bommer and two anonymous reviewers provided useful comments.

Abstract

The Study of Northern Alaska Coastal Systems project provided the opportunity to examine cryogenic soils and permafrost features using exposed bluffs along the coastline. More than 50 study sites were selected along the 1,957 km coastline of the Beaufort Sea. The soil exposures that were sampled represent the soils and permafrost in similar landforms with similar microtopography and permafrost features 20–50 miles inland. Nearly all the soil profiles described along the exposed bluffs and drilled cores from deltas were classified in the Histel, Turbel, and Orthel suborders of the Gelisol order. The presence and depth of ice wedges, cryturbation features, gleyed horizons, and the abundance of organic matter differentiated the soils into great groups and subgroups. Soil morphological features suggest the multigenic origin of soil carbon. Classification of soils associated with different microtopography will facilitate soil mapping on the Arctic Coastal Plain.

Keywords: arctic tundra; coastal erosion; Gelisols; soil classification.

Introduction

A soils map is an important tool needed for land resource management. A detailed soils map is greatly needed for ecosystem/land management, land-based research, and most recently, accurate estimation of terrestrial carbon stock and other major and minor nutrients levels. The currently existing soils map of arctic Alaska was based on an exploratory survey (Reiger 1979) and was mapped at a scale of 1:1,000,000, much too crude for site-specific resource management. Thus, the National Cooperative Soil Survey in Alaska is planning a soil project for arctic Alaska which involves the cooperation and partnership of federal and state, the University of Alaska Fairbanks and all other interested parties. Most soils in the arctic tundra are cryoturbated. To correctly describe and classify the soils it is necessary to observe the soil profile under the whole cycle of patterned ground (Agriculture Canada Expert Committee on Soil Survey 1998, Kimble et al. 1993). However, based on past experience (Ping et al. 1998), soil inventory in the permafrost regions is time consuming and usually limited to shallow depths due to logistical limitations. Because of the nearly flat or very gentle slopes of the Arctic Coastal Plain (Brown & Kreig 1983), the landforms at different segments of the coast extend inland for 10s of km. Thus, the soils information gained from the coastal bluffs can be extrapolated to similar landforms inland.

The study of arctic coastal erosion and the fate and transformation of soil carbon, which is a component of the Study of Northern Alaska Coastal Systems (Jorgenson et al. 2005), provided pedologists with the opportunity to study the soils on wide and deep coastal exposures along the Beaufort Sea coast. The project was designed to study the carbon flux and transformation and material transfer across the land-sea boundary across 1,957 km of coastline of the Beaufort Sea (Jorgenson & Brown 2005, Jorgenson et al. 2005).

Along the Beaufort Sea coast, there are five types of coastal exposure identified by Jorgenson & Brown (2005): deep bays and inlets, deltas, exposed bluffs, lagoons, and tapped basins. Deep bay and inlets are composed of ice-rich marine silt and are most common in the western portion of the coast. The landforms resulted from coalescence of large lakes and subsequent flooding during sea level rise in mid-late Holocene. The bluff heights are 2–3 m. Large and small deltas are found across the Beaufort Sea coast. Exposed bluffs occur primarily along the western and eastern portion of the study area. Bluff heights range from 2–4 m. The reworked marine silt of early Holocene to late Pleistocene on the western part is ice-rich, about 20% ice wedges by volume. The late Pleistocene sand deposit in the middle part is ice-poor. Lagoons are bordered seaward by barrier islands, thus the erosion rates are lowest among the above-mentioned coastal types. The lagoons have the same exposures as that of the exposed bluffs. Tapped basins occur in ice-rich marine silt in the western portion of the coast. This type is characterized by large thaw lakes with raised ridges between them. Ice wedge contents increase with age up to 20% in older surfaces.

Methods

A total of 50 extensive study sites were systematically distributed along the 1,957 km of Beaufort Sea mainland coast. The sites included all five coastal types. At each site, geomorphic characteristics, surface cryogenic features, shoreline morphology, and land cover types were recorded. A vertical face along the coastal bluffs was cleaned to expose the soil profile and the ground ice stratigraphy. At

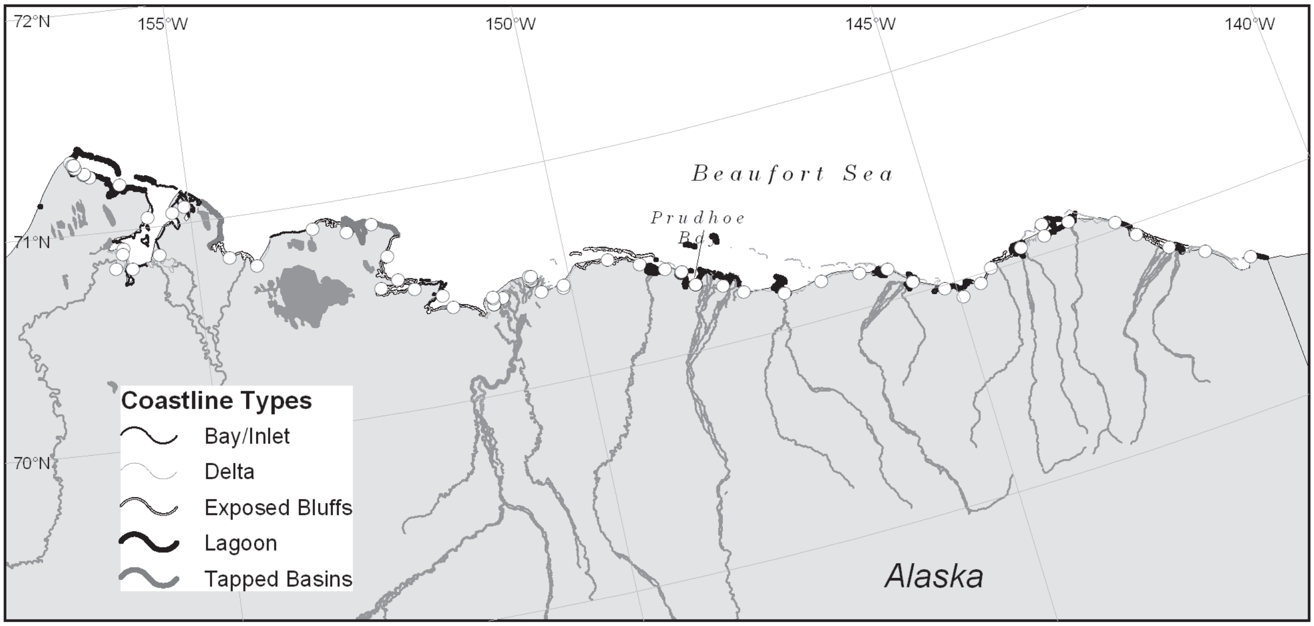

Figure 1. Five types of coastal exposure along the Beaufort Sea Coast.

sites along the thawed lake sequence, which were nearly all sea-level deltas, soil pits were excavated to the top of seasonal frost then a 7.5 cm diameter SIPRE core was used to drill the frozen cores, usually to 2 m. Geomorphic units were classified according to standard engineering geology terminology developed for Alaska. Soil morphological properties were described according to Schoeneberger et al. (1988) and soil classification according to Soil Survey Staff (2006). Ground ice structure and cryogenic features were described based on Shur & Jorgenson (1998).

Result and Discussion

Morphology and classification

The patterned ground type, cryogenic process involved, and soil classification of the study sites were summarized in Table 1. The deep bay/inlet coast type has mixed surface morphology of tapped basin and lagoon, but with fewer ice wedges (<20%). Thus there are both low- and high-centered polygons and thaw lake sequences. Ruptic Histoturbels and Typic Aquiturbels dominate the high-centered polygons with frost boils, Typic Histoturbels and Histic Aquiturbels dominate the low-centered polygons, whereas Fibric Glacistels and Glacic Historthels dominate the very poorly drained troughs between polygons.

In newly formed river deltas, the permafrost table is generally below 1 m and there are no diagnostic horizons with little or no cryoturbated features. Since these soils were frequently inundated by tidal or flooding waters, they were classified in the Aquic suborder of Entisols, i.e., Aquents. The mean annual soil temperature (MAST) at 50 cm was estimated to be below freezing; thus all soils found in recently formed deltas are Typic Gelaquents. However, where the deltas were vegetated with mostly sedges, and the deltas become estuaries, the repeated inundation and deposition of fine textured minerals on the vegetation mat caused repeated burial of thin vegetation layers. In addition, there were large areas of deltas and estuaries with sulfur-rich fluvial deposits. The surface had patches of bare ground with a thin crust of rusty red color over black mud, indicative of quick oxidation of ferrous Fe. These soils had subsurface horizons rich in iron sulfite (pyrite), which has a characteristic color of 4/N according to the Munsell Color Chart. They keyed out as Sulfuric Aquorthels. Those soils had stratified organic and reduced mineral horizons, a combined thickness of organic horizons generally greater then 6 cm within the top 50 cm, a permafrost table within 1 m, lacked cryoturbation, and were keyed out as Fluvaquentic Historthel. Both the Sulfuric and the Fluvaquentic Historthels had strong H_2S odor when the pits were opened.

Exposed bluffs and lagoon coastal types have similar morphology except the prevalence to the open ocean. In the eastern and western portions of the coast, high bluffs contained massive ice wedges occupying more than 20% of the exposed face. The surface of these coastal types is characterized by flat polygons and high-centered polygons dotted with frost boils. The troughs between the polygons were wide, generally 3–4 m due to deterioration of the underlying ice wedges. The ice wedges were usually within 1 m of the surface; thus the soils were classified as Sapric Glacistels and Glacic Histoturbels. Soils formed in the high-centered polygons were highly cryoturbated, and the continuity of the surface organic horizons were interrupted by frost boils; Ruptic-Histic Aquiturbels become the dominant soil type. In the flat polygons, Typic Histoturbels were the dominant soil type. In the ice-poor sand sheet in the mid-coastal zone, there was less cryoturbation, existing only at the margin of the polygons. The drainage in this area was moderately well to somewhat poor and the soils contained dark organic-rich mineral surface horizons; thus the dominant soil types were Aquic Molliorthels.

In the tapped basin/thaw lake basins, a microtoposequence formed following the lake draining. In the recently drained lake beds, there was a continuous organic horizon under sedge vegetation that was generally more than 14 cm thick over stratified reduced mineral and organic horizons. They lacked cryoturbation. Most of these soils have ice wedges or ground ice within 1 m and thus keyed out as Glacic Historthels. Soils without a glacic horizon within 1 m keyed out as Typic Historthels. Where the surface-organic layer was thin the soils keyed out as Ruptic-Histic Aquorthels and Glacic Aquorthels. Toward the slightly elevated edge of the drained-lake basin flat-polygons formed which have observable cryoturbation around 20–40 cm. These soils had thin organic horizons and some have ice wedges within 1 m, and thus keyed out as Typic Aquiturbels and Glacic Aquiturbels, respectively. Between the drained lakes there were raised broad ridges with high-centered polygons formed from ice wedge deterioration in the troughs. There was a high degree of cryoturbation under the polygon center in that the surface organic layers were broken and the underlying reduced mineral horizons were mixed with cryoturbated organics (Bg/Ojj or Ojj/Bg). Thus, these soils keyed out as Ruptic-Histic Aquiturbels. Glacic Aquiturbels appear as a minor component in this microtopography. In the troughs, the thick organic horizon sits on top of ice wedges, and thus the soils keyed out as Fibric Glacistels.

Mode of carbon accumulation

The arctic tundra soils are known to accumulate and sequester organic carbon (Michaelson et al. 1996). In most soils examined in the five coastal types, cryturbation was prevalent throughout most landform types except deltas. In the deltas, organic carbon accumulated through burial by fluvial sedimentation by the rivers. Organic horizons only formed after the establishment of sedge marsh vegetation.

In the tapped basins, organic carbon accumulated when marsh vegetation grows in the drained-lake basins, followed by mixing and burial from bank erosion/collapsing and flooding. Once the lakes were drained and the land surface was raised due to ice wedge formation, there was increased cryoturbation evident that churned the surface organic matter down into the lower active layer and upper permafrost. Carbon sequestration reached the maximum in the high-center polygons formed in between the drained lakes due the increased surface age and cryoturbation. In the exposed bluffs and lagoons, carbon accumulated and was sequestered through two main mechanisms. First, through the commonly known near-surface cryoturbation associated with patterned-ground formation that churns surface organic matter generally within the top 1 m. (Bockheim et al. 1998, Ping et al. 1998, 2008). Second, this field investigation found that ice wedge formation also plays an important role in carbon sequestration because the pressure from the expanding ice wedge deforms the surface organic matter down as far as 3 m deep, as seen in both sites 2 and 40.

Summary

In landforms dominated by high-centered polygons, Ruptic Histoturbels and Typic Histoturbels are the main soil types with Histic Aquiturbels and Glacic Histoturbels as minor components. In landforms dominated by flat and low-centered polygons, Typic Histoturbels and Typic Historthels are the main soil types with Glacic Historthels as minor components. In landforms dominated by thaw lake basins, Typic Historthels and Glacic Aquorthels are the main soil types and Ruptic Histurbels and Glacistels are minor components. In deltas, Typic Aquorthels and Typic Historthels are the dominant soil types with Glacic and Sulfuric Historthels as minor components. As found in this study, soil types were more related to microtopography rather than the physiographic classification of the coastal types, with the exception of delta. Also found in this study, organic-carbon accumulation and sequestration in arctic Alaska as examined from the exposed Beaufort Sea coast are multigenic and not just the result of cryoturbation.

Abstract

Permafrost degradation has been hypothesized as being one of the main causes of rockfalls and rock wall instability in the recent past in high mountain areas. Ongoing rock wall permafrost evolution remains poorly understood because of the lack of systematic measurements; models are often validated and driven by few existing instrumented sites. In rock wall subsurface temperature modeling, thermal diffusivity (κ) is one of the main parameters to be considered. In this study, thermal diffusivity data series were inferred from rock temperature data in order to understand their annual variation, their distribution in different temperature ranges, and their relation to atmospheric conditions. A harmonic analysis was performed to define amplitude and phase of the daily temperature waves at different depths by means of a least square minimizing optimization procedure. The analysis conducted shows that changes in κ values are influenced by different factors such as depth, season, rock temperature, aspect, and snowfall.

Keywords: rock wall temperature; thermal diffusivity.

Introduction

Steep bedrock slopes in high mountain areas are subjected to permafrost action. During the very hot summer of 2003, many rockfalls occurred in the European Alps, and sometimes massive ice was visible in the exposed detachment zone (Gruber et al. 2004b). These observations suggest that permafrost degradation may be one of the main causes of rock wall instability observed in recent years in high mountain areas (Dramis et al. 1995, Noetzli et al. 2003, Gruber et al. 2004a).

Thawing and degradation of rock wall permafrost is very fast if compared to permafrost in gentle morphology because of the lesser amount of ice content and the absence of a debris insulation layer (Gruber et al. 2004b); moreover, steep bedrock morphologies are abundant in many cold mountain regions and contain a significant proportion of permafrost (Gruber & Haeberli 2007).

Present and future global warming (IPCC 2007) will likely lead to a significant increase in frequency and intensity of rockfall events caused by variations in rock wall thermal regimes (Davies et al. 2001). Consequently, its degradation is spatially a widespread problem (Gruber & Haeberli 2007) which causes an increment in risks for people and infrastructures in high mountain areas (Harris et al. 2001).

In order to obtain a better understanding of rockfall trigger mechanisms and processes linking slopes warming and their local destabilization, an increase in knowledge on rock wall temperature regimes and their evolution is very important (Gruber & Haeberli 2007). Quantitative understanding and models of surface temperature distribution within steep rock faces in complex topography exist and have been validated with near-surface measurements (Gruber & Hoelzle 2001, Gruber 2005). However, many questions about active layer and sub-surface rock wall permafrost evolution remains poorly understood because of the lack of deeper systematic measurements and models.

In purely diffusive and stationary state models, thermal diffusivity is considered the only petrophysical parameter of importance (Yershov 1998), and in permafrost modeling, it is often considered as constant. Nevertheless, the continuous variability of water content linked to environmental conditions (Saas 2005), together with the latent heat effect associated with thawing and freezing (Mottaghy & Rath 2006), may cause great variability in thermal diffusivity in the active layer. These mechanisms may affect deeper temperature regimes and cause a probable "thermal offset" (Gruber & Haeberli 2007) between the rock surface and the top of permafrost.

The main purpose of this work is to evaluate the annual course of thermal diffusivity on some alpine permafrost rock walls and its variability related to environmental conditions. Using rock wall temperature data series measured at different depths of the active layer, a harmonic analysis was used to define amplitude and phase of daily temperature waves by means of a least square minimization procedure. Optimized amplitude values at each depth were used to obtain hourly data of rock thermal diffusivity κ. These data series were analysed in order to understand their annual variation, their distribution in different temperature ranges, and their relation to atmospheric conditions inferred from in situ meteorological collected data.

Research Strategy

Field measurements

All data series were collected within the international project PERMAdataROC started in March 2006, during which several measurement sites were equipped on high steep slopes in six different areas in the western European Alps. For this study, two of the six areas were selected because they are characterized by long data series and by a higher number of measured variables. One is the SW ridge of the Matterhorn, and the other is the peak of the Aiguille du Midì in the Mont Blanc massif (Fig. 1).

In each area the measured variables are: rock wall temperature at depths of 3, 30, and 55 cm; air temperature and relative humidity (10 cm from the rock surface); and solar radiation, wind speed, and wind direction, measured by means of an automatic weather station (MAWS), installed on the rock wall with sensors parallel to the rock surface (Table 1).

Measurements started in November 2005 at the Matterhorn site, and at the end of December 2006 at the Aiguille du Midì site. For this study, a total of eight data series were used; data series characteristics are shown in Table 2.

In order to identify snow events, daily albedo values were calculated from radiation data, and a snow index (S_i) was defined as the ratio between daily and mean albedo: snow index values greater than 1.25 are caused by snow events. Since some problems in snow index definition may occur, mainly in winter due to snow deposition on MAWS's sensors during snowfalls events, sonic anemometer, air temperature, and humidity data series were also used as further confirmation of snow events.

Table 1. Instrumentation

Parameter	Instrument	Log. interval
Rock temp.	Geoprecision - M-Log 6	60 min
Air temp. & hum.	Geoprecision - M-Log 5	60 min
Radiation	Kipp&Zonen - CNR-1	10 min
Wind	Vaisala - WMT50	10 min

Thermal diffusivity evaluation

Rock temperature data were used for thermal diffusivity evaluation. Signal detrending using running-mean was performed on rock temperature data series in order to remove low frequency oscillations as seasonal and annual ones. Assuming that temperature variation at any depth is sinusoidal, the thermal diffusivity of rock, κ ($m^2\ s^{-1}$), can be calculated with the following equation (1) (Matsuoka 1993):

$$\kappa = \frac{\pi}{P}\left[\frac{Z_1 - Z_2}{\ln(A_1 / A_2)}\right]^2 \tag{1}$$

where P is the period of one complete harmonic oscillation (24 hours) given in seconds, A_1 and A_2 are the amplitude of temperature waves (°C) at depth Z_1 (i.e., 0.03 m) and Z_2 (i.e., 0.3 m).

A harmonic analysis of rock temperature data was performed to define amplitude A_1 and A_2 of daily temperature waves at different depths using the following equation which describes a general harmonic oscillation:

$$T_{(z,t)} = A_{(z)} \sin(\omega t + \phi) \tag{2}$$

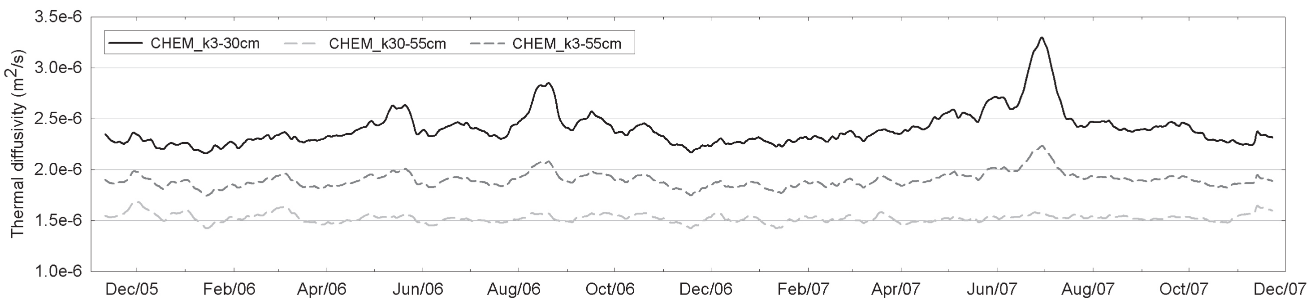

Figure 2. Annual course of computed thermal diffusivity at the Cheminèe site (Matterhorn) smoothed over 15 days.

where ω is the angular frequency of the oscillation (i.e, for daily cycles ω=(2π/24) h^{-1}), $A_{(z)}$ is the amplitude of temperature oscillation at depth z, and Φ is the phase angle.

A least-square minimization procedure was applied using equation 2 in order to obtain estimates of unknown parameters A(z) and Φ. A(z) is the parameter chosen for thermal diffusivity evaluation. Amplitude values at different depths were used in equation 1 to obtain hourly data of rock thermal diffusivity κ. As rock temperature data at three different depths were available, three different couples of amplitude data series were used: 3÷30cm, 30÷55cm, and 3÷55cm. The fitting procedure was computed on every series using a three-day running-window, moving with an hourly step. The standard error of computed thermal diffusivity values was evaluated using a bootstrap resampling technique. In the bootstrap procedure, the original dataset is randomly resampled N times (in this study N=500); in this way, for each hourly step, 500 synthetic thermal diffusivity datasets were generated. Instead, as described in Efron and Tbshirani (1993), the standard deviation of the distribution of these 500 values is a good measure of the parameter's standard error. The parameter standard error was used as an indicator of the reliability of amplitude values. Finally, the resulting thermal diffusivity data series was smoothed with a median filter of three hour's width, to avoid rapid fluctuations.

Results and Discussion

Annual course of thermal diffusivity

In order to show the annual variations in thermal diffusivity at each depth, the longer available data series (CHEM) is considered in Figure 2. Table 3 shows mean values of κ and standard errors of the whole data series and for cold (autumn plus winter) and warm (spring plus summer) periods.

The first 30 cm of rock show a mean value of about 2.4×10^{-6} m^2s^{-1} and great annual variability, with values generally below the mean during the cold season, and above the mean during the warm season. This observed variability decreases with depth: oscillations of deeper thermal conductivity data series are strongly reduced, and the seasonal behaviour underlined for the shallower rock layer cannot be seen. These differences are probably due to the different variability in water content during the year: greater in the first centimetres of rock and lesser at depth. Moreover, mean κ values of 30–55cm depth interval are significantly reduced, probably because of the different degree of saturation in comparison to the shallower rock layer.

To gain an understanding of the reliability of the diffusivity values presented, laboratory measurements of thermal conductivity were performed on gneiss samples collected at the Matterhorn study site. The results give a mean value of thermal conductivity equal to 2.7 $Wm^{-1}K^{-1}$. Using a mean tabled value of volumetric heat capacity for granitic rock equal to 1.75×10^6 $Jm^{-3}K^{-1}$ (Yershov 1998), the resulting value of thermal diffusivity is 1.54×10^{-6} m^2 s^{-1}, a value which is very similar to the mean of the whole series calculated for the 30–55cm depth interval (1.52×10^{-6} m^2 s^{-1}).

These results seem to suggest that significant differences in thermal diffusivity values can be obtained by considering the first centimetres rather than the deeper rock layers. This matter should be taken into account when thermal diffusivity values are applied to heat conduction models for the projection in depth of rock wall temperature.

Distribution of κ values in different rock temperature ranges

Figure 3 show the distribution of 3–55cm thermal diffusivity values above and below 0°C both at the north and south Aiguille du Midì sites.

The 30 cm depth data series was used as the rock temperature reference at each site. In the period considered, on the northern site only 10% of rock temperature data were

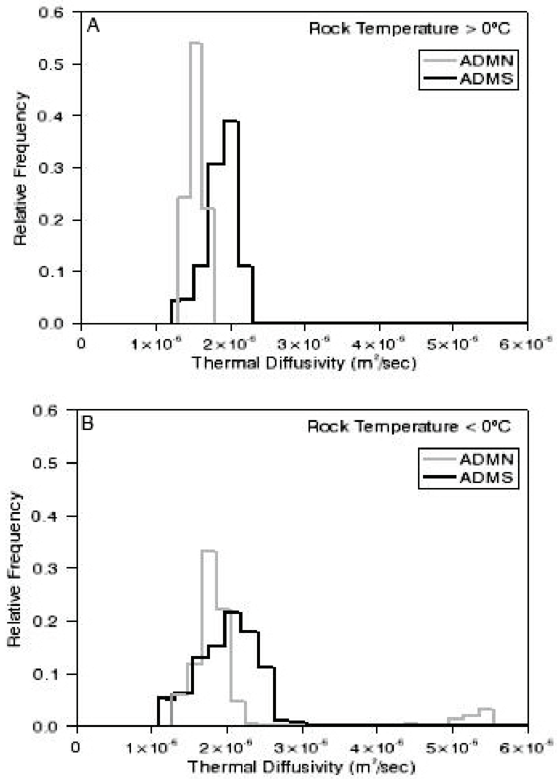

Figure 3. Distribution of thermal diffusivity values (3–55cm depth interval) below and above 0°C at ADM northern and southern sites.

above 0°C, whereas in the south, this proportion was around 50%. Moreover, minimum north and south values were -17.97°C and -14.06°C respectively, while the maxima were 3.97°C and 16.4°C, respectively.

The histograms in Figure 3 show the effect of rock wall aspect and different conditions on thermal diffusivity.

Regarding aspect, the northern site showed values lower than the southern one and less dispersed around the mean. Lower values suggest that northern exposures may be more saturated than southern exposures, as indicated in previous studies (Saas 2005). On both aspects, κ values are generally greater below 0°C; this is probably due to the substitution of water by ice in the pore space and fractures of frozen rock (Williams & Smith 1989).

Thermal diffusivity variations caused by snow events and rock wall temperature

Evaluation of the effect of snow events on thermal diffusivity was conducted by choosing some meaningful summer and winter events in the Matterhorn and Aiguille du Midì data series. Using a smoothed (24-hour) thermal diffusivity normalized deviation index κ_{di} (defined as κ/κ_{mean}), the temporal evolution of the CCS and ADM thermal diffusivity data series was analysed, considering 3–55cm depths.

In the CCS data series, an intense summer snow event (2nd half of August 2006) was considered. As shown in Figure 4, when the snow index increases, κ_{di} decreases (maximum

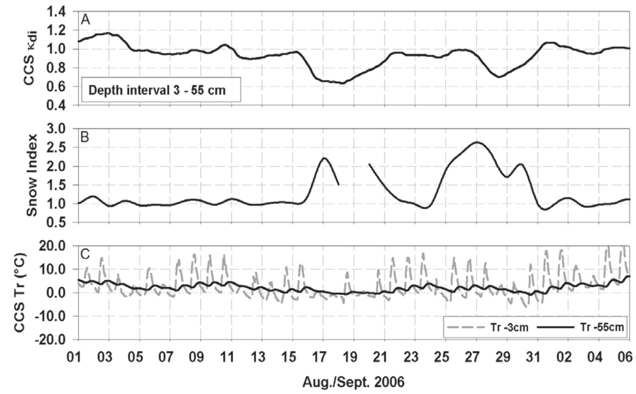

Figure 4. Comparison between CCS thermal diffusivity deviation index, snow index, and rock temperature.

reduction of about 40% of the mean value) and vice-versa: as the S_i starts decreasing κ_{di} rises closer to the mean value. During snowy days, shallower rock (-3 cm) temperature crosses above and below 0°C several times, while the deeper one (-55 cm) is closer to zero. In such a condition, phase changes may occur in the active layer: thus the consumption and release of latent heat due to thawing and freezing of percolating water cause the variation in apparent heat capacity. This variation affects κ which is inversely proportional to apparent heat capacity (Mottaghy & Rath 2006). The decrease in thermal diffusivity shown in Figure 4a during snow events is probably linked to water phase changes.

Similar considerations can arise from the observations of thermal diffusivity data series at ADM northern and southern sites (Fig. 5). During the spring-summer period κ_{di} temporal evolution, and the magnitude of its variation during snow events, are similar to what is observed in CCS data series. The southern face shows thermal diffusivity reduction related to snow events starting from the end of March (Fig. 5c); the same behaviour is observed on the northern side (Fig. 5a) only at the end of spring, when rock temperature rises toward 0°C (Fig. 5b), suggesting a possible role played by rock temperature on water availability.

On the other hand, during winter, κ_{di} variations related to snow events show an opposite behaviour: a strong increase in κ_{di} is observed on both faces, with a general higher intensity on the northern one, where a doubling of thermal diffusivity value occurred.

On the southern face, a strong increase of κ_{di} values, comparable to those in the north, occurred at the end of February. During this event, the southern face rock temperature showed values of about -10°C at the depth of 55 cm: a value closer to annual minima and similar to northern face rock temperature in the same period (-13°C). This means that the thermal conditions of the south wall were very similar to those experienced by a northern wall, suggesting, once again, that rock temperature may influence thermal diffusivity variability. However, further investigations are needed in order to understand the reliability of these winter increases.

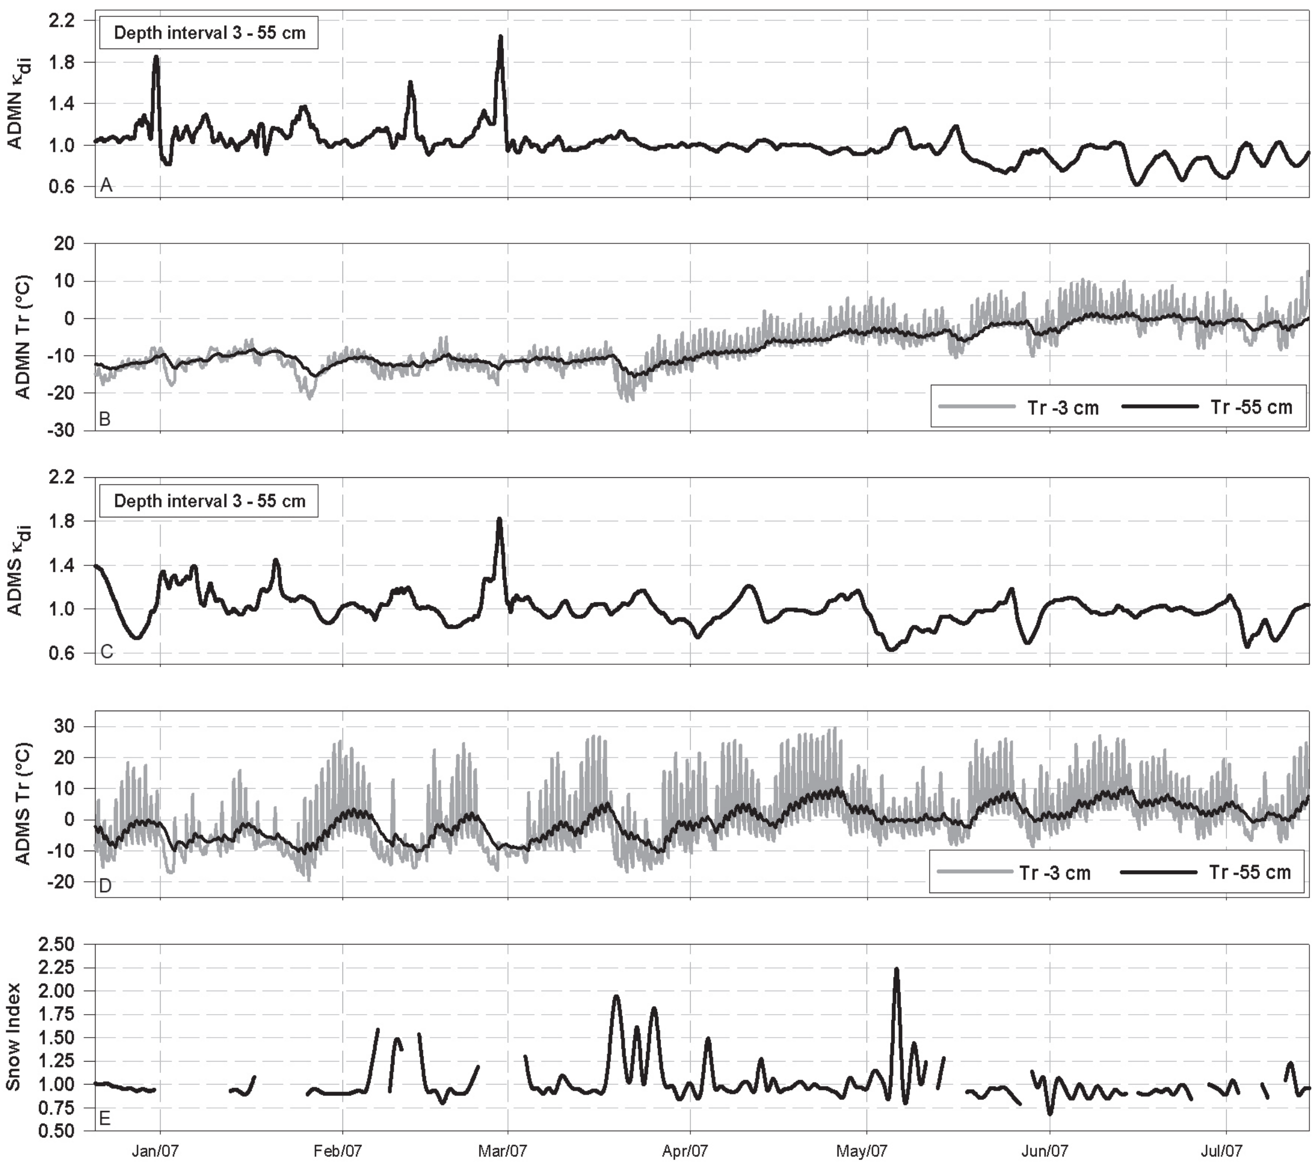

Figure 5. Temporal variation of thermal diffusivity deviation index at Aiguille du Midì northern (A) and southern (C) face. Rock temperature data at Aiguille du Midì north (B) and south (D) at depths of 3 and 55 cm. Snow Index value (S_I) used to identify snow events (E). All data series are smoothed with a 24-hour moving average, with the exception of the Snow Index (daily data).

As outlined in Figure 5d, periods of strong rock wall warming can be followed by thermal diffusivity reductions: κ_{di} variations observed at the end of April on the ADM southern face may have been caused by the previous 10 days of rock temperature above 0°C.

This reduction is more likely related to this rock warming period, rather than to the snow event which occurred during the first days of May, when the κ_{di} reduction had already reached its maximum value. A similar situation can be observed at the end of May. Moreover, on the northern face, a late May κ_{di} reduction occurred when rock temperature was above 0°C (Fig. 5b).

These observations suggest that thermal diffusivity variability may be influenced both by snow events and rock temperature and their interactions. Summer κ_{di} reductions can be explained by an increase in water circulating in the rock heap resulting from snow melting, and from ice-filled discontinuities melting due to warming periods. Winter thermal diffusivity increases, which occur during snow events, appear to be related to cooling intensity rather than to water supply as discussed in Williams & Smith (1989).

Conclusions and Outlook

The analysis conducted in this study leads to the following conclusions:

The estimation of thermal diffusivity variability, from rock temperature data measured at different depths, is possible, and the applied methodology gives reliable values. Changes in thermal diffusivity values are influenced by different factors such as depth, season, rock temperature, aspect, and snowfall. Thermal diffusivity variability decreases with depth, and its mean values in deeper layers are significantly reduced with respect to shallower ones. This should be taken into account when using heat conduction models on the whole rocky heap.

Mean northern κ values are lower than southern ones: this difference may be related to the higher degree of saturation experienced by northern exposures. κ values are greater below 0°C because of the substitution of water by ice in the pore space and fractures of frozen rock.

Reductions in thermal diffusivity related to snow events were observed both on southern and northern faces during warm periods and are probably linked to water phase changes. Winter thermal diffusivity increases, which occur during snow events, appear to be related to cooling intensity rather than to water supply. Thermal diffusivity variations seem to be related to rock temperature, as well: warming periods may result in strong reductions in κ values, likely due to an increase in water circulating in the rock wall.

Such behaviours were observed on both monitoring sites: they, therefore, appear to be independent of system variables such as lithotype, degree of fracturing, and aspect.

In order to test the reliability of these first observations, it is necessary to wait for the results of the PERMAdataROC project: longer data series are needed in order to better understand the behaviour of thermal diffusivity variability.

A first application of computed thermal diffusivity values can be found in energy balance estimation. k values. and rock temperature data at different depths allow calculation of heat conduction which, coupled with net radiation measurements, may allow estimation of the ratio of available energy dissipated through turbulent fluxes. This information may be useful in heat conduction modeling.

Massive Ground Ice in the Eureka Sound Lowlands, Canadian High Arctic

Wayne H. Pollard, Nicole Couture
Department of Geography, McGill University

Abstract

This paper documents the nature and significance of massive ground ice and thermokarst in the Eureka Sound lowlands in central Ellesmere and Axel Heiberg Islands in the Canadian High Arctic. We characterize the stratigraphic, ice content, and distribution patterns of ground ice, estimate potential thaw, and document recent trends in the rate and pattern of thermokarst. The Eureka area (~80°N) is characterized by cold polar desert conditions (mean air temperature of -19.7ºC) and permafrost up to 600 m thick. A total of 189 natural exposures of massive ice were mapped between 1991 and 2007, including 91 that were active in 2007. Most of these exposures are in the headwall of retrogressive thaw slumps. Repeated surveys of headwall positions have provided both short- and long-term retreat rates. Since 2004 there has been a detectable increase in thermokarst activity, including retrogressive thaw slumps, development of new thaw ponds, and degraded ice wedges.

Keywords: cryostratigraphy; ground ice; High Arctic; polar desert; thermokarst.

Introduction

Ground ice plays a major role in the evolution of landscapes underlain by continuous permafrost. Thawing permafrost, widespread terrain instability and resulting infrastructure problems are often cited as serious problems facing polar regions in response to global warming (ACIA 2005, IPCC 2001). Information about ice content and distribution is extremely variable across the Arctic. For example, there is considerable detailed information about the nature and distribution of ground ice for parts of Siberia (Astakov 1986, Astakov & Isayeva 1988, Streletskaya & Leibman 2003), the Alaskan coastal plain (Lawson 1986), and the western Canadian Arctic (Mackay 1971, 1989, Mackay & Dallimore 1992, Murton & French 1994), but by comparison, ground ice occurrence in the High Arctic has received limited attention (Robinson 1993, 2000, Pollard 1991, 2000a, 200b, Pollard & Bell 1998). Several studies have alluded to increased thermokarst as an outcome of climate change (Lawrence & Slater 2005, Nelson et al. 2001, Zimov et al. 2006). However, little is known about its anticipated pattern or the potential magnitude of thermokarst because it is entirely dependent on information about near-surface ground ice. Detailed information about the active layer is also needed before a realistic prediction about thaw subsidence can be made. Areas where the active layer is relatively thin, like the High Arctic, are more vulnerable to even small increases in summer temperature and the duration of the thaw season because the buffering capacity of the active layer is limited.

This paper documents massive ground ice, ice-rich sediments and thermokarst for the Eureka area in central Ellesmere and Axel Heiberg Islands in the Canadian High Arctic (Fig. 1). Recent data on the nature and distribution of ground ice conditions, ice content, and potential thaw are presented along with observations on the rate and pattern of thermokarst. The objectives of this paper are (i) to describe the nature and distribution of ground ice in the Eureka Sound Lowlands; (ii) to describe permafrost stratigraphy and ice contents, and (iii) to describe current patterns in thermokarst activity in this area. Preliminary findings on massive ice in the Eureka area were presented in Pollard & Bell (1998) and Couture & Pollard (1998), the current paper presents new findings, is based on new data and focuses more on thermokarst.

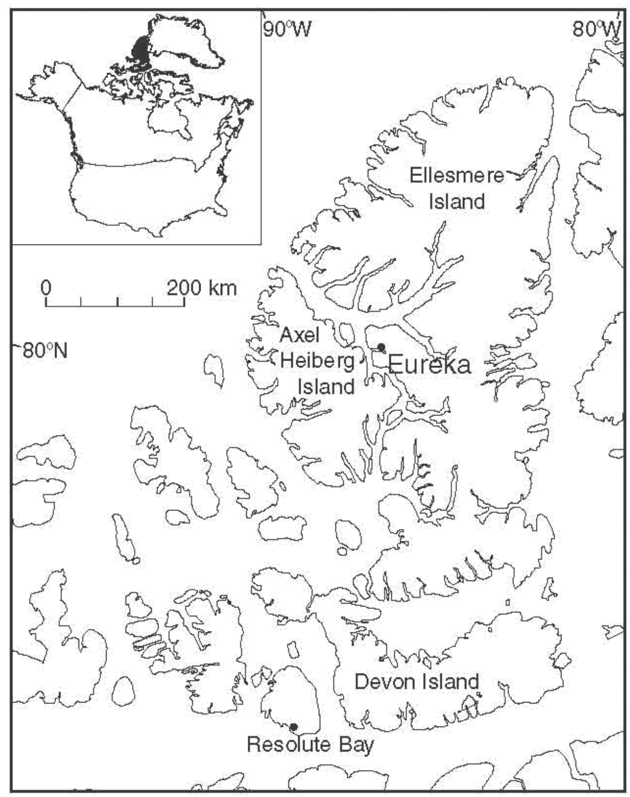

Figure 1. Map showing the location of Eureka in the Eureka Sound lowlands.

Ground ice remains one of the most problematic aspects of permafrost and a major obstacle to development in arctic regions. Knowledge about ground ice, particularly massive ice and ice-rich sediments, is necessary not only to understand the Late Quaternary landscape evolution of this region, but also to assess the potential geomorphic response of the landscape to natural and anthropogenic disturbances of permafrost regimes. Thermokarst and erosion associated with the Eureka weather station and the Panarctic Gemini E-10 well site reflect the sensitive nature of surficial sediments and icy permafrost in this part of the Arctic (Couture & Pollard 2007). Concern that global warming will not only cause a shift in the pattern of permafrost distribution but will also induce widespread thermokarst (Lawrence et al. 2005) in areas underlain by ice-rich sediments provides additional impetus for ground ice investigation. Ground ice studies may also provide useful proxy information on paleoclimates and paleogeomorphology.

Study Area

This study focuses on massive ground ice located in the Eureka Sound lowlands on west-central Ellesmere Island and east-central Axel Heiberg Island (Fig. 2). Eureka Sound is bordered by gently rolling lowlands surrounded by glacierized mountains rising to elevations of more than 500 m a.s.l.

The landscape is incised by several short river channels and dotted by numerous tundra ponds. Ice wedge polygons are ubiquitous over most of the area and active layer detachment and retrogressive thaw slump scars are common. This area is underlain by poorly lithified Mesozoic and Cenozoic clastic rocks of the Savik, Awingak, Deer Bay, Isachsen, Christopher, Hassel, Kangkuk and Eureka Sound Formations (oldest to youngest). Outcrops of weathered bedrock are widespread at elevations above marine limit and resistant sandstones of the Heiberg Formation form steep ridges in excess of 500 m a.s.l. Fosheim Peninsula lies east of (beyond) a glacial drift belt that marks the Late Pleistocene glacial limit (Bell 1996). Approximately 30% of the peninsula lies below the Holocene marine limit, which is approximately 140–150 m a.s.l. (Bell 1996). Below this elevation a blanket of thinly laminated sandy silt and silty clay from <1 to ~15 m thick covers most surfaces.

Pollard & Bell (1998) developed an emergence history for the Fosheim Peninsula (from dates for articulated bivalves of marine origin) that constrain the age of ground ice deposits for different elevations. A fine-grained till and diamicton overlying bedrock is described by Hodgson (1985) for the northern part of Fosheim Peninsula. The Quaternary history and the extent of Pleistocene glaciation in this area are still poorly understood (Bell 1996, Pollard & Bell 1998) and could have a strong bearing on the interpretation of massive ground ice origin, in particular its age and the possible preservation of buried glacier ice. Thus, a particular concern of field mapping and section description is the identification of fine till or diamicton units and their association with massive ice.

The study area is characterized by cold polar desert conditions (the Eureka weather station has a mean air temperature of -19.7°C based on a 50-year record) and permafrost up to 600 m thick (Pollard 2000b). Preliminary studies indicate that the marine sediments are extremely ice-rich (Pollard 1991, 2000a). Of particular interest is the widespread occurrence of massive ice in the lowlands surrounding Eureka Sound, Slidre Fiord and the Slidre River Valley, where it frequently occurs as extensive bodies of massive tabular ice (Couture & Pollard 1998, Robinson 1993, Pollard 1991, Pollard & Bell 1998, Pollard 2000a).

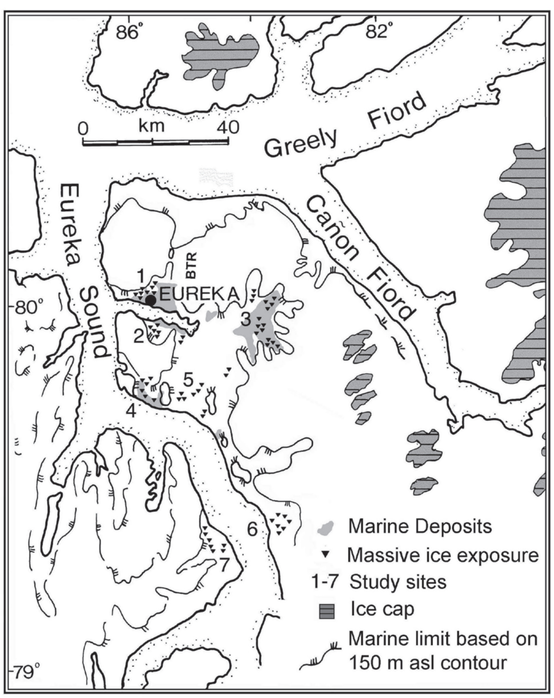

Figure 2. Map of the Eureka Sound Lowlands showing the location of ice-rich permafrost, massive ground ice exposures and study sites 1–7 (see text for details). BTR refers to Black Top Ridge.

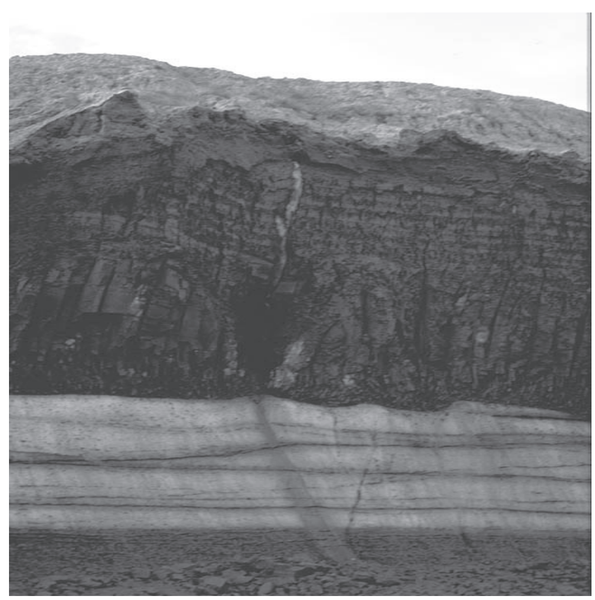

Figure 3. Massive ground ice (~3 m thick) conformably overlain by 5+ m of laminated marine sediments containing reticulate ice veins.

Ground Ice Conditions

Ground ice conditions

Fieldwork on massive ground ice in this area began in 1991 by examining natural exposures (retrogressive thaw slumps, river banks and block failures), but since 2001 has included coring (~40 cores <5 m and 5 cores between 5–17 m) and geophysical investigations (GPR and resistivity).

Ground ice distribution

Seven ice-rich areas characterized by numerous ground ice exposures with massive ice as well as both active and inactive thermokarst features and tundra ponds have been identified (Fig. 2). Study sites include: (1) Eureka, (80°00′N, 85°57′W); (2) South Slidre Fiord (79°56′N, 86°05′W & 79°54′N, 85°30′W), (3) Slidre River, (79°55′N, 84°14′W) including Hot Weather Creek (79°59 & 84°28′W) and Gemini (79°58′N, 84°10′W) (4) Blue Man Cape, (79°44′N, 85°57′W) (5) Eureka Sound (79°43′N, 84°30′W) (6) South Fosheim (79°28′N, 84°20′W) and (7) May Point (79°25′N, 84°29′W). The Romulus Lake (79°52′N, 84°55′W) and the Depot Point (79°22′N, 86°24′W & 79°24′N, 86°00′W) areas also display widespread thermokarst, but only a few exposures of massive ice. A number of isolated massive ice exposures and retrogressive thaw slumps have also been mapped. Retrogressive thaw slumps frequently contain relatively large bodies of massive ice and ice-rich permafrost (excess ice). The distribution of massive ice corresponds closely with the distribution of fine-grained marine sediments identified by Bell (1996), in fact 181 exposures (96%) occurred in marine sediments. The nature of the ice is also stratigraphically controlled by these and other surficial materials. The most significant ice exposures occur where marine deposits >7 m thick form flat to gently dipping plateaus.

Of the 189 natural exposures containing massive ice and ice-rich sediments 88% are retrogressive thaw slump head walls, 8% river cuts and 4% block failures. These data are supplemented by 20 core holes.

Cryostratigraphy

Most exposures include horizontally layered massive ice several meters thick conformably overlain by 1–7 m of massive to weakly laminated marine sediment (Fig. 3). The ground surface is often littered with cobble to boulder-sized clasts and a fine gravel lag deposit in areas of wind erosion. A typical section includes a thin surface layer 5–20 cm thick of massive fine sand with a few large sub-rounded clasts (gravel to cobble sized) that grades into a massive fine silty sand. The fine sand unit varies in thickness between 1–3 m. This unit grades into a finely laminated silt and silty sand. Layers (laminae) 1–1.5 cm thick of well sorted silt and fine sand are interpreted as rythmites associated with episodic glacial melt water deposition into a shallow marine (brackish) system (Bell 1996). Soil salinities range between 0.2%–0.5%. The active layer is typically 30–70 cm deep.

Ice contents are initially high immediately below the base of the active layer. This unit grades into 0.5–2.0 m of faintly laminated to massive silty clay. It is extremely ice-rich, ice occurs in a regular to irregular reticulate cryotextures with vertical fissures initially predominating. Salinities are between 0.4%–0.6%. Ice content tends to increase with depth forming a network of vertical and horizontal segregated ice lenses which grades into massive ice with angular blocks of silty clay 2–5 cm in diameter. The contact between the silty clay unit and the massive ice is abrupt but conformable. Sediments in the ice are similar to the sediments in the overlying silty clay unit. There is also chemical continuity in the major ions and environmental isotopes.

The massive ice unit ranges from 2–10 m plus in thickness. Given that basal contacts are rarely observed in natural exposures the total thickness is inferred from geophysical surveys and a few deep core holes. Massive ice displays horizontal to gently dipping bands of sediment and sediment-rich ice. Ice color varies between white (bubble rich) and clear (appears black). Ice petrofabrics range from strong preferred vertical c-axes with large (1–3 cm long) euhedral crystals in the middle of the unit to random c-axis orientations and small anhedral crystals near sediment bands and at the upper contact. The basal contact is observed in 3 core holes from the Eureka area. In all 3 cases the ice grades into ice-rich bedrock (poorly lithfied sandstone). Technically this is an unconformity however there is chemical continuity between the massive ice and ice retrieved from 10 cm into the bedrock.

In the Eureka Sound Lowlands the pattern in ground ice content is closely linked to the thickness of marine sediments, and although considerable variation exists both locally and regionally, the presence of terraced marine deposits has proven to be an extremely good indicator of massive ice. Several sections at each massive ice site were analyzed for ice content. For convenience, ice content values are expressed as percent volume although most of the measurements

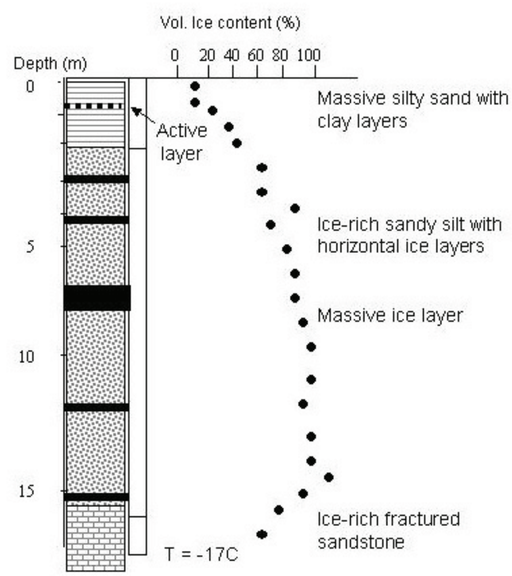

Figure 4. Typical cryostratigraphic profile through a massive ice body, based on a 17 m core taken near Eureka obtained using a modified seismic drill.

were done gravimetrically. Gravimetric ice contents were converted to volumetric ice contents following a procedure outlined in Pollard & French (1980). The base of the active layer formed the top of most measured profiles. Active layer depths display considerable variation ranging from 60–70 cm for dry south-facing surfaces to 30–40 cm for damp north facing or shaded locations. For much of Fosheim Peninsula, particularly above marine limit where surficial materials are coarse, the permafrost is quite dry and ice contents average between 3–10% by volume.

Ice content profiles

In the ice-rich areas below marine limit three patterns in ice content profile occur (Fig. 5). The first is marked by moderately high ice contents (20%–30%), occurring as pore ice and thin discontinuous ice lenses and layers near the base of the active layer. Beneath the active layer, ice contents increase sharply so that at depths of roughly 1.0–1.3 m they reach 60%–99% where layers of pure ice and muddy ice predominate; the sediment in the ice is mainly silt or clay sized. In this pattern, high ice contents extend between 2–7 m to depths of up to 8–9 m. In only a few instances is it possible to obtain data below the base of the massive ice zone, and in such cases the ice contents drop dramatically (10%–30%).

Pore and lens ice occur where the lithology changes to coarse sandy material or weathered bedrock. The second pattern includes a layer of weakly laminated sandy silt 5–7 m thick with ice contents ranging from 8%–15% near the base of the active layer, to 12%–17% at depths of 2–3 m. Near the base of this unit, ice contents increase to 30%–40% as the clay and silt contents increase. Pore and lens ice grade into more regular vertical and reticulate patterns of ice veins. At depths ranging from 7–10 m, faintly laminated silty clay materials abruptly change to massive ice with fragments or layers of silty clay (60%–70% ice) to pure horizontally foliated massive ice (90%–100% ice). The third pattern is intermediate between the first and second patterns. In this case, ice contents increase gradually (15%–30%) with depth usually reflecting a rise in silt content. At a depth of roughly 4–5 m, interbedded layers of silty ice and icy silt with ice

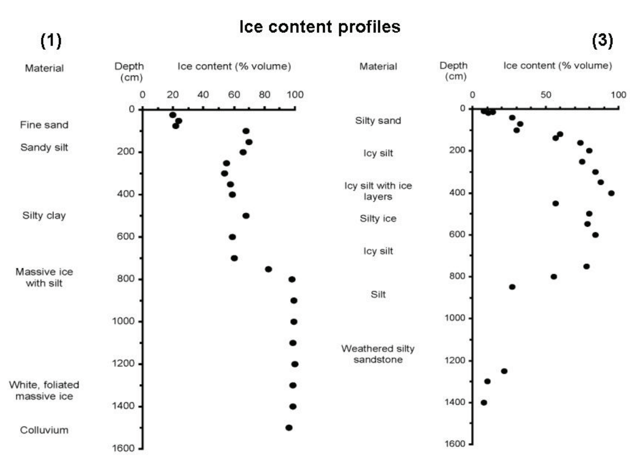

Figure 5. Ice content profiles, patterns 1 & 3.

contents of 65%–78% (sometimes higher) predominate for up to 5 m. At a depth of 9–10 m ice contents decrease to 50%–60% and below this depth, they drop off dramatically (5%–10%) as materials grade into a weathered bedrock substrate.

Various forms of ground ice occur in the surficial materials in the Eureka Sound Lowlands. Pore ice occurs in virtually all perennially frozen unconsolidated sediments and in places is a source of excess ice. Similarly, ice-wedge polygons occur on most surfaces except resistant bedrock outcrops and ridges (e.g., Black Top Ridge). High centered polygons are most common and polygon dimensions are highly variable, ranging from 7–20 m in diameter depending on setting and materials. In low-lying areas ice-wedge troughs are usually well developed, but at higher elevations and in coarse-grained materials they are poorly defined. Ice wedge dimensions are also highly variable and depend on a combination of setting, age and water supply. In the Eureka area, for example, ice wedges range from small fissures 10–30 cm wide and 100–200 cm deep, to classic V-shaped wedges 100–200 cm wide and 350 cm deep. The average ice wedge trough width based on the measurement of 350 wedges in 5 different areas (70 x 5) is 130 cm. Following the method described in Pollard & French (1980, Equation 8), it is estimated that ice-wedge ice comprises approximately 10%–12% of the upper 5 m of permafrost; this is comparable with estimates from the Mackenzie Delta and Yukon Coast. Segregated ice ranges through a full spectrum of forms from thin discontinuous ice lenses, to fully developed reticulate textures, to thick tabular bodies of massive ice (Fig. 3). It is particularly significant in fine-grained marine silts, silty clays and sandy silts that were deposited during the late Quaternary and have subsequently been exposed to cold subaerial permafrost conditions (Bell 1996). Roughly 25%–30% (~4000 km^2) of the Eureka Sound lowlands lie below the Holocene marine limit (150 m a.s.l.). Above this elevation, dry, weathered coarse-grained Tertiary deposits are widespread. Apart from large, widely spaced ice wedges (Lewkowicz 1994), areas above marine limit do not seem to contain significant amounts of ground ice. Elevated, more resistant bedrock surfaces display no evidence of ground ice, but at Hot Weather Creek thick layers of pure ice were observed at depth in consolidated rock strata of the Eureka Sound Formation. Buried ice is present in relatively small quantities as buried snow bank deposits in the stabilized headwalls of retrogressive thaw slumps. Buried glacier ice could be present in various till deposits but to date has not been observed. These studies have shown that pore ice and wedge ice form a significant contribution to the total volume of ground ice in the upper 10 m of permafrost (Couture & Pollard 1998). Buried snow bank ice is present in small amounts in areas of active thermokarst and buried glacier ice occurs in association with moraines formed by modern ice caps and glaciers.

Following a methodology presented in Pollard & French (1980) and modified in Couture and Pollard (1998) we attempt a first approximation of ground ice in the top 7 m of permafrost in the Eureka Sound Lowlands, an area of roughly 12,000 km^2. The total volume of ground ice is calculated by estimating the areal extent of various types of ice-rich terrain in the study area. We establish percentages of ice content by volume for each type of terrain unit. This study considers the top 7.5 m of soil because this was the lower limit of most of our sample data, and because the immediate effects of surface disturbance are unlikely to penetrate to much greater depths. Our estimates concern only the volume of permafrost, or frozen materials, so we subtract the average active layer thickness of 0.6 m, so that the thickness of materials actually used in calculations is 6.9 m. Ice content profiles were used to calculate the average volumetric ice content associated with pore ice and massive ice based on terrain type. A combination of air photo analysis and field data were used to estimate the volume of ice associated with ice wedges. The highest ice volumes (65%) were associated with marine terraces. Below marine limit, pore ice segregated ice comprise 45% by volume of frozen sediment while in areas underlain by bedrock they account for 9.5%. Ice wedges comprise only 5% of the volume of frozen sediments. This low value reflects the relatively small size of ice wedges. Ground ice in all forms makes up approximately 30% of the upper 6.9 m of permafrost.

Thermokarst

Thermokarst is an important erosional process unique to areas underlain by ice-rich permafrost and refers to landforms resulting from the thawing of ground ice. The importance of thermokarst is often discussed in terms of its potential occurrence as an impact on human activity (e.g., as a response to construction of pipelines and highways) or global warming; however, it should not be forgotten that thermokarst is a naturally occurring erosional process. The nature and magnitude of thermokarst is directly related to two important variables, (i) the thermal stability of the upper part of permafrost, including the depth of the active layer, and (ii) ground ice contents. Retrogressive thaw slumps (also called retrogressive thaw flow slides) are one of the more spectacular forms of backwearing thermokarst and also involve thermal erosion (Fig. 6). Preliminary observation on thermokarst in the Eureka area are presented in Robinson (2000).

Most of the 189 natural massive ice exposures were in retrogressive thaw slumps. In comparison with similar landforms in the Mackenzie Delta-Yukon Coastal Plain area the retrogressive thaw slumps in the Eureka Sound Lowlands are relatively small. The average length of exposed headwall was <80 m (the largest was 158 m) and average headwall height was 5–7 m. The highest head wall was 12 m but heights around 4–5 m were common. Through the course of this study the headwall position of 3–4 slumps in each of the study areas was monitored by a combination of DGPS, total station surveys and tape surveys. In addition late July thaw depths (active layer) were also monitored in the vicinity of the headwall. Climate data from the Eureka weather station and an automatic weather station in the Eureka area allowed

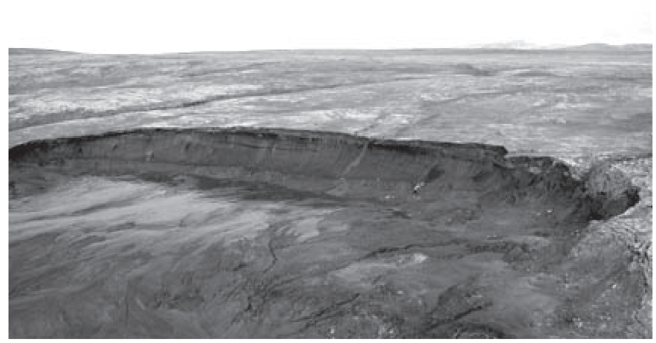

Figure 6. A retrogressive thaw slump near Depot Point. The exposed headwall is approximately 80 m long.

us to compare retreat rates with air temperature. The average mean daily temperature for July (the warmest month) was +5.7°C and the average number of thawing degree-days for July was 176.7.

July 1998 and 2003 were the two warmest Julys during this study. Through the course of this study 30 slumps were surveyed. In some cases sites were measured annually, but most were surveyed every second or third year. With the exception of two slumps that remained active through the entire study (one at South Slidre and one at Blue Man Cape—sites 2 and 4 respectively) most (70%) stabilized after 7–8 years, (20%) after 10 years and (4%) stabilized only 2–3 years after their initiation. Slumps stabilized very quickly following 1–2 years with of rapid retreat. Stabilization occurs when the sediment from the active layer is not removed (by viscous flow) fast enough and buries the head wall. Retreat rate varies across the headwall of every slump; maximum retreat at a point along the headwall can be misleading so we took the average of the most active 10 m section. Over 17 years of observation the average retreat for all sites is 6.9 m/yr, the highest annual retreat was 21 m. A comparison between average annual retreat based on all the slumps and mean July temperature does not show a particularly strong relationship although the highest single retreat rates occurred in years with warmer than average July temperatures. The number of active slumps seems to correspond with years with warm mean July temperatures. Between 1990 and 1995, there were 85–90 active slumps, from 1995–2000 the number dropped to 67–70, from 2000–2005 the number of slumps went back up to 75–77, but since 2005 the number has risen to 91–93. There is a close relationship between July thaw depth and mean July temperature. In 1998, 2003 and 2006 mean July temperatures were 3°C–4°C warmer than average and July thaw depths we 10% higher than average. Since 2000 many of the ice wedge polygons in the vicinity of the monitoring sites exhibited significant thaw degradation and deepening of ice wedge troughs. Numerous new thaw ponds have formed with ice wedge troughs and intersections.

Conclusions

This paper summarizes 15 years of observations on massive ice in the Eureka Sound Lowlands. Three main conclusions can be drawn from this research. First, massive ground ice is a significant component of surficial sediments in the Eureka Sound Lowlands, which represents one of the more ice-rich regions in the Canadian Arctic. Second, the nature and distribution of massive ice is closely linked to the presence of marine sediments and sea level history. And thirdly, shallow massive ice and ice wedges are highly vulnerable to thermokarst. Prior to 2005 there appeared to be little relationship between warmer-than-normal July temperatures and thermokarst, but from 2005–2007 the number of thermokarst features and the amount of thermokarst has been increasing.

Long-Term Monitoring of Frost Heave and Thaw Settlement in the Northern Taiga of West Siberia

Olga Ponomareva

University of Alaska Fairbanks, Department of Civil and Environmental Engineering, Fairbanks, Alaska USA

Abstract

Monitoring of frost heave and thaw settlement has been carried out for 37 years in the discontinuous permafrost zone of West Siberia. Long-term frost heave is a modern process in the natural condition of the discontinuous permafrost zone. The rise of old frost mounds and the formation of new ones has been observed. Old mound development occurs non-uniformly in time and is associated with cold winters. The rate of frost heave is maximum in the central part of frost mounds and minimal at the margins. Long-term frost heave in flat peatland has also been observed; it occurs at about the same rate but is more spatially uniform. The exception is represented at peripheral sites in flat peatland with a lowered permafrost table. Contemporary thermokarst is inactive in natural conditions. Thaw settlement is very intensive after the removal of a vegetative cover and part of the soil layer. The subsidence rate decreases substantially after 2–3 years. The maximum observed thermokarst subsidence reached 1 m during the period of monitoring.

Keywords: climate; human-induced disturbances; long-term frost heave; thermokarst.

Introduction

Frost heave and thermokarst-related features occur widely in the northern taiga of Western Siberia (Melnikov et al. 1983) where permafrost is discontinuous. Frost heave forms are represented by individual mounds, ridges (with length many time greater then width and height), and vast flat elevated areas. Heights vary from 0.5 to 10 m (Veisman et al. 1976). These forms develop both in natural and disturbed areas (Fig. 1)

Contemporary forms related to thermal subsidence occur primarily in disturbed areas along the Nadym-Punga gas pipeline. Their depth reaches 1 m. There are different opinions on the contemporary activity of these cryogenic processes. According to Evseyev (1976), frost mounds in the region are relic and degrading forms. Nevecherja (1980) described modern frost mounds and has evaluated the growth rate in the northern taiga of Western Siberia. However, he believed that the majority of frost mounds, ridges, and frost-heaved areas were formed long ago, and do not currently grow, and some mounds degrade in the contemporary environment. According to Nevecherja (1980), frost mound growth stops after the frozen nucleus reaches about 10 m. Recently, changes in vegetation on old frost mounds associated with their rise was described by Moskalenko & Ponomareva (2004).

Study Site

A long-term monitoring program was established by N. Moskalenko, V. Nevecherja, and Y. Shur in 1971 to study the impact of pipeline construction on permafrost stability, and on the development of permafrost-related processes in the pipeline right-of-way and surrounding terrain. In this paper, we present data from the Nadym site to demonstrate contemporary dynamics of frost heave and thermokarst in natural areas and those impacted by pipeline construction.

Figure 1. Disturbed frost mounds.

The Nadym monitoring station is located 30 km to the south from the city of Nadym (Fig. 2), in a subzone of northern taiga. It encompasses three geomorphological levels: the third lacustrine-fluvial plain, the flood plain of the Hejgi-Jaha River, and the second fluvial terrace of the Nadym River. The relief is nearly flat with numerous lakes and mires.

The studied region is characterized by two layers of permafrost, which can be defined as surface permafrost and deep permafrost. The surface permafrost is discontinuous and sporadic on the lacustrine-fluvial plain and the flood plain of the Hejgi-Jaha River. Patches of permafrost are confined to peatlands, tundra, and frost mounds. On the terrace of the Nadim River, the permafrost table is lowered and does not merge with the bottom of the active layer.

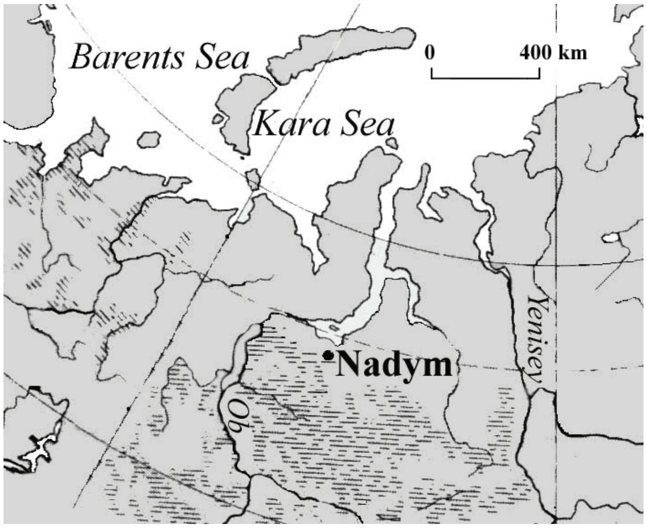

Figure 2. Study site near Nadym.

Depending on terrain conditions, mean annual permafrost temperature varies from 0 to -2°C. The warmer permafrost temperature is typical for dry forest-covered sandy soils. Extensive peatlands have the coldest permafrost temperature. The active layer varies from 0.5–0.7 m on peatlands, and up to 4 m on blowout sand.

The depth of seasonal freezing varies from 0.3 to 0.8 m in peatland, and from 1.5 to 2.5 m in forest with well-drained sandy soil. Recently the permafrost temperature and seasonal thaw depth has increased in both natural and disturbed settings, which is reflected in the dynamics of natural processes (Moskalenko 1998)

Research Objectives and Methods

The analysis of climatic conditions is based on long-term observations at the Nadym weather station.

Observations of long-term frost heave and thaw subsidence were conducted along four transects that cross the gas pipeline right-of-way, the surrounding disturbed zone, and the terrain unaffected by construction that has remained in a natural state. Measurements of frost heave and thaw settlement were made relative to deeply anchored reference bench marks. Elevation surveys and vegetation descriptions were carried out yearly at the end of August. The active layer thickness and permafrost temperature were measured in September.

Analysis of Results

The analysis of the climatic data

According to long-term data, air temperatures and the precipitation amount in in the study region vary markedly from year to year (Fig. 3). The long-term mean annual air temperature is -5.6°C; the difference between annual mean temperatures of the coldest and warmest years reached 5.69° during last 40 years. Despite such fluctuations, a 10-year moving average of annual mean air temperature shows an increase in the period from 1966 to 1997, and small variations

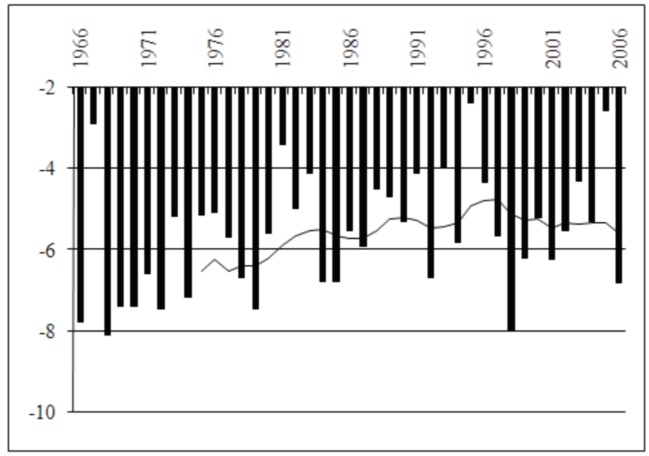

Figure 3. Annual mean temperatures with a 10-year moving average, °C.

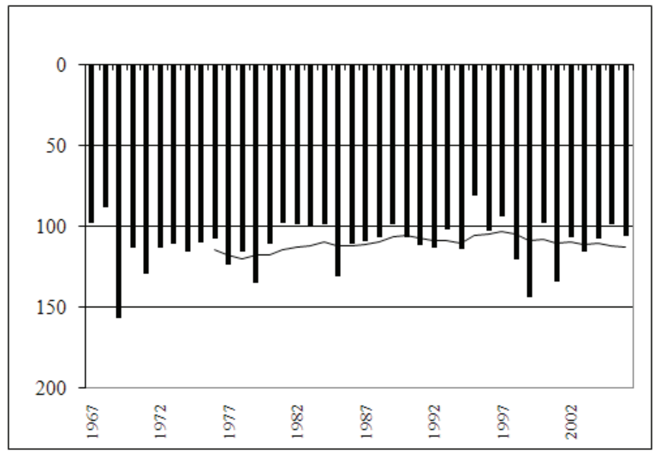

Figure 4. Freezing indices (in °C months) with a 10-year moving average. One degree-month is equal to 30 degree-days.

from 1998 to 2006 (Fig. 3).

Figure 4 shows the freezing Iindices and Figure 5, the thawing indices for the same period. The winter of 1995 had the smallest freezing index for the entire observation period. It was equal to 80.5°C-month, and occurred at the end of the period of warming. The most severe winters occurred in 1999 and 2001 following the warm period, with freezing indices of 144 and 134° C-months. An exception was the cold winter of 1985. Freezing and thawing indices in this paper are presented in °C-months because they were evaluated from available information on monthly mean air temperatures. Their presentation as °C-days would create the wrong impression about the data, but can be estimated by multiplying °C-months by 30.

Thawing indices (Fig. 5) show continuous increase; with time, this will lead to a steady deepening of the active layer and thawing of the ice-rich upper layer of permafrost. However, thermokarst activation under natural conditions has not been detected so far.

The annual mean precipitation is shown in Figure 6. Winter and summer precipitation for the same period is shown in Figure 7 and Figure 8.

It was expected that the abundance of precipitation during

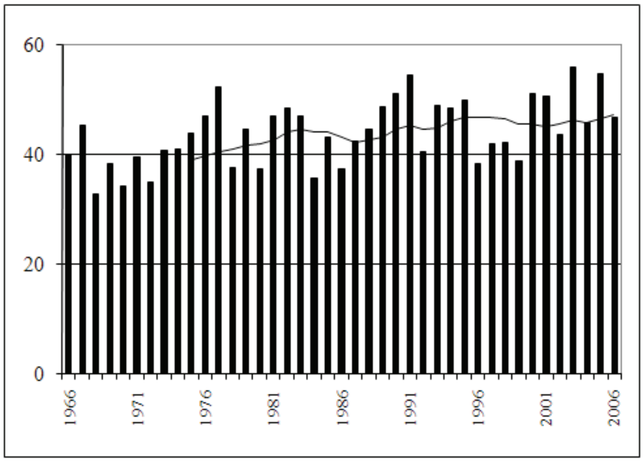

Figure 5. Thawing indices (in °C-months) with a 10-year moving average. One degree month is equal to 30 degree-days.

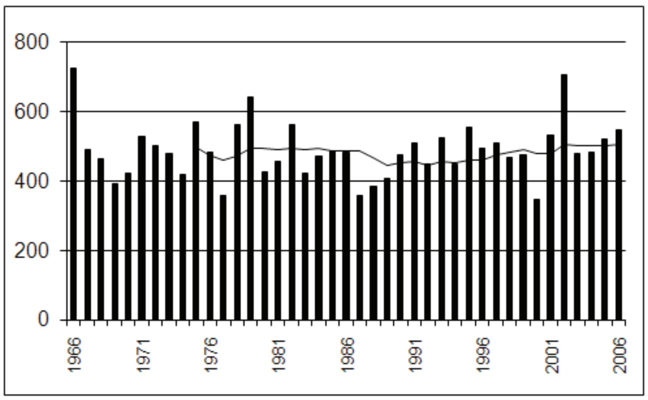

Figure 6. Annual mean precipitation (mm) with a 10-year moving average.

the period with negative air temperatures would lead to a decrease in the intensity of frost heave, and the amount of precipitation for the period with positive temperatures would impact bog development. According to the data presented in Figure 6, the total amount of yearly precipitation increases after 1987, as did the summer precipitation (Fig. 7). The increase in summer precipitation after 1987 has caused an expansion of the bog and lake area, as revealed by 1989 and 2004 satellite images. There is no visible trend in winter precipitation (Fig. 8).

Long-term frost heave of soils of third lacustrine-fluvial plain

Frost heave of soils in the third lacustrine-fluvial plain was studied at 327 points along four transects. Transects were located across various landscapes. The survey of surface elevation was conducted once a year, at the end of August or beginning of September, when seasonal thaw depth had reached its maximum and surface elevation reflected the effects of long-term frost heave processes with minimum seasonal effects. The survey was performed with reference to deep permanent benchmarks.

Transect I-I (Fig. 9) crosses a series of peat-mineral and mineral frost mounds that are surrounded by mires. A survey of frost mounds surfaces shows that frost heave is not

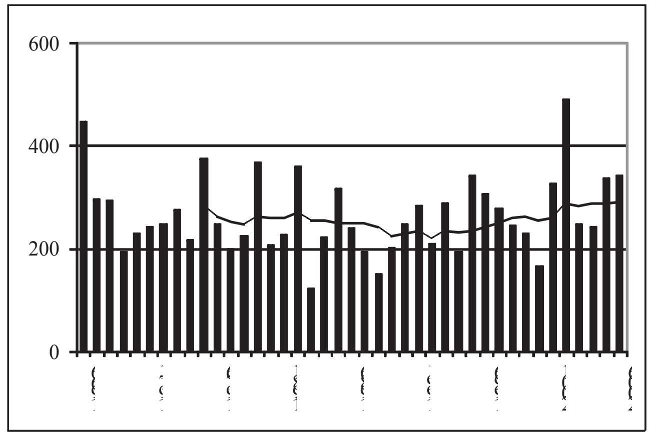

Figure 7. Summer precipitation (mm) with a 10-year moving average.

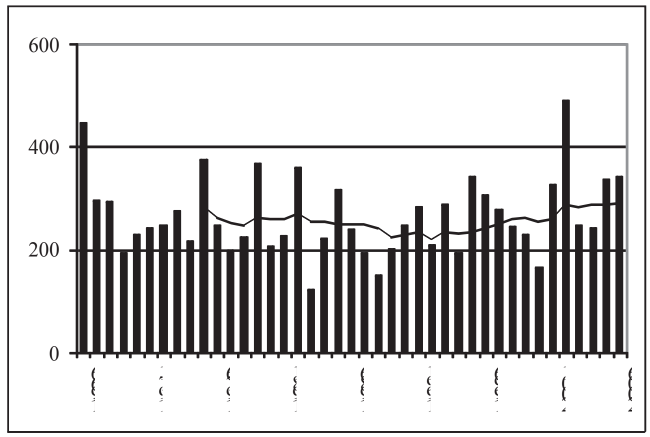

Figure 8. Winter precipitation (mm) with a 10-year moving average.

uniform; there is a steady rise of mound tops and sporadic rise of slopes which is intermittent with subsidence. They rise in the coldest winters;. dDuring the monitoring period, maximal rise occurred in the most severe winter of 1999. During the last 26 years, the central part of one peat-mineral frost mound rose 70 cm, while a mineral frost mound rose 30 cm. For the analysis of frost heave intensity, it is important to note that a thin snow cover occurred nine9 times, including 1985, 1995, 2000, and 2001, during which intensive frost heave took place. The winters of 1985 and 2001 were especially severe. The snow thickness impact on frost heave was obvious in the warm winter of 1995 with low snow thickness. The rise of frost mounds tops with subsidence of their slopes was observed in 2005.

Maintenance work along the gas pipeline in 2004 initiated new surface disturbances and changes in the drainage conditions, which led to the formation of small lakes and widespread flooding (Fig. 10). It decreased the growth of frost mound tops and led to subsidence of their slopes in 2005 and 2006.

Transect II-II was established on the flat peatland and bogs of the third lacustrine-fluvial plain (Fig. 11). The thickness of peat along transect II-II varies from several centimeters to 1.75 m. To a depth of 5 m, peat is underlain by fine and

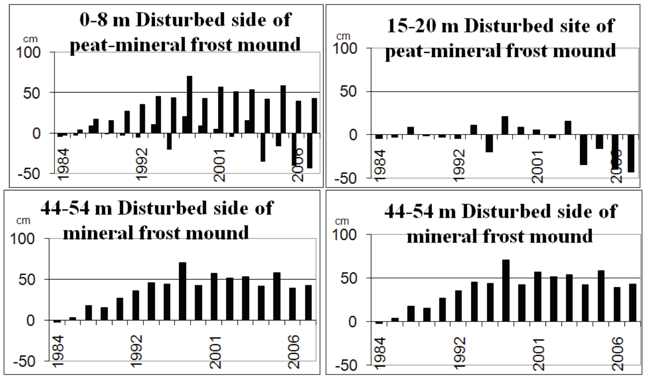

Figure 9. Changes in surface elevation (cm) along transect I-I relative to surface elevation in 1980. Annual values represent averages for that segment of the transect.

Figure 11. Flat peatland along transect II-II.

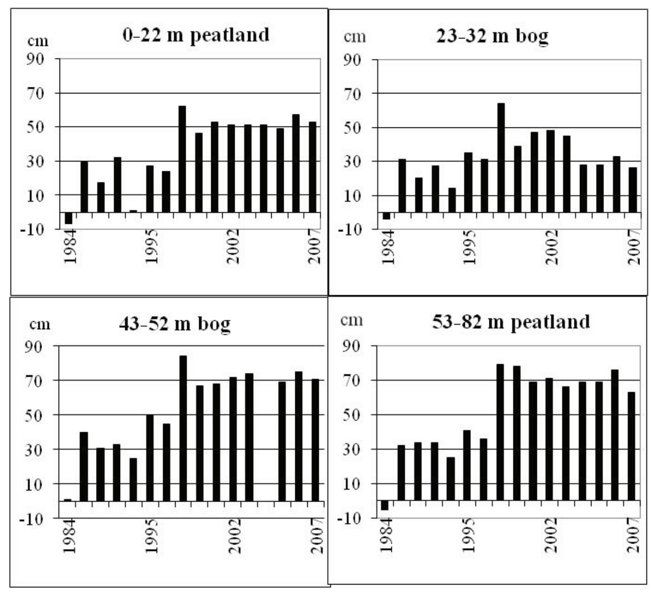

Figure 12. Deviation of surface elevation (cm) along transect II-II from elevation in 1980. Annual values represent averages for labeled segments of the transect.

silty sands and seams of sandy loam with some gravel and pebbles. The layer of sandy loam continues to a depth of 7 to 8 m, where it is underlain by sand. The layer of surface permafrost associates with flat peatlands here.

It was found that the surface along transect II-II experienced a rise in the severe winters of 1985 and 1999 , and in 32 years has became higher by 67 cm than it was in 1980. Frost heave of the flat peatland is uniform in the study area. After 1999, surface rise has slowed down. (Fig. 12).

Transect III-III includes flat peatland and hummocky tundra. Peat, which varies in thickness from several to 80 cm, is underlain by loamy sand to a depth of 3 to 8 m, with loam below. The permafrost table here is lowered to a depth of 3.5 to 4 m. Pereletoks are formed in some years above it. (aA pereletok is a layer of frozen ground which formed as a part of seasonally frozen ground and remained frozen for several summers ([van Everdingen 1998)]). Frost heave on transect III-III (Fig. 13) in one year is intermittent with thermal settlement in another, and the accumulated surface rise for the monitoring period is only 12 cm. The maximal rise of the surface occurred in the cold winter of 2001, with a thin snow cover in the previous winter.

Transect IV-IV is located on a peat-mineral frost ridge, disturbed in 1971 during construction of the gas pipeline. Removal of the vegetation cover triggered thermokarst, an increase in permafrost temperature, and a lowering of the permafrost table (Shur 1981). Vegetation recovery reverses these processes and is favorable to frost heave, although its intensity is very low. It is possible to identify two periods in the direction of processes on the soil surface. The period 1972–1977 is characterized by surface subsidence following construction, and the period which began in 1978 is the period of slow rise of the surface (Fig. 13). During the first period, the surface subsidence was 104 cm on average. The slow rise of the surface (by 50 cm on average) during the second period did not compensate for the earlier subsidence.

Thaw subsidence

In natural conditions, inactive thermokarst forms associated with thawing ice-wedges are typical for peatlands (Fig. 14). Ice-wedge pseudomorphs are also widespread in the region (Fig. 15). Distinguishing forms which could be attributed to contemporary thermokarst in natural conditions are rare, local, and occur on the margins of flat peatlands mainly in association with thermal erosion. Observation show that,

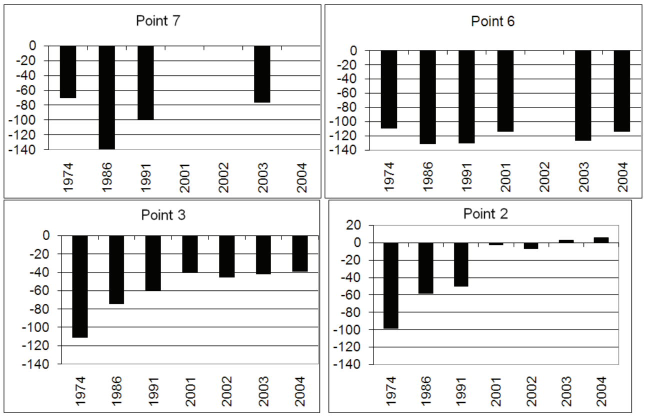

Figure 13. Deviation of surface elevation (cm) along transect IV-IV from elevation in 1972. Annual values represent deviations for every point along the transect.

Figure 14. Inactive thermokarst forms in the vicinity of transect III-III.

Figure 15. Ice-wedge pseudomorphs in the vicinity of transect I-I

despite the lack of notable thermokarst forms, uniform thermal settlement takes place. From 2000 to 2005, the rise of frost mounds and peatlands slowed down, and thermal settlement increased. It reached 31 cm on a peat-mineral frost mound, 47 cm on a mineral frost mound, and up to 64 cm on flat peatland. However, settlement has not led to formation of prominent thermokarst features. Our observations confirm Vejsmana's (1976) conclusion about weak development of modern thermokarst features under natural conditions. This conclusion is correct for natural, undisturbed terrestrial complexes. Presumably, thermokarst will develop at the margins of lakes as their area increases. We expect that our ongoing studies will reveal this.

Conclusions

1. The formation of frost mounds in the discontinuous permafrost zone of West Siberia is a contemporary process on lacustrine-fluvial plain and flood plains in the northern taiga of West Siberia. During the last 30 years, their height has increased from 30 to 70 cm, with a maximal rise occurring in the coldest winters of 1999 and 2001.
2. In areas disturbed during pipeline construction, peat frost mounds occur in three stages: thaw settlement, surface stabilization, and frost heave. The last two stages largely depend on vegetation recovery.
3. Thermokarst is not active under natural conditions. It is triggered by construction work, and is very active in the first several years. The total thaw settlement in the study area reached 100 cm during the period of observation.

Acknowledgments

This research was partly funded by the Polar Earth Science Program, Office of Polar Programs, National Science Foundation (ARC-0632400 and ARC-0520578). Natalia Moskalenko has been our long-term companion in the field and our mentor on terrain analysis. Comments by reviewers and their advice were very helpful. Ken Hinkel provided valuable suggestions that improved the manuscript.

Abstract

We have studied the permafrost in the Imuruk Lake volcanic field area (Alaska) from an astrobiological perspective. Our main goal was to test in terrestrial permafrost the type of instrumentation designed to search for biosignatures in this environment to obtain a performance baseline, should the instrument be used on a future space mission to explore Mars. Permafrost characterization was performed using geophysical sounding and drilling, and different levels of the rock cores were analyzed to determine the mineralogy, geochemistry, and microbiology. Thirteen lines of electric tomography from the Imuruk Lake coast up to the hill of the Imuruk formation were analyzed. Three perforations were made at strategic locations along the slope of the hill. Samples were collected at several depths in the three holes for mineralogical, geochemical, and biological analysis. Here we present the results of the subsurface mapping performed to locate the permafrost and of the analyses of the core samples.

Keywords: Alaska; astrobiology; electrical tomography; Imuruk Lake; permafrost.

Introduction

The study of terrestrial permafrost has become a priority for planetary missions focused on Mars. The main reason is that the martian permafrost likely represents the current main water reservoir of the planet (Clifford & Parker 2001). From an astrobiological perspective, permafrost is important not only because of the role of the water in the planet's hydrological cycle and the fact that it may hold a direct record of the planet's paleoclimatic record, but also because it may be a potential habitat for microorganisms (or preserve biomolecular tracers of past life) since it (a) acts as a thermally stable shelter, (b) is a source of moisture, and (c) is a shield against incoming radiation (Gomez et al. 2004). Consequently, robotic exploration of permafrost on Mars is being considered for future missions by the international suite of space agencies (Smith & McKay 2005, Shotwell 2005). At present, direct study of the martian permafrost has not been possible due to technical limitations and uncertainties. However, terrestrial analogues to Mars' permafrost are currently being investigated from novel perspectives that include space technology and astrobiology. The results are being used to develop instrumentation for future space missions focused on the search for life.

Some characteristics of martian permafrost have been modeled by using data from planetary exploration missions. At the present time, this dataset is continuous at circumpolar latitudes, where an active layer (the top layer of permafrost that seasonally thaws) is absent. At middle latitudes, permafrost is continuous although a thin active layer may exist, especially if salts are present to depress the melting point. In the tropical zone, ground temperatures exceed 273 K during the summer, and annual mean temperatures indicate that continuous permafrost exists, but ice is absent or patchy at best due to hyperaridity (Squyres et al. 1992). Recently, *Mars Odyssey* mission data have defined the periennial underground ice stability zone from latitudes higher than 60º (Feldman et al 2002, Mellon et al. 2004).

The Alaskan permafrost now serves as a martian analogue for the planetary science community. The permafrost of the Imuruk Lake area (Seward Peninsula, Alaska) offers a valuable and relatively accessible location for testing instruments for remote mapping and searching for life in the water underground. There are few studies about this area, though some report the general geology (Hopkins 1963) or different analyses of cores from several drill sites in the area, which were cored to constrain the climatic events that have occurred in the area (Colinvaux 1964, Colbaugh 1968, Marino 1977, Shackleton 1982, Hamilton 1991). None of the reports, however, covers permafrost mapping, mineralogy, geochemistry, and biology simultaneously. Nor do any reports consider the recent interest in the permafrost as an analogue environment of Mars. The permafrost on this area is considered continuous (Péwé 1975), and it extends in some parts to more than 50 m thick (Hopkins 1963). Ice wedges and polygons are frequent in the Imuruk Lake area. It has been suggested from analyses of the stratigraphy that certain ice wedges in frozen ground are at least from the early Wisconsinan glacial period.

We show here the results of a field campaign performed during the summer of 2005 in the Imuruk Lake area. With the intent to develop future instrumentation for remote life detection systems, we pursued three main objectives: (1) permafrost localization by geophysical techniques and drilling the permafrost, (2) microbial diversity analysis, with special interest on the deeper part of the cores given the older age of this permafrost (i.e., the preservation pattern of biosignatures in cold environments is of extraordinary astrobiological interest), and (3) understanding of the cold ecosystem for the purpose of detecting and mapping permafrost niches. Geophysical sounding for mapping the permafrost was made before we sampled it. Three cores in the mapped area were taken. Clean drilling techniques were used, following planetary protection rules. Geochemical and biological analyses were made in the laboratory, though they were previously prepared in situ.

Regional Setting

The Imuruk Lake area is on the Seward Peninsula, a few kilometers above the polar circle. It is north of the Bendeleben Mountains in a Cenozoic lava plain. Landscape heights of the surrounding area vary from 45 to 600 m, with the highest topography caused by Mesozoic granitoid intrusions and Paleozoic metamorphic rocks, which constitute the geological rock basement. The central part of the area is characterized by monogenetic volcanoes, active from the late Paleogene. Five volcanic formations have been distinguished in the Imuruk Lake area, among which mantles of windblown silt with different extent and thickness have been deposited (Hopkins 1963). Volcanism is basaltic to andesitic, mainly with pahoehoe lava flows, although locally there are some dome structures. Permafrost in these materials is especially interesting with regard to the interaction between rocks and ice, from which we derive analogies to important martian landforms and materials. Ice-rich permafrost is primarily continuous—tens of meters thick, except under and near the major lakes and rivers. In addition, parts of the lava flows interrupt the permafrost, thus allowing groundwater circulation.

The Imuruk Lake occupies a basin configured by a distorted northwest trending graben. Tectonics during the Cenozoic formed several fracture systems in three different stages. The lake area was uplifted to the northwest, as well as bent, as shown by the study of the terraces. Three levels of terraces have been identified: The low level is presently occupied by active beaches on the east shores of the lake; intermediate terraces are cover by peat and silt; and the higher terrace is a wave cut not associated with sediments.

Current climate in the Imuruk Lake area is cold, with a mean temperature of 266 K and minimum values during winter of 213 K. Annual precipitation is 20 cm, from which 50% is between July and September, and 25% is as snow.

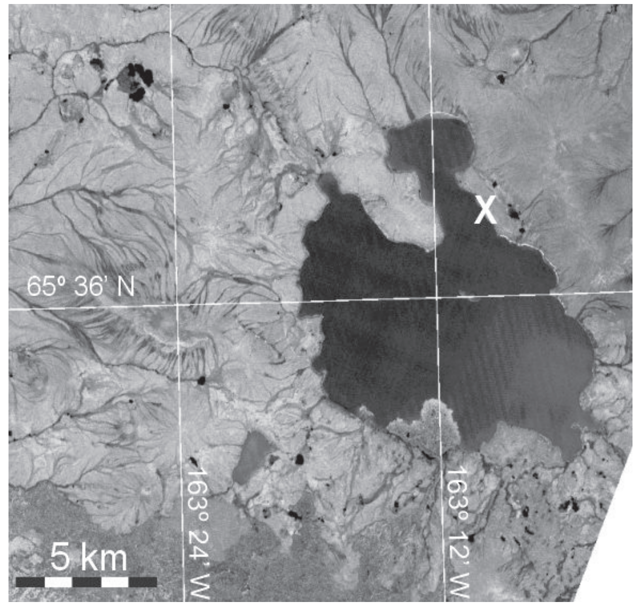

Figure 1. Imuruk lake area. Field work of 2005 campaign was made at the east shore of the lake (X).

Glaciations have affected the Imuruk area from lower Pleistocene: Nome River, Salmon Lake and Mount Osborn glaciations altered the successive volcanic rocks, which were erupted and produced eolic silts that covered them.

Considering the bad accessibility of the area, some analysis of ASTER images was performed in order to constrain the study area before the fieldwork campaign. The selection of the study area was made among the most ancient volcanic formations, where surface materials showed a low brightness temperature during summer and the topography is smooth enough to facilitate the drilling. Fieldwork performed during the 2005 expedition was made in the eastern part of the Imuruk Lake between Nimrod Hill and the lake itself (Fig. 1). This area was mapped by Hopkins (1963) as the named Imuruk volcanic formation, which is dominated by basalts and basaltic andesite lava flows overlain by 1–6 m of windblow silt. A cover of peat is present at the top. Surrounding the volcanic hill, some lake sediments, gravel, sand, silt, and peat of intermediate terraces have been mapped already (Hopkins 1963).

Geophysical Survey

To map the permafrost underground, electrical resistivity tomography (ERT) sounding was performed. ERT is a geophysical prospecting technique designed for the investigation of areas of complex geology. The principal applications of this technique are (Telford et al. 1990, Reynolds 1997, Hauck & Mühll 2003, Kneisel 2004; Šumanovac 2006) mapping stratigraphy and aquifer boundary units, such as aquitards, bedrock, faults and fractures, delineation of voids in karstic regions, mapping saltwater intrusion into coastal aquifers, identification of contaminated groundwater plumes, mapping of mineralization zones, exploration of

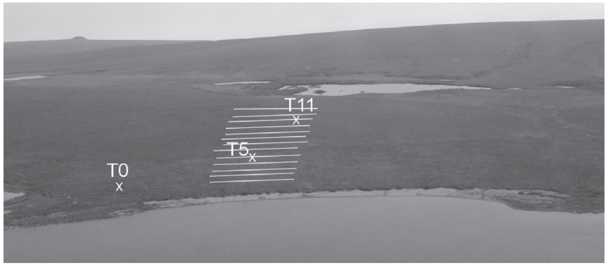

Figure 2. Image of the area where the 13 ERT lines were done. T0, T5, and T11 are the locations of the drill sites.

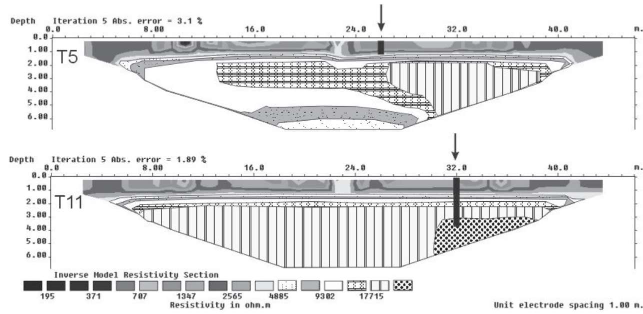

Figure 3. Tomographic profiles 5 and 11. Black arrows indicate the drilling sites.

sand and gravel deposits, as well as mapping permafrost in mountainous regions, among others.

Several standard electrode arrays are available, such as Wenner, dipole-dipole, and pole-dipole arrays, with different horizontal and vertical resolution, penetration depth, and signal-to-noise ratio. The Wenner array provides good vertical resolution, though it also gives reasonable horizontal resolution (Sasaki 1992). This method has a greater signal-to-noise ratio than others (e.g., the dipole-dipole method) because the potential electrodes are placed between the two current electrodes. These features provide greater depth of investigation.

Syscal KID Swich-24 equipment was used for taking the measurements. Thirteen parallel lines from the Imuruk lake coast up to the hill of Imuruk formation were accomplished (Fig. 2). Each ERT line was 48 m long, with 2 m between each pair of electrodes. The space between lines was around 15 m, depending on the difficulty of the topography for settling the electrical lines.

The resistivity field dataset comprises resistance measurements between various electrodes and related geometry information. An apparent resistivity value is calculated, which depends only on the resistance measurements and the array geometry. These data are plotted as a pseudosection, which is a plot of the apparent resistivity values based on the geometry of the electrodes. These pseudosections, which are difficult to work with, are then converted into sections with true resistivity values and depths via a data inversion procedure that helps in the interpretation process. An inversion of the data produces a plot that shows a resistivity value for each horizontal and vertical node. This resistivity inversion section is then used to interpret the subsurface lithology. The data are inverted with RES2DINV software. Data processing steps include removing bad data points, selecting the inversion method, and then interpreting the data.

The resulting ERT data for our study indicated that permafrost in the region analyzed is at a mean depth of 0.50 m under the surface, sometimes even shallower. The presence of peat materials at the top of the stratigraphic column acts as an insulator layer, maintaining very effectively the low temperature below.

From the analysis of the 13 ERT profiles, 2 clearly distinctive units were identified (Fig. 3): an upper unit that extended from the surface to 0.5–1 m depth, characterized by resistivity values ranging from 130 to 680 ohm·m, and a lower unit that reached 6 m depth (the maximum depth of investigation), defined by a resistivity that ranged from 12,400 to 30,000 ohm·m. Taking into account the in situ drilling observations, the study area was comprised by silt overlain by a thin level of peat.

Typical resistivity values for silt and peat are 10–200 ohm·m (Telford et al. 1990, Reynolds 1997, Comas et al. 2004), a value that depends mainly on the water content and ionic concentration. Permafrost resistivity values are typically greater than 10^3–10^4 ohm·m (Reynolds 1997, Hauck & Mühll 2003, Kneisel 2004) due to the strong resistance of the ice. Bearing this in mind, the upper low-resistivity unit could be related to the presence of peat and silt material with unfrozen water, whereas the lower high-resistivity unit represents the permafrost developed in silt materials. Vertical heterogeneities in electrical resistivity were observed in the upper part of all the profiles, which have been interpreted as the edges of the polygonal terrains (Fig. 3). Thus, the lower resistivity values in the upper unit correspond to finer grained and higher water content materials of the polygonal terrains, whereas higher resistivity values are associated with the coarser materials (i.e., at the edges of the polygonal terrains).

The high resistivity in the lower unit represents the permafrost developed in silt materials, which reached a thickness of at least 5–5.5 m in all the profiles. At first glance, this unit is much more homogeneous than the upper unit, although some spatial variations were measured. ERT profiles 1 to 8 exhibited resistivity values for permafrost that ranged from 12,500 to 21,000 ohm·m, with higher values at the end of the profiles than at the center. In addition to this, ERT profiles 6 and 7 showed resistivity values at 6 m depth (about 5,000 ohm·m), similar to the ones that defined the top of the permafrost at 0.5–1 m depth. This fact makes evident that the base of the permafrost in these profiles is located near the maximum depth of investigation. The resistivity values for the permafrost in ERT profiles 9 to 13 ranged from 24,000 to 30,000 ohm·m, being much more homogeneous than in profiles 1 to 8. The resistivity did not decrease in depth, so the lower boundary of the permafrost must be below 6 m depth. Only profiles 12 and 13 showed a spatial variation in the resistivity of the permafrost, with higher values to the western end.

Drilling Survey

A Cardi E-400 driller—small, portable, and fuel-operated—was employed in this expedition. By connecting 0.5 m bits, a maximum 5 m long drill was obtained. The diameters of the bit and the recovered core were 50 mm and 40 mm, respectively. No refrigerant substances were applied to preserve the area from contamination.

Drilling points were selected on the basis of the permafrost depth known from the ERT data analysis. Three perforations were done along the hill (Fig. 2). The first core obtained, which was placed in the ERT line 5 (T5), was about 1 m long. It consisted of peat and brown silt with abundant organic matter. The permafrost started at 0.3 m underneath the surface. The second core, drilled at ERT line 11 (T11), reached 3.6 m depth. Permafrost was found at 0.55 m. The peat cover above it was smaller. Below it, brown silt with organic matter was observed to a depth of 3.0 m. The sand fraction of the silt was composed of quartz and plagioclases (albite and anorthite), while the fine fraction was composed of clinochlore, montmorionite, illite, and vermiculite. From this point to the core bottom, the materials were green-yellowish silt, almost free of organic material (Fig. 4). The third core was drilled out of the study area by tomographic lines closer to the lake, and penetrated a 2 m depth (T0). Permafrost was at 0.50 m, at the same depth as the peat cover. Below that level, we found the green-yellowish silt with transversal lenses of both clean ice and organic silt. The silt found in this core was free of quartz. The sand fraction was made by anorthite, labradorite, and microcline as plagioclases, with diopside, augite, and acmite as pyroxenes. From 1.5 m down, the materials are basaltic-andesitic pebbles inlayed in a silt matrix (Fig. 5).

Samples were collected at several depths in the three holes for mineralogical, geochemical, and biological analysis. They were fixed in situ with formaldehyde to maintain them until biological laboratory analyses were developed. Several types of fresh growth media were inoculated with samples from different depths in the field for microbial enrichment. The mineralogy of the core samples was analyzed by XRD, FTIR, petrographic microscope, and SEM.

Laboratory Analysis

Core sampling for further laboratory analyses was performed in all 3 cores, starting at 50 cm from the surface. Geochemical analysis of selected samples of the melted ice and sediment along the cores was run by ICP- MS Perkin Elmer Elan 9000 and an elemental analyzer LECO CHNS-932. Mineralogical studies were performed with XRD and microscope thin sections analysis.

Dating and correlation with other cores

Samples from cores 11 and 5 were taken for age analysis. The C^{14} dating analyses were done in the Angström Laboratory of Uppsala University (Sweden). Measurements were performed on the sediments after the roots and carbonates were removed. Our analysis indicated that the age of the silt sediment at 2.0 m in the T11 drill site is 11155±75 BP, and 12705±90 BP at the bottom of the core (3.6 m). We found that the T0 core ages are 13450±100 at 1.5 m and 20250±225 years BP at 2 m depth.

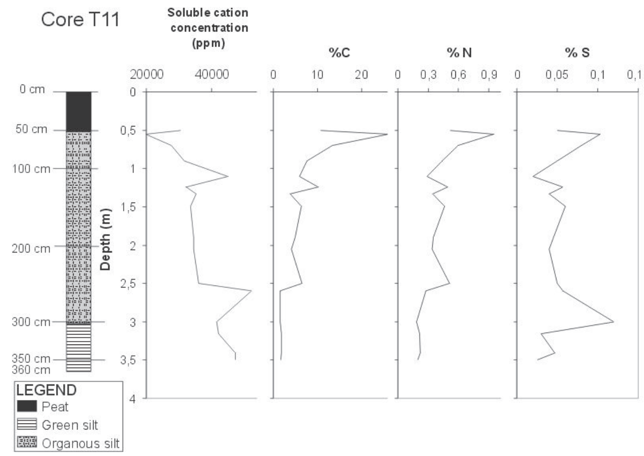

Figure 4. Lithology and distribution of soluble cation concentration, %C, %N, and %S in core T11.

Some other drilling studies, which included C^{14} dating analysis, are available in the bibliography. All of the cores in our study were obtained from the lake floor. Colinvaux (1964) reported the results from some cores, named cores I and V, made in Imuruk Lake between the east shore and the Gull Islands. Core I is the more relevant and longest one (8 m long). It consists of layers of mud from the weathering of the volcanic rocks, as well as sand layers that were transported from the beach in low-water-level episodes of the lake. The mud layers are enriched with montmorillonite and kaolinite. Dating of this core was problematic because: (a) two of the youngest dates were measured near the core base (probably due to tectonics), and (b) there are some gaps in the sediment record (possible erosion occurred during the lower-water-level episodes). Later revisions of the core data were done by Colbaugh (1968), Shackleton (1982), and Hamilton (1991) to constrain the climatic events that occurred in the area. Marino (1977) studied the paleomagnetism of the cores. It is worth noting that no detailed petrologic descriptions of the core sections are published, so we are unable to correlate the cores we collected with any others.

Geochemistry.

In cold areas, the mineralogy of the sediment is made up of many chemical elements, though some soluble ions are commonly removed or concentrated, depending on the availability of liquid water (Chegue-Goff & Fyfe 1997, Kokelj & Burn 2003, 2005). These soluble elements can indicate the depth of the active layer of the permafrost. CHNS elemental analysis is useful for delimiting the peat and organic-rich layers in the sediment cores. The entire core T5 is peat, with a carbon content that ranged from 34.7 to 40.9 %. In core T11, the concentration of carbon had a maximum peak of 26% at 0.55 m, though it decreased with depth. The peat should end at 0.6 m. The silt from 0.6 to 2.5 had an average of 7% C, and from 2.5 to 3.6 m, the green silt had an average of 1.6% C (Fig. 4). Samples taken from below the T0 core (Fig. 5) had a very low carbon concentration, except

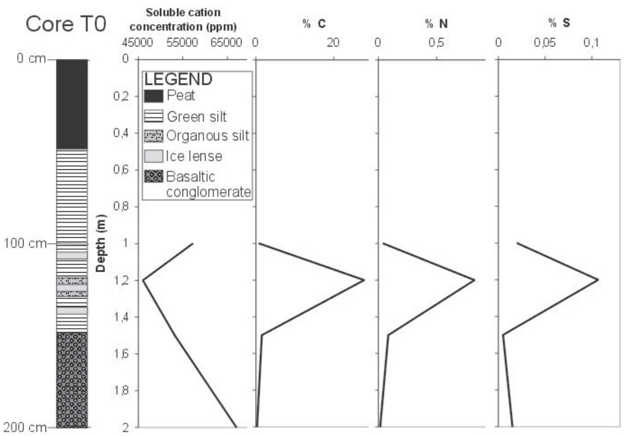

Figure 5. Lithology and distribution of soluble cation concentration, %C, %N, and %S in Core T0.

in a thin layer at 1.2 m. In the three cores, the trend of H, N, and S are well correlated to C, except for S in core T11, where there was a positive anomaly at 3 m.

Soluble cations (Na, Mg, Ca, K) are good indicators of permafrost active layer fluctuation. These elements are mobilized when liquid water is present and they are concentrated above the ice table (Fig. 4 and 5). Note the lack of data from the upper centimeters of the T11 and T0 cores. The T11 core data showed a positive anomaly at 1.1 m and 2.6 m. The anomaly at 1.1 m is mostly due to Na and K, which are probably related to an enrichment of feldspars in the sediment. In the 2.6 m anomaly, the presence of all four cations in the mineralogy of the silt contributed to the change. The T0 core was found to be enriched in Ca and Mg in the upper part, and there was a negative anomaly at 1.2 m due to the organic rich and clean ice water layers at this level. The total content of cations increased at the bottom of the core as a result of the presence of K and Na in the feldspars and clays.

Biology

In situ hybridization techniques were used to document the distribution of targeted microorganisms in the study area. Samples were fixed in the field with formaldehyde (4% v/v) and refrigerated for 2 h. After incubation, samples were washed twice with PBS and filtered. Filters were stored under frozen conditions in PBS-ethanol (1:1). Samples from several depths were chosen for further study with different DNA-specific probes. Cell counts were measured using the optical microscope.

The abundance of cells per mg of sample was analyzed in the first 60–70 cm of the column (the permafrost active layer). Elemental chemical analyses determined an active layer of 50–70 cm (according to the microbiological studies; see Gomez et al. 2008).

Hybridization with DNA-specific probes determined a high presence of bacteria in the upper part of the T11 column. In contrast, lower concentrations of active cells of bacteria were found deeper in the sample. From 2.1 m to 3.6 m depth, we found that the Archaea were the most abundant cell types in the samples.

Discussion

Our ERT survey in the Imuruk Lake area revealed the occurrence of two units: an upper low-resistivity unit that consists of peat and silt with unfrozen water, which was vertically heterogeneous due to the structure of the polygonal terrains; and a lower unit of higher resistivity, which was found associated with the development of permafrost in silt materials. Variations in resistivity in this lower unit revealed that permafrost in the southern part has a higher content of liquid water that decreased in thickness towards the central part of the study area, where the base could be located at around 6 m depth. In contrast, we found that permafrost in the northern zone contains a lesser volume of liquid water and/or reaches a greater thickness. Geophysical sounding by ERT or GPR (Corbel et al. 2006) could be useful in a planetary mission for mapping the stratigraphy, structure, and position of ice-rich permafrost on Mars before deploying the complex instrumentation needed to drill on Mars.

When ice-rich permafrost is drilled on Mars, in situ analyses should (a) confirm the presence of the liquid phase and its movements, for example, by following the salts; (b) characterize the environment, for example, by recording the temperature and pH; and (c) search for biosignatures. Mineral analysis would reveal elements that might be used by some microorganisms. The changes in the oxidation state of the elements and the pH of the liquid phase would affect the state of the organic matter (Vogt & Larqué 2002). The secondary mineralogy that would result from this type of interaction could be detected by space missions, and might indicate the presence of life. Microbial activity may be traced by direct or indirect fingerprints on the minerals. Mineral biosignatures may be distinguished by textural and chemical changes due to dissolution and the growing kinetics variation shifted by metabolism, such as the formation of nanometric particles of iron oxyhydroxides during the iron-oxidizing bacterial enzymatic catalysis, or the reorganization of mineral paragenesis when equilibrium is perturbed biologically.

Given the thermal stability of permafrost (at temperatures less than 0ºC), such a deposit could harbor extinct organisms. Living organisms could thrive if they are able to extend the adaptation processes because of the slower metabolism at low temperatures. However, sudden changes of activity due to the seasonal melting of ice could occur inside the active layer of the permafrost. The metabolic state and the biochemistry of permafrost organisms have not been well studied to date. Microorganisms living in the permafrost could survive frozen during long periods of time (Gilichinsky et al. 2007) and could be activated instantaneously as indicated by some biogeochemical manifestations (for instance, enzymes suddenly working, presence of metastable iron sulfides and nitrates, or lipids, protein, and ADN synthesis) (Rivkina et al. 2004, Vorobyova et al. 1997). Moreover, the study of biosignature preservation in permafrost environments will reveal whether they might be useful places to search for evidence of life in future missions to Mars.

Conclusions

We are studying the permafrost in the Imuruk Lake volcanic field area (Alaska) from an astrobiological perspective. Terrestrial permafrost is an essential reference for potential habitable environments on Mars.

Studies like this will help guide future planetary explorations and guide the interpretation of their data by providing directions on how to (1) develop new instrumentation for detecting and mapping the permafrost on Mars; the current or ancient (but now frozen) active layer could be search with geophysical methods such as the ERT used in this study, though more fieldwork is needed to be capable of interpreting data from Mars; (2) define preservation patterns of biosignatures in cold environments that may be used in future missions; and (3) develop new instrumentation for detecting life, in situ and remotely. The extreme environment in which this kind of work was accomplished entails a suitable testbed for developing robust and effective techniques that warranty the success of the mission.

What Dictates the Occurrence of Zero Curtain Effect?

Jaakko Putkonen
Department of Earth and Space Sciences, University of Washington, Seattle, WA 98195, USA.

Abstract

Zero curtain effect refers to the persistence of ground temperatures at or close to 0°C during annual ground freezing or thawing. This phenomenon is related to both active layer underlain by permafrost and seasonally frozen ground. Zero curtain effect in the permafrost areas is traditionally contributed to the ground water freezing in the fall and resulting release of the latent heat. If the phase change of water to ice or vice versa is the primary reason then the zero curtain should be found in the fall and spring in both the active layer and seasonally frozen soils, which is not the case. Through thermal modeling it is shown that the annual evolution of the subsurface thermal field leads into the establishment of isothermal soil near 0°C between two phase change fronts only in special cases. The modeled occurrence and timing of zero curtain effect corresponds well with the observations.

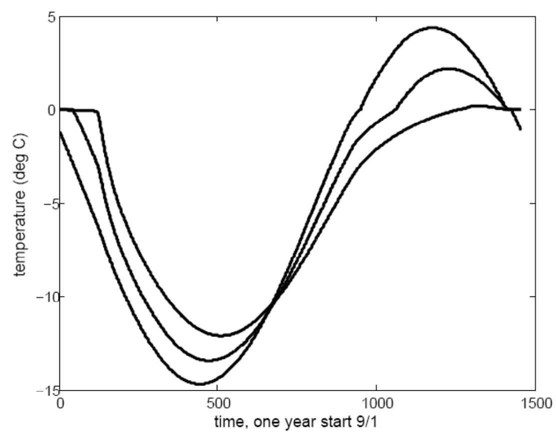
Keywords: active layer; ground ice; permafrost; thermal modeling; unfrozen water; zero curtain.

Introduction

Zero curtain is defined in the *Glossary of Permafrost and Related Ground-ice Terms* as the persistence of a nearly constant temperature, very close to the freezing point, during annual freezing (and occasionally during thawing) of the active layer (van Everdingen 2005). Outcalt et al. (1990) provide a good history of the definition and related research, and a suggestion of the correct usage of the term which is followed here.

Figure 1A shows prominently the modeled zero curtain in the fall that is a characteristic feature of active layer annual thermal regime and has important implications to water migration in soil and related ice lensing and frost heave (e.g., Hallet et al. 2004). For good examples of zero curtain in natural soils see Washburn (1979, Figure 3.34) and French (1996, Figure 4.5). This phenomenon is explained to result of the latent heat that is released through the phase change of water into ice (Washburn 1979, Williams & Smith 1991, French 1996, Osterkamp & Romanovsky 1997, van Everdingen 2005). A careful examination of the evolution and maintenance of the zero curtain has revealed mass and heat fluxes in the forms of water and vapor in some cases (Hinkel et al. 1990, Outcalt et al. 1990, Hinkel & Outcalt 1994) and only heat conduction and phase change in others (e.g., Osterkamp & Romanovsky 1997).

The release of latent heat through freezing of water is generally found to be the primary explanation for the occurrence of the zero curtain effect that is often seen in the fall in the thermal record of active layer underlain by permafrost. Therefore it is intriguing that those same thermal records often show no zero curtain in the spring, when the same amount of soil ice melts. Simplistically one would expect to see approximately similar zero curtain in the spring as is seen in the fall at a given field site. Yet, typical field observations show active layer temperatures at any given level in the soil to cross 0°C in the spring at a steady rate. This is also well represented in Figure 1B.



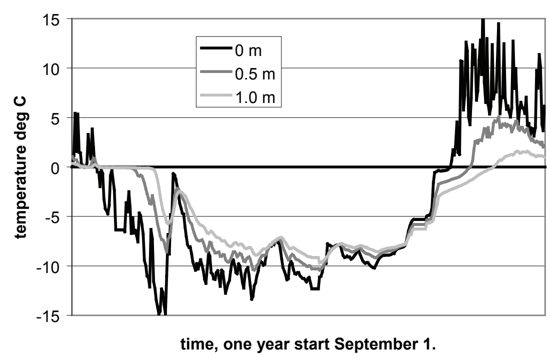


Figure 1. A. Modeled soil temperatures over one year at 0.1 (largest amplitude), 0.5, and 1.0 m (smallest amplitude) below ground surface. Mean annual temperature of the surface forcing is -5°C. B. Measured soil temperatures over one year at a field site in Spistbergen (Putkonen, 1997). Note prominent zero curtain in the fall in both model and observations and the lack of zero curtain in the spring.

No clear explanation has been given in the literature for the intriguing lack of the zero curtain in the spring in the permafrost areas or the intriguing reversal of zero curtain effect occurring in the spring and no zero curtain effect in the fall in seasonally frozen ground.

This apparent contradiction between observations and the simplistic phase change governed explanation motivated the analyses that are presented here.

The purpose of this paper is not to model or explain all the possible soil thermal processes such as non-conductive heat transfer that potentially contribute to the maintenance and longevity of the zero degree curtain. However, the objective of this analysis is to provide a clear explanation for the characteristic occurrence (fall or spring) of the zero curtain effect and the intriguing contrast in timing of zero curtain effect between permafrost and seasonally frozen soils.

It is suggested here that the occurrence of zero curtain is primarily controlled by the soil thermal regime rather than just the existence of the water or ice and related phase change at or near 0°C. In the case of the soil that is underlain by permafrost where the mean annual soil temperature is below 0°C, the time lag in the penetration of the annual thermal wave into the soil will make the soil almost isothermal close to 0°C at the beginning of the fall freeze up regardless of the water content. Because of the almost vanishing thermal gradient at shallow subsurface (~0.5 m), and the presence of water in the soil, the temperatures are changing only near the surface and at depth. This explains why the soil is retained for a prolonged period at the 0°C. On the other hand, in the spring the time lag in the penetration of the annual surface thermal wave enhances the steepness of the thermal gradient near 0°C, the isothermal soil domain is too cold to be affected by phase change of ice to water, and therefore the energy is effectively transferred through the whole soil column. This results in slow but steady temperature increase at all levels in the soil. Therefore the soil temperatures increase at a steady rate through the spring at all levels without any significant slowing in the warming rate at or near 0°C.

In some instances the soil surface temperature may be held at 0°C for weeks due to the melting of the snow and resulting ice/water bath at soil surface. However, this will only modify the driving temperature and potentially slow the overall warming of the soil, but it will not result in zero curtain effect.

The above suggestion that the occurrence of zero curtain effect is dictated by the annual evolution of the soil thermal profile leads to three robust and testable predictions: 1) in soils that are underlain by permafrost and where mean annual soil temperature is <0°C, the zero curtain effect occurs in the fall and there is no significant zero curtain effect in the spring, 2) in areas of seasonally frozen ground (mean annual soil temperature >0°C) the zero curtain effect occurs in the spring rather than in the fall and remarkably there should be no significant zero curtain effect in the fall, and 3) in the areas where the mean annual soil surface temperature is close to 0°C, there should be a short and weak zero curtain effect at both fall and spring.

To study the annual evolution of the thermal regime of soil that contains ice and water, a soil thermal model is used. Finally the model results are qualitatively compared to representative soil temperatures from three field sites that correspond to the above mentioned three soil thermal regimes.

Soil Thermal Model

A one-dimensional thermal model (Putkonen 1998, Putkonen et al. 2003, Putkonen & Roe 2003) is used where soil heat flux (Eq. 1), q is given as

$$q = k\frac{dT}{dx} \tag{1}$$

where k is thermal conductivity [W/m K], and dT is the temperature difference [K] at two points separated by dx, the distance in x direction [m]. When the soil heat flux (Eq. 1) is combined with an expression for the conservation of energy, they lead to the differential equation that describes the time dependent soil thermal evolution (Eq. 2)

$$\frac{dT}{dt} = \frac{dq}{dx} \tag{2}$$

where dt is time difference [s]. This leads to the general formulation of thermal diffusion (Eq. 3):

$$\frac{dT}{dt} = K\left(\frac{d^2T}{dx^2}\right) - dT \cdot LE\left(V_{ufwater}\left(T_{t=t-1}\right) - V_{ufwater}\left(T_{t=t}\right)\right) \tag{3}$$

where $V_{ufwater}(T_{t=t-1})$ is the volume of unfrozen water [kg/m^3] at the temperature $T_{t=t-1}$ [K] at the time step t = t − 1, and K (Greek Kappa) is the thermal diffusivity [m^2/s].

In the model the phase change of water is distributed over a wide temperature range rather than occurring sharply at 0°C. This formulation is based on direct determination of unfrozen water content of a representative frozen soil sample at varying temperatures (Putkonen 1997). The initial soil water content is 295 kg/m^3.

To achieve maximum clarity in the model results the soil surface temperature is forced by a simple sinusoidal thermal wave with annual amplitude of 20°C. The initial soil thermal state is generated by running the model with five consecutively repeated annual cycles that carry over the soil moisture and temperatures from the end of previous year to the beginning of the following. After this initializing sequence the maximum difference between soil temperatures at the end of model years 4 and 5 is less than 0.02°C.

The lower boundary condition in the model is adiabatic (no flux across the boundary) at 20 m below ground surface where the initial temperature is the mean of the annual surface forcing (-5°C, 5°C, or 0°C depending on the case).

Soil thermal properties and surface thermal forcing that are used in the model are representative of general permafrost soils and are inspired by actual measurements at a field site in Spitsbergen (Putkonen 1997). However, these model runs do not attempt to reproduce any actual observations. The mean annual temperature of the forcing corresponds to the three climatic cases.

Soil thermal conductivity of a frozen soil with all water frozen is 3.0 W/m K; thawed soil thermal conductivity is 2.6 W/m K. The frozen soil thermal conductivity that contains unfrozen water scales between the completely frozen and completely thawed stages with the unfrozen water content. The thermal conductivity of the bedrock is 5.0 W/m K. The heat capacity of the soil mineral matter is 1.7x10^6 J/m^3 K. The heat capacities of water and ice are 4.18x10^6 J/m^3 K and 1.92x10^6 J/m^3 K respectively. The soil bulk heat capacity is a sum of the constituent heat capacities and therefore varies continuously as the water is freezing or thawing in the soil.

The internal consistency of the thermal model was tested by contrasting the modeled soil surface heat flow over a given time period (W/m^2) against the energy involved in the water phase change and soil temperature change. These two independent calculations of the soil energy were within 2% of one and other. This is probably as close as a finite difference formulation can be expected to be.

Results

As shown in Figure 1A, the model reproduces the zero curtain effect in the fall and does not reproduce a zero curtain effect in the spring exactly as reported for typical active layer underlain by permafrost (Washburn 1979, Williams & Smith 1991, French 1996). This same pattern is also seen in the field data obtained in Spitsbergen (Putkonen 1997) and shown for comparison in Figure 1B.

When the same model is run for the seasonally frozen ground (mean annual soil temperatures >0°C) a zero curtain effect is seen only in the spring (Figure 2A), which is also seen in the field data. And finally when the model is run for the case where mean annual soil temperature is exactly 0°C, short and weak zero curtain effect is seen both in the spring and fall (Figure 3A).

Discussion

It is counterintuitive that the soil temperatures from a given field site show a distinct zero curtain in the fall (Fig. 1, mean annual soil temperature is -5°C) and no zero curtain in the spring, although same amount of water is freezing in the fall as ice is melting in the spring. To illustrate the reasons for this phenomenon it is useful to consider the soil thermal gradient and the annual evolution of the soil vertical thermal profile (temperature vs. depth below surface).

It is well known that the original amplitude of the thermal wave at the soil surface decreases as it penetrates into the soil and that there is a time lag that increases with depth for a thermal perturbation to travel into the soil (e.g., Turcotte & Schubert 1982). For those reasons the soil thermal gradient in the spring when the surface starts to thaw is almost constant, which makes the soil temperatures at all levels to increase slowly but at steady rate (Fig. 4). Even though the ice is melting in the soil no sections of the soil profile remain persistently at or near 0°C.

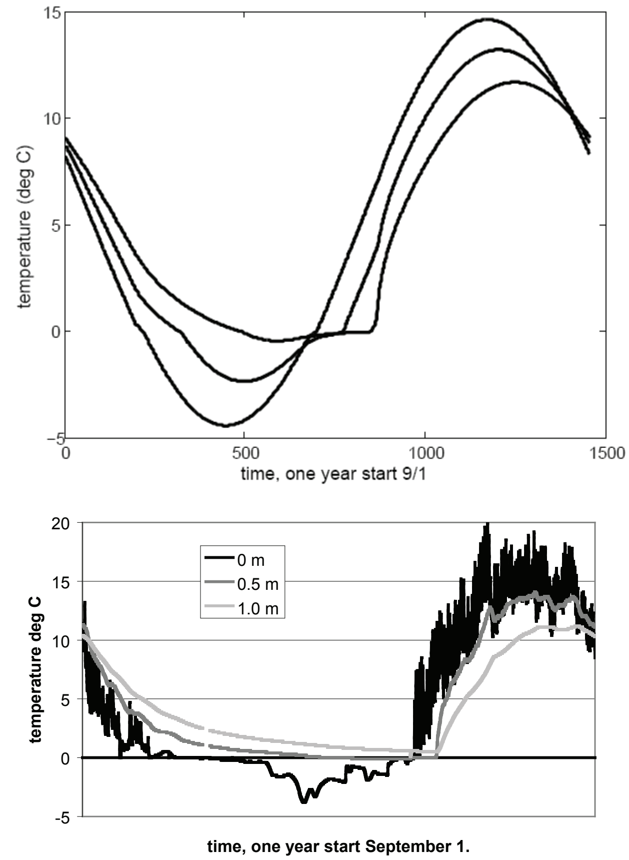

Figure 2. A. Modeled soil temperatures over one year at 0.1, (largest amplitude) 0.5, and 1.0 m (smallest amplitude) below ground surface. Mean annual temperature of the surface forcing is 5°C. B. Measured soil temperatures over one year at the Bonanza Creek Experimental Forest's primary upland weather station LTER1 (Hollingsworth et al. 2005). Note prominent zero curtain in the spring in both model and observations and the lack of zero curtain in the fall.

In the fall the soil temperatures between about 0.5–1.0 m below surface are above freezing but already close to 0°C. A moderate amount of cooling at the surface and at the depth below 1.0 m suffices to bring the soil temperatures to freezing point in the layer 0.5–1.0 m below surface. At that point the thermal gradient in this middle layer approaches 0°C/m and consequently the temperature in that domain do not change until a thermal gradient is re-established.

For these reasons it is clear that two conditions have to be met for the zero curtain to develop in the soil: 1) the active layer has to contain ice or water, and 2) the thermal gradient in the soil has to become 0°C/m at or near 0°C.

Since water and ice are common in the natural soils the soil thermal gradient near 0°C appears to dictate the timing and presence of zero curtain effect.

Although present at some field areas, the non-conductive heat transfer processes (Outcalt et al. 1990) do not appear to be necessary for the zero curtain effect to develop because the zero curtain effect is seen both at the sites without non-conductive heat transfer and it is also well developed in the model without non-conductive heat transfer.

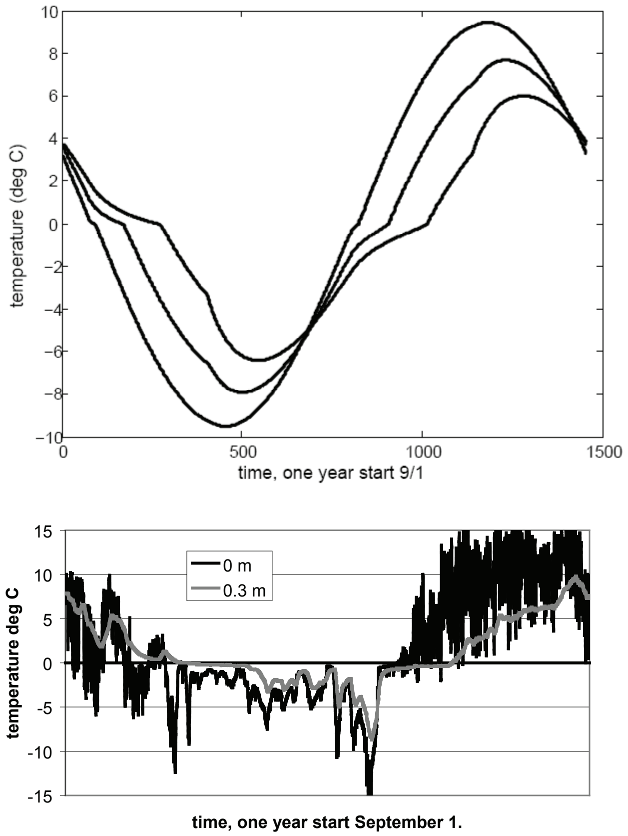

Figure 3. A. Modeled soil temperatures over one year at 0.1, (largest amplitude) 0.5, and 1.0 m (smallest amplitude) below ground surface. Mean annual temperature of the surface forcing is 0°C. B. Measured soil temperatures over one year at the USDA SCAN site #2065, Aniak, AK, USA (USDA, 2007). Note the absence of the zero curtain in the fall and spring in both model and observations.

Two phase change boundaries in close proximity bracket the domain of the soil where zero curtain effect is seen (Osterkamp & Romanovsky 1997). However, as shown in this paper the first order explanation for both the presence of the two phase change boundaries, and the zero curtain effect is the annual evolution of the soil thermal profile which clearly predicts the timing (fall and/or spring) of the zero curtain effect.

When soil temperatures from real field sites are studied it is important to keep in mind that seasonal snow cover may affect the soil thermal forcing and render the annual soil surface temperature cycle significantly different from the modeled sinusoidal annual thermal wave.

Conclusions

If zero curtain effect was caused only by release or consumption of the latent heat in the soil then there should be symmetrically a zero curtain both in the fall and spring. Or at the least there should be a zero curtain effect present in the fall in both permafrost underlain and seasonally frozen soil which is not the case.

For the clear conceptual description of the occurrence of the zero curtain effect let's assume that the soil surface thermal forcing follows a simple sinusoidal pattern that repeats itself in the annual time scale. When the forcing temperature at the soil surface crosses 0°C and approaches the mean annual soil temperature, the near surface soil thermal profile becomes inverted and a section of the soil just below it becomes nearly isothermal near 0°C. Two separate phase change fronts develop in the soil as pointed out by Osterkamp & Romanovsky (1997). The soil domain in between of the two phase change fronts quickly approaches 0°C and the zero curtain effect develops. However, when the forcing temperature at the soil surface crosses 0°C again approximately six months later in the following transitional season (either spring or fall depending on the case) and diverges further from the mean annual soil temperature, the near surface soil temperature inversion underlain by a nearly isothermal soil domain develop again, but at this time the isothermal soil is thermally far from 0°C and no phase change is present. Without phase change the isothermal soil quickly develops a monotonic thermal gradient and consequently only one phase change front develops. Therefore no zero curtain effect is present.

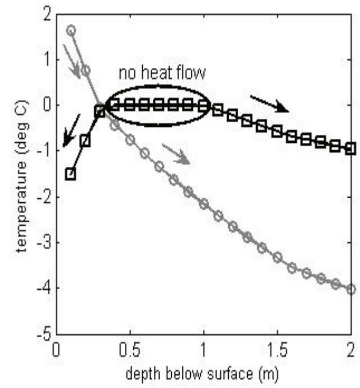

Figure 4. Modeled soil vertical thermal profiles for spring (gray) and fall (black) for a soil with mean annual thermal forcing of -5°C. The segment of the profile marked with black oval represents the zero curtain. As is illustrated by the spring (gray) profile the presence of significant thermal gradient at this time ensures that all levels of the soil are warming in concert and zero curtain can not develop. In the fall the soil at 0.5–1.0 m below surface quickly reaches freezing point and the thermal gradient vanishes. Therefore no heat flows through this segment of soil and the temperatures remain at or near 0°C until all the water has frozen. The black and gray arrows show the direction of heat flow during fall and spring respectively.

The above explanation highlights the importance of the soil thermal regime and annual thermal evolution in determining the timing and occurrence of the zero curtain effect. The phase change of water to ice or vice versa is necessary as well but it fails to explain the timing and the lack of zero curtain effect in fall in seasonally frozen soil.

It is also important to notice that the zero curtain is not only limited to condition where water is freezing (fall). In the case of seasonally frozen ground (mean annual soil temperature >0°C), the zero curtain appears in the spring when the soil ice is melting.

Abstract

This paper attempts to give a definition of "warm frozen soil" according to the mechanical behavior of frozen soils with K_0 compression. K_0 compression tests were carried out on ice-rich frozen silty clay to investigate its straining properties. Three groups of samples were tested, with ice contents of 40%, 80% and 120%, respectively. The samples were compressed under a constant load and with stepped temperature rising from about -1.5°C to -0.3°C. Strain rates at different temperatures were examined. It was found that the strain rate at around -0.6°C increased abruptly. At the same time, strain rates under temperatures higher than -0.6°C were not as temperature-sensitive as was generally understood. Analysis of compressive coefficients was made on the data both from our own testing program and from the literature, which showed that at about -1°C was a turning point in the compressive coefficient against temperature. Based on both our work and taking into account the unfrozen water content vs. temperature, the range of -1°C to -0.5°C seems to be the temperature where the mechanical properties change greatly. For convenience, -1.0°C can be defined as the boundary for warm frozen soils.

Keywords: compressive coefficient; K_0 compression; strain rate; warm frozen soil.

Introduction

The mechanical properties of soils have been extensively studied in the last century. For unfrozen soils, various strength criteria and constitutive models have been proposed and applied to practice in geotechnical engineering. On the other hand, due to their sensitivity to temperature and ice content, the mechanical properties of frozen soils are more complicated, and many investigations have been carried out to study these properties (Jessberger 1980, Landanyi 1981, Morgenstern 1981, Sayles 1988). However, many of these studies were carried out on frozen soils at relatively low temperatures. When the temperature of frozen soil is close to 0°C, its plastic deformation must also be taken into consideration (Landanyi 1999), especially with high ice contents (Phukan 1983). Monitored temperatures of the soil layers underneath the embankments of the newly built Qinghai-Tibet railway on the Tibetan Plateau show that a warmer frozen zone formed after a certain period of time (Fig. 1). In this case, neither the theories for unfrozen soils nor those for cold frozen soils are suitable for describing the soils' mechanical properties. This kind of frozen soil can be named *warm frozen soil*.

In the literature, the term *warm frozen soil* is often used to describe a frozen soil at a relatively high temperature. However, what "warm" really means has not been clearly and logically defined. It is generally accepted that a warm frozen soil has higher unfrozen water content and therefore has less ability to resist loads and is more temperature-sensitive (Tsytovich, 1975). For these materials, the mechanical properties should be used to define the temperature boundary between "warm" or "cold" frozen soils. Tsytovich (1975) defined temperature boundaries for stiff and plastic frozen soils for different soil classifications according to their failure characteristics, for instance, -0.3, -0.6, -1.0 and -1.5°C for fine sand, silty sand, silty clay, and clay. This is reasonable because the fine grains lower the freezing temperature to a certain degree. However, these definitions are difficult to apply to engineering practice. On the one hand, failure is only the ultimate stage of loading for the safety of engineering constructions. On the other hand, from the point of view of engineering practice, a simple boundary may be convenient for engineers to follow, as long as it is reasonably accepted.

During construction of the Qinghai-Tibet railway on the Qinghai-Tibetan Plateau, a preliminary rule was made where *warm permafrost zone* was defined as the region with a mean annual ground temperature higher than -1°C. This was mainly based on the investigation of damage to embankments of the Qinghai-Tibetan highway. It is a rather geographical definition (Preliminary Regulations for Design of the Qinghai-Tibet Railway in Permafrost Regions, 2002). Where the frozen soil is concerned, it would be more rational to take into account the mechanical properties to define what a warm frozen soil really is. In this field, much confusion can be found from previous studies. For instance, Shields et al. (1985) studied the creep behavior of sand at a temperature between -2.5°C and -3.0°C, and called that warm permafrost. Foster et al. (1991) studied permafrost with a temperature of about -1°C which was regarded as warm permafrost. It is recognized that the term *warm* is a rather relative definition without a clear and reasonable basis.

In this paper, silty clay obtained from the Qinghai-Tibetan plateau along the newly constructed railway was

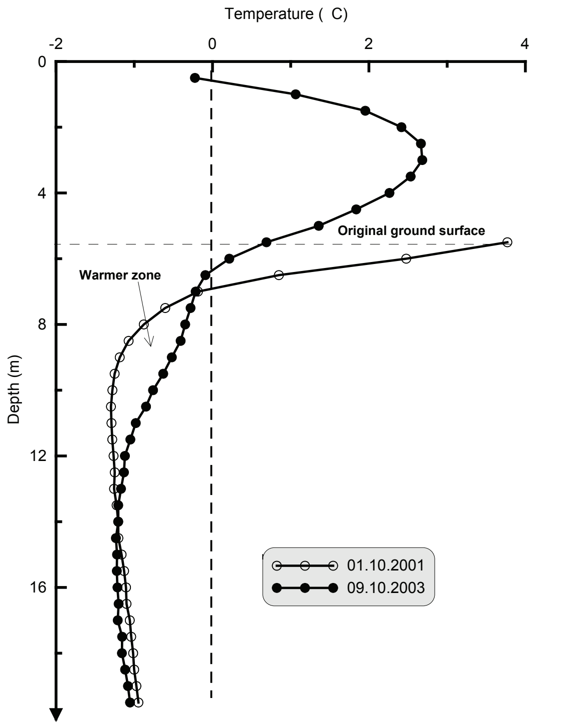

Figure 1. A warmer frozen zone formed in the layers underneath the embankment of the Qinghai-Tibet railway.

studied using K_0 compression under constant load and stepped temperature. The strain rate at each temperature step was studied. Data from the literature on the relationship between the compressive coefficient and temperature were re-analyzed. Based on these two testing programs, the temperature boundary for warm frozen soils as a material will be defined.

Description of the Testing Program

In the study of the mechanical properties of warm frozen soils, the temperature must be controlled precisely. To meet this demand, a new apparatus was designed, where a refrigerator was combined with a fan to control the temperature. An oedometer was placed in the box of the refrigerator for K_0 compression tests, as is shown in Figure 2. From the results, it can be seen that the temperatures could be controlled very well, and temperatures showed only small variations as will be seen in the next section of this paper.

The soil obtained along the Qinghai-Tibet Railway has a plastic limit and liquid limit of 18.8% and 36.5%, respectively. Its grain size distribution is shown in Figure 3. The freezing temperature of the soil is -0.2°C. Soil samples were prepared with ice contents of 40%, 80% and 120%. The dimensions of the samples were 61.8 mm in diameter and 40 mm in height. Loads of 0.1, 0.2 and 0.3 MPa were applied. Altogether 9 tests were carried out on samples with different ice contents and different loads.

The samples were installed in the oedometer and then placed in the refrigerator box. The desired temperature of about -1.5°C in the box was kept constant for 24 h, then

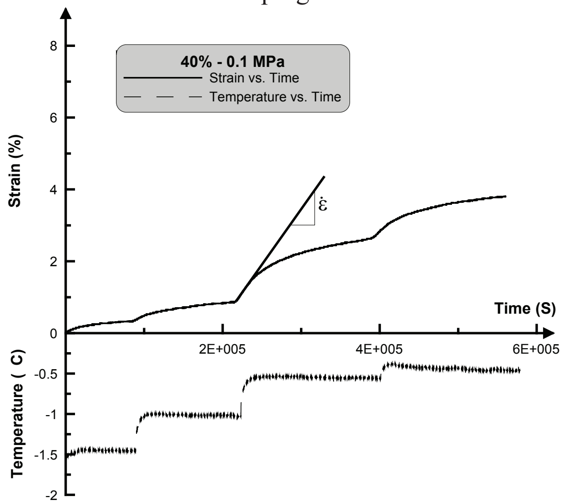
a load was applied to the sample. When the strain became constant, the next higher temperature was adjusted and new strain occurred. In all, 5 temperature steps were applied in each test, approximately -1.5, -1.0, -0.6, -0.5 and -0.3°C.

Test Results and Discussion

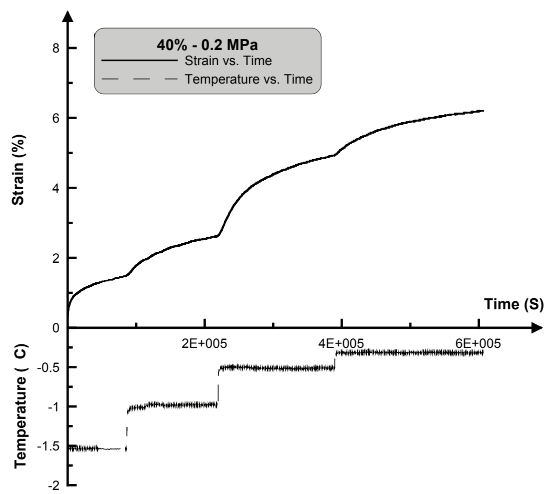
Strain rate vs. temperature in this testing program

Figure 4 shows the development of strain against time with change in temperature for the soil with an ice content of 40%. It can be seen that at every step the temperature was controlled quite well, even at higher than -0.5°C. From the three tests shown in Figure 4, it seems that when the temperature rose above a certain value, the strain developed more quickly. This phenomenon was also found in the other 6 tests. In this paper, the strain rate at each temperature step was used for analysis. The strain rate is defined as the inclination of the tangent line at the starting point of the new strain-time curve when the temperature rose to a new step, as is shown in Figure 4 (a).

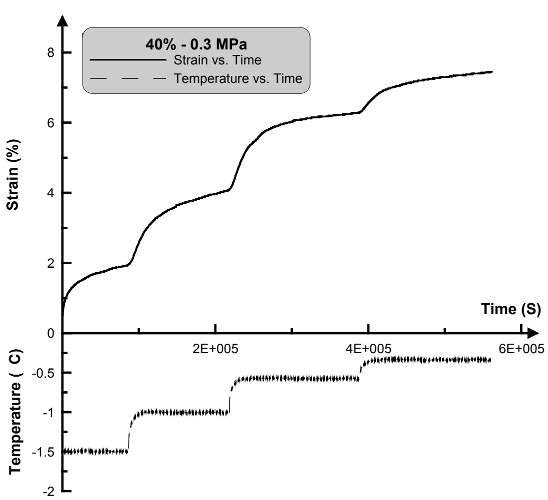
Five strain rates corresponding to the five temperature steps were obtained from each test, allowing a curve of strain rate against temperature to be plotted. Nine curves were obtained from the 9 tests in the whole program. These are all shown in



a. Ice content 40% and load of 0.1 MPa.



b. Ice content 40% and load of 0.2 MPa.



c. Ice content 40% and load of 0.3 MPa.

Figure 4. Temperature change with time and the corresponding strain development for the soil with water content of 40% and loads of 0.1, 0.2, and 0.3 MPa.

Figure 5. It can be seen in Figure 5 that the strain rate increased with the increase in temperature up to about -0.6°C, then decreased dramatically. In previous studies it was thought that, with a small increase in temperature, the mechanical properties for the warm frozen soils would change greatly. However, this is not found (see Fig. 4). The strain rates increased again when the temperature rose to about -0.2°C, which was very close to the freezing point of the soil.

It should be pointed out that the data corresponding to the first temperature step (about -1.5°C) were excluded in order to get rid of the influence induced by the experiment setup.

Compressive coefficient

Another mechanical property, the compressive coefficient (C), was examined in this work. This parameter was defined as the ratio of the strain to the corresponding load range by the following formula:

$$C = \frac{\Delta \varepsilon}{\sigma_2 - \sigma_1} \tag{1}$$

In this paper, C is the change in strain when stress increases from 0 to 0.2 MPa. Figure 6 shows that for the soil used in this testing program, C decreases with the decrease in temperature, and -0.6°C seems to be the turning point.

Confined compression of frozen soils was also studied by Zhu et al. (1982). In their testing program, a silty clay from the Qinghai-Tibet plateau and a medium-grained sand from Lanzhou were tested under different temperatures with stepped load. For the silty clay, different water content ranges were also investigated The temperatures investigated were in a relatively wide range from -0.5°C to -7.0°C, and the applied load was up to 0.8 MPa.

The relationship between the compressive coefficient of the silty clay and temperature at different water content range is shown in Figure 7. It can be seen that with the decrease in temperature, the compressive coefficient decreases. The turning points are all near a temperature of about -1°C. The frozen Lanzhou sand showed similar results.

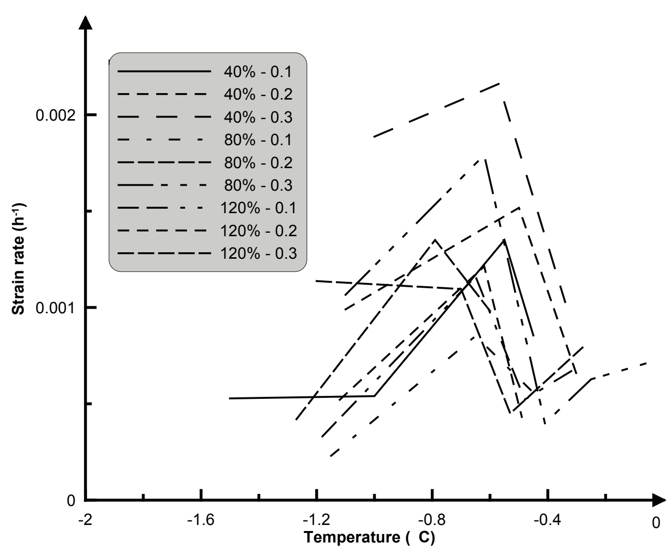


Figure 5. Strain rate against temperature (40% – 0.1: 40% refers to the water content, and 0.1 in MPa is the applied load).

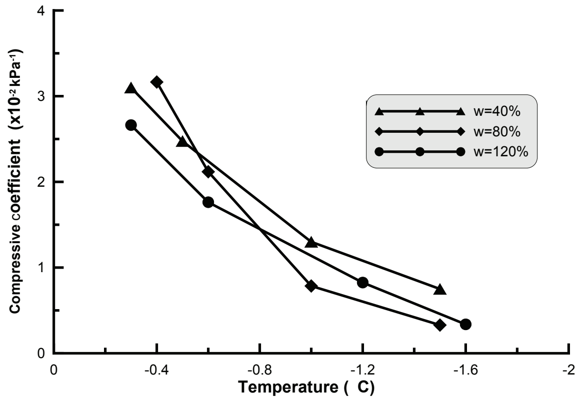

Figure 6. Compressive coefficient against temperature for silty clay in own testing program.

Unfrozen water content vs. temperature

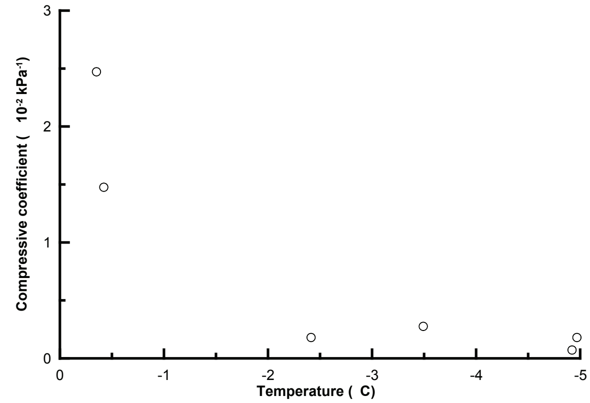
It is widely accepted that changes in mechanical properties of frozen soils are due to changes in unfrozen water content with temperature. Loads also lower the freezing point of water in frozen soils, but this is only noticeable under loads of tens of MPa (Chamberlain et al. 1972). In the loading range discussed in this paper, this effect can be ignored.

The unfrozen water content of the soil in the tests carried out for this investigation was measured using Nuclear Magnetic Resonance (NMR) in a separate testing program. Figure 8 shows the relationship between unfrozen water content and temperature of the soils in these tests and in the work by Zhu et al. (1982). Both soils show that the unfrozen water content increases with an increase in temperature. For both soils, the most rapid change of unfrozen water content occurs within the temperature range of about 0～-1.0 °C. Considering that both testing programs showed that the mechanical properties changed more rapidly at temperatures between -0.6°C and -1.0°C, it seems reasonable that the temperature boundary for warm frozen soils should be -1.0°C. This is also in accordance with the temperature boundary for the warm permafrost zone in permafrost engineering.

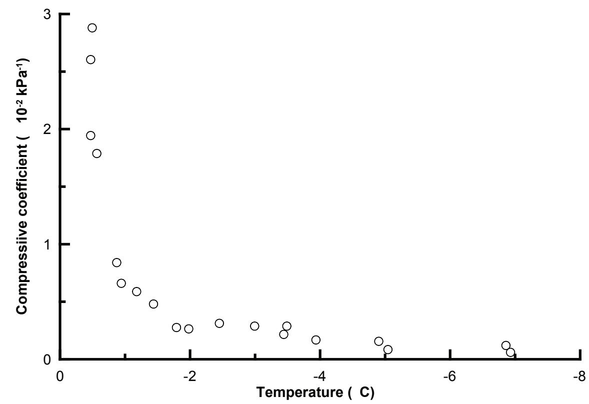
This temperature boundary is based on testing data on sand and silty clay which are often encountered in engineering practice in permafrost regions on the Qinghai-Tibet plateau. On rare occasions variations can be expected. For instance, Tsytovich (1975) pointed out that for clayey soils with montmorillonite minerals, the temperature boundary for stiff and plastic frozen soil could be as low as -5.0°C.

Conclusions

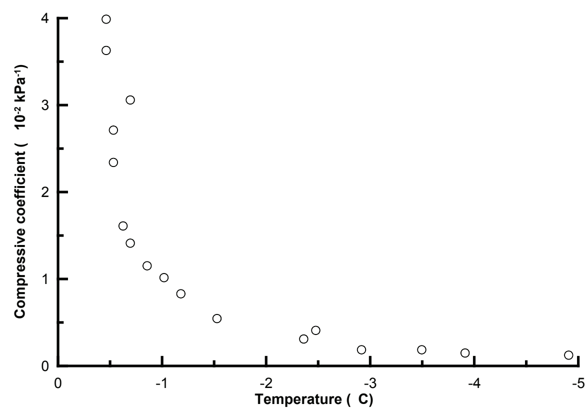
As a material, the temperature boundary of warm frozen soils should be defined by mechanical properties. According to the tests carried out and the testing program in the literature on sand and silty clay, it can be concluded that -1.0°C should be defined as the temperature boundary for warm frozen soils. This seems reasonable taking into consideration the relationship between unfrozen water content and temperature. It is also convenient for the engineers because it coincides with the temperature boundary for the "warm permafrost



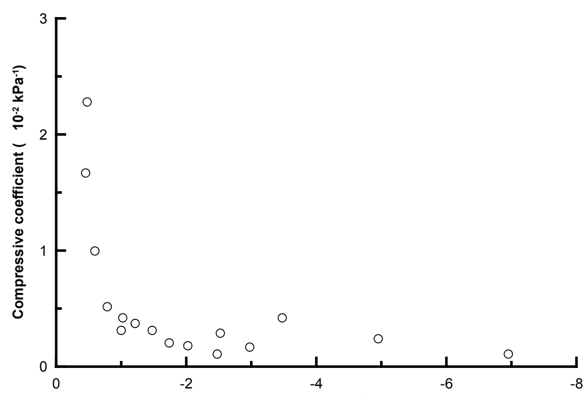
a. Water content of less than 17%.



b. Water content of 18%-28%.



c. Water content of 30%-40%.



d. Water content of 50%-90%.

zone." Previous ideas that the mechanical properties of frozen soils would change dramatically with any small change in temperature was not found in the relationship between the strain rate and temperature.

Abstract

This paper describes the active layer thermal regimes in two shallow boreholes, Sofía 275 m a.s.l. and Incinerador 35 m a.s.l., for which the ground temperature series has been recorded continuously from 2000 to 2006. The monitoring sites are located in Livingston Island, South Shetland Archipelago, Antarctica. This is one of the most sensitive regions of Earth to climate change, with a major warming trend over the last 50 years, of ca. +2.5ºC in the Mean Annual Air Temperatures (MAAT). This region is located near the climatic limit of permafrost, since MAAT at sea level is close to -2ºC. Lineal fits of the ground temperatures series for the study period at different depths in these boreholes show positive slopes. An outcome from the analysis of freezing and thawing indexes is that most of the ground warming seems to concentrate in the summer.

Keywords: active layer; freezing index; shallow boreholes; ground temperatures.

Introduction

The climate of the Antarctic Peninsula region has experienced a major warming trend over the last 50 years with annual mean air temperatures at Faraday/Vernadsky station having increased at a rate of 0.56ºC/decade and 1.09ºC/decade during the winter (King 1994, Turner et al. 2005).

Several factors contributing to the anomalous warming in the Antarctic Peninsula and the Weddell Sea region have been proposed, some of them related to the increase in westerlies observed over the last 30 years (Marshall 2002).

Increasing air temperatures and precipitation may cause the degradation or even the disappearance of permafrost in the sporadic permafrost zone, where current climatic conditions produce near-zero annual air temperatures, like in the South Shetlands Islands, north of the Antarctic Peninsula.

The energy exchange between the ground surface and the atmosphere depends on the radiation balance, ground heat fluxes and turbulent heat fluxes at the ground and snow surfaces. These are especially complex in the alpine or polar maritime areas, where the relief is mountainous and snow cover influence is particularly strong (Van Lipzig et al. 2004, King & Turner 1997, King et al. 2003). The seasonal snow cover, which presents a barrier to ground heat loss in winter, is a leading factor in the ground thermal regime and active layer depth (Romanosky & Osterkamp 2000, Ling & Zhang 2004). Snow has a high surface albedo and high emissivity, inducing cooling of the snow surface, while its low thermal conductivity makes it a good insulator. The ground heat flux is another important magnitude in the energy balance and the main factors that control it in permafrost terrain are: (i) moisture content in the active layer, (ii) thaw effects at the free boundary, and (iii) non-conductive heat transfer effects (variable thermal diffusivity).

The active layer thickness and dynamics are extremely important factors in polar ecology. Since most exchanges of energy, moisture, and gases between the atmospheric and terrestrial systems occur through the active layer, its thickening has important effects on physical, geomorphic, hydrologic and biological processes (Nelson & Anisimov 1993). Furthermore, the issue of active layer response to climate change is of increasing concern, particularly in what respects to its degradation and consequent physico-chemical influences on the biogeochemical cycle of carbon and on global change modeling (Anisimov et al. 1997, Osterkamp 2003).

Compared to the Arctic, very little is known about Antarctic permafrost (Bockheim 1995). In 2004 only 4 active layer boreholes were being monitored in the Antarctic Peninsula Region and a number as small as 21 in the whole Antarctic region (Bockheim & Hall 2004). Complex logistical and maintenance problems and the remoteness of the Antarctic are the main causes for this scarcity. The limited knowledge of the ground temperature conditions led to a recent effort in order to increase active layer and permafrost research in the Antarctic under the framework of international programs. Two core projects of the International Polar Year 2007–08 where Antarctic permafrost plays a central role are under way: ANTPAS – Antarctic and Sub-Antarctic Permafrost, Soils and Periglacial Environments and TSP – Permafrost Observatory Project - Thermal State of Permafrost (Guglielmin 2006, Bockheim & Hall 2004). The present research is integrated in these projects and intends to monitor and model the active layer temperature regime in two shallow boreholes in Livingston Island (South Shetland Islands, Antarctic Peninsula) (Ramos & Vieira 2003, Ramos et al. 2007).

The study's ultimate aim is to document the influence of climate change on permafrost degradation in this area which has a very strong influence on the regional climate warming.

Study Area

Livingston Island is located in the South Shetlands Archipelago at (62º39′S, 60º21′W) (Fig. 1). The climate at sea level is cold oceanic, with frequent summer rainfall in the low areas and a moderate annual temperature range. The climate reflects the strong influence of the circum-Antarctic low-pressure system. Meteorological conditions in summer are dominated by the continuous influence of polar frontal systems (Simonov 1977, Styszynska 2004). Relative humidity is very high, with average values ranging from 80 to 90%.

Data from different stations in King George Island (South Shetlands Archipelago) show a mean annual air temperature of -1.6ºC near sea level and an annual precipitation of about 500 mm. Data that we collected in Livingston Island at 15 m a.s.l. show a MAAT from -3.2ºC to -1.5ºC. From April to November, average daily temperatures at sea level generally stay below 0ºC and from December to March they are generally positive. The MAAT (2003 to 2006) at 275 m a.s.l. in Reina Sofia Hill, near the Sofía borehole, was -4.2ºC. This corresponds to a lapse rate of -0.8ºC/hm and to an air freezing season about 1 month longer than at sea level.

Permafrost in the South Shetland Islands is widespread above the Holocene raised-beaches (ca. 30 m a.s.l.) (Serrano & López-Martinez 2000). Meteorological and geophysical data indicate that environmental conditions close to sea-level are marginal for the maintenance of permafrost (Hauck et al. 2007).

Table 1. Freezing season length (in days) in Incinerador and Sofia boreholes from 2000 to 2006. Temperatures at 15 cm depth at 30 min intervals.

Year	INC	SOFIA	Sofia-INC
1999		273	
2000	197	238	41
2001	211	294	83
2002	201	294	93
2003	225	332	107
2004	211	290	79
2005	176	246	71
2006	197	262	65
Mean	203	279	76

Methodology

Shallow boreholes

Borehole sites are in the vicinity of the Spanish Antarctic Station Juan Carlos I in Livingston Island. One of them is located at Reina Sofia hill (275 m a.s.l., 0.9 m active layer thickness) in a diamicton with a water content of 22.1% in saturation conditions. The other borehole is located at Incinerador point (35 m a.s.l., 2.4 m of seasonal frost, with possible permafrost below) in quartzite bedrock with negligible interstitial water content. Both boreholes were drilled in 2000, providing a 7-year series of active layer temperatures.

Thermal diffusivity, calculated by analyzing cuasi-stationary sinusoidal temperature signals using inverse modeling (Blanco et al. 2007), has a mean winter value in the Incinerador borehole of 1.5 10^{-6} ms^{-2} . In Sofía borehole, in winter the value is 0.55 10^{-6} ms^{-2} (Ramos & Vieira 2003).

In the Incinerador borehole a chain composed of six data loggers measures temperatures at 5, 15, 40, 90, 150, and 230 cm depth. At Sofia borehole, four temperature dataloggers are installed at 5, 15, 40, and 90 cm. The logging interval is 30 min and the accuracy of the data loggers (Tiny Talk Gemini Co.) is 0.2ºC. Due to data logger limitations during the first years the series present a short period with lack of data for the thawing season in both boreholes.

At the monitoring sites there is no vegetation and in the islands, mosses and grasses are very sparsely distributed.

Following the Berggren equation, active layer thickness is a square root function of the freezing index (Andersland & Ladany 1994). Freezing and thawing indexes have been calculated for different depths in Sofía and Incinerador boreholes and these are used to estimate the evolution of the active layer thickness.

Results and Discussion

The analysis of the ground temperatures is based on the comparison of the temperatures at 15 and 90 cm depths in both boreholes. Temperatures at 230 cm from the Incinerador borehole complement the analysis. In the Sofía borehole the mean ground temperatures at 15 and 90 cm, from 2000 to

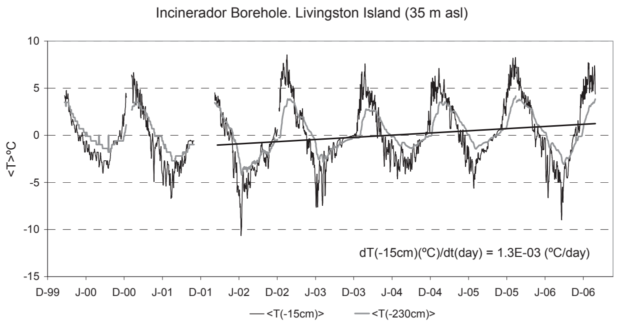

Figure 2. Temperatures at the Incinerador borehole from 2000 to 2006 at 15 and 230 cm depth. The lineal fit corresponds to the 15 cm sensor for the period of 2002–2006.

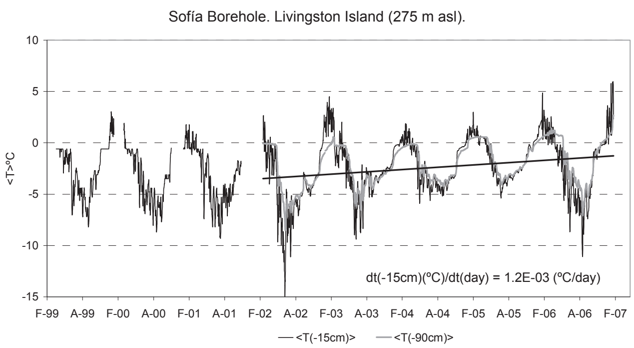

Figure 3. Temperature series at the Sofia borehole from 1999 to 2006 at 15 and 90 cm depth. The lineal fit corresponds to the 15 cm position sensor for the period of 2002–06.

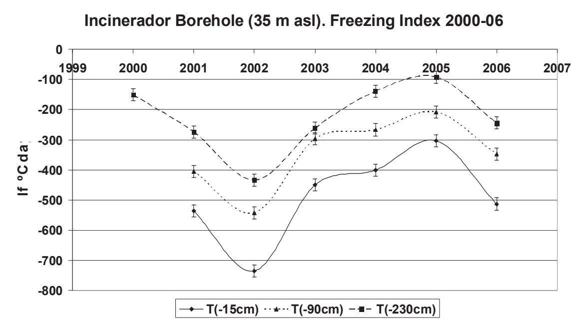

Figure 4. Incinerador freezing index evolution in the periods 2000 to 2006 at 15, 90, and 230 cm depth.

2006, were -2.6ºC and -2.1ºC respectively. In the Incinerador borehole (35 m a.s.l.) at the same depths, values of -0.1ºC and 0.2ºC were recorded for the same period. The differences between both places are close to the regional atmospheric lapse rate that has a value of -0.8ºC/hm (Ramos & Vieira 2003). The mean length of the freezing season in the Sofia site is 279 days per year, which is roughly two months longer than at the Incinerador site (see Table 1).

During the 7-year period the thermal regime in the Incinerador borehole showed the behavior of a typical annual period wave within a dry homogeneous material. Figure 2 shows the temperature oscillations around 0ºC at 15 and 230 cm. Signals at 15 and 230 cm are delayed more or less 5 days as a function of the ground thermal inertia.

Table 2. Lineal best-fit slopes (dT/dt x 10^{-3} ºC/day) of the daily ground temperatures in Sofía and Incinerador boreholes from 2002 to 2006.

depth (cm)	15	90	230
Incinerador	1.3	0.8	0.8
Sofía	1.2	1.2	--

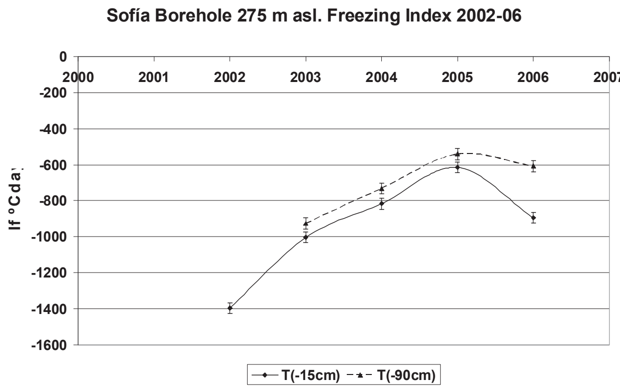

Figure 5. Sofía freezing index evolution in the periods 2002 to 2006 at 15 and 90 depth.

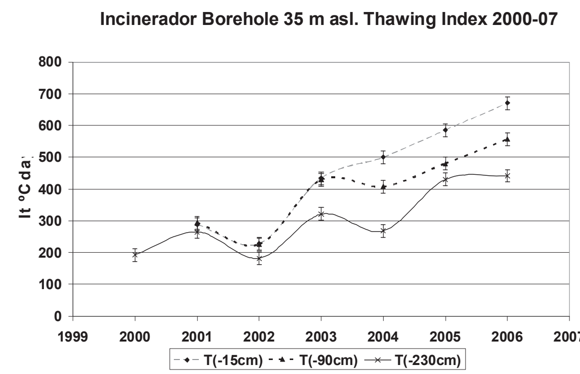

Figure 6. Incinerador thawing index evolution during the periods 2000 to 2006 at 15, 90, and 230 cm depth.

The lineal fit for the period with a complete data series for both boreholes (2002 to 2006) shows a warming trend at all depths, with similar values in both of them (see Table 2).

Direct observations in pits and temperature data show that from 1999 to 2002 the top of the permafrost table in Sofía borehole was at 90 cm, but since 2003 its depth increased.

Figure 4 shows the freezing index evolution in Incinerador borehole at 15, 90, and 230 cm depth. The curve shows a wave shape with a 5-year period and amplitude of more or less 300ºC-day. The mean at 15 cm depth for the period of 2002 to 2006 is -480ºC-day. In Sofía borehole (Fig. 5) the value for the same period, at the same depth is -945ºC-day.

Figure 6 shows the thawing index evolution from 2000 to 2006 at 15, 90, and 230 cm in the Incinerador borehole. In this period a very significant warming trend is observed at all depths, with, almost, a doubling of the thawing index. It changes from 300ºC-day at 15 cm depth in the summer of 2001, to more than 600ºC-day in the summer of 2006. Despite the short time-series, this trend seems to support a significant warming during the summer.

Conclusions

The scarcity of ground temperature data in the Maritime Antarctic has driven us to install shallow boreholes in Livingston Island. Theses are used for monitoring the impact of climate change on the active layer temperatures and on permafrost.

Lineal fits of the ground temperatures at different depths in Sofía (275 m a.s.l.) and Incinerador (35 m a.s.l.) boreholes show positive slopes. This confirms that the climate warming trend identified by other authors is contributing to ground warming. The similar positive slopes in both boreholes indicate that they are probably more influenced by a regional signal, than by local site-specific influences. The increase in active layer thickness at Sofia borehole has been confirmed by the direct observations of permafrost thaw at 90 cm depth. The short period of the data series limits the conclusions and therefore no absolute trends in the climate signal are presented here. An outcome from the analysis of freezing and thawing indexes is that most of the ground warming seems to concentrate in the summer. This is in agreement with climatological data for the Antarctic Peninsula region published by various authors.

Circumpolar Relationships Between Permafrost Characteristics, NDVI, and Arctic Vegetation Types

Martha K. Raynolds and Donald A. Walker
University of Alaska Fairbanks

Abstract

An understanding of the distribution and characteristics of vegetation found on different types of permafrost is necessary input for modeling permafrost response to climate change. Interactions between climate and soil thermal regime are modified where vegetation exists, and >75% of permafrost on land in the Arctic is covered by non-barren vegetation types. A circumpolar spatial analysis was conducted to compare mapped permafrost characteristics with the Normalized Difference Vegetation Index (NDVI), mapped vegetation types, and environmental characteristics. A General Linear Model (GLM) analysis found that, when added to a model that included climate and lake cover, permafrost characteristics accounted for an additional 11% of the variation in NDVI. High ice content in permafrost had the strongest effect, lowering NDVI. Over 65% of areas with thin overburden is vegetated by low-stature, low-cover, low-biomass vegetation types that have little impact on thermal regimes. This climbs to >82% for areas that also have high ice content permafrost. Over 83% of areas with thick overburden have vegetation types with denser, taller vegetation, which alters the interaction between climate and permafrost. Including vegetation characteristics in permafrost models will be particularly important in areas with thick overburden and medium or high ice content.

Keywords: arctic vegetation; Circum-Arctic Map of Permafrost and Ground Ice Conditions; Circumpolar Arctic Vegetation Map; NDVI; permafrost.

Introduction

Permafrost, its characteristics, and its vulnerability to change are increasingly in the public eye as a result of attention focused on climate change and the Arctic. Climate change is occurring at a faster rate in the Arctic than other biomes and is resulting in an increase in temperatures in almost all parts of the Arctic (Comiso 2006, Hassol 2004). The effects on the Arctic Ocean have resulted in dramatic loss of summer sea ice, especially in the summer of 2007 (Comiso et al. 2008). The effects on land, both to permafrost and vegetation, are a focus of on going research, particularly during the 2008 International Polar Year.

Most permafrost, even in the Arctic, is covered with vegetation, and the interactions between the permafrost and the vegetation affect both the growing environment for arctic plants and the thermal environment of the permafrost. Permafrost strongly affects vegetation by affecting landscape and soil characteristics. Permafrost underlying the annually-thawed active layer limits soil drainage and results in cryogenic features such as polygons, gelifluction lobes, circles, and mounds (Washburn 1980). Permafrost ice content can raise surface elevations through aggradation or lower it due to degradation (Jorgenson et al. 2001). Permafrost affects the characteristics of the active layer, such as its depth, soil temperatures, and soil moisture (Schuur et al. 2007).

Vegetation affects permafrost by changing the thermal characteristics of the soil. Vegetation shades and insulates the soil, reducing the transfer of summer warmth (Kade et al. 2006, Shur & Jorgenson 2007). Vegetation also cools the surface through evapotranspiration. Vegetation has the opposite effect in winter; well-vegetated areas are insulated by the plants and the snow they trap, while unvegetated soils are more exposed to winter temperatures (Kade et al. 2006). The types and strength of the effect of vegetation on the climate-soil interactions vary with vegetation type and depend on the amount of total plant biomass, plant lifeforms, and continuity of plant cover (Kade et al. 2006, Walker et al. 2003).

In order to understand the effects of climate change on permafrost, it is important to understand the distribution of vegetation types in permafrost areas and the characteristics of those vegetation types that affect the thermal regime of the soil. This study compares vegetation distribution in the Arctic, the area north of the treeline, with permafrost characteristics. The vegetation was characterized using both a vector vegetation map and satellite raster data of the normalized difference vegetation index (NDVI). This spatial comparison of arctic vegetation types and NDVI with permafrost distribution help define areas where vegetation has the strongest influence on permafrost, with implications for the possible effects of climate change.

Methods

The permafrost map

The extent and ground ice content of permafrost and depth of overburden in the Northern Hemisphere (20°N to 90°N), were mapped on the Circum-Arctic Map of Permafrost and Ground-Ice Conditions (Brown et al. 1997, http://nsidc.org/data/ggd318.html), and summarized by Zhang et al. (1999). The map was printed at 1:10,000,000 scale, and the digital format at 12.5-km pixel resolution was used for this study. Permafrost extent was mapped as continuous (94% of Arctic land area), discontinuous (3%), sporadic (2%), or isolated (1%). Ground-ice content was divided into low

Table 1. Vegetation types of the Circumpolar Arctic Vegetation Map (CAVM Team 2003).

Code	Vegetation Type
B1	Cryptogam, herb barren
B2	Cryptogam barren complex (bedrock)
B3	Noncarbonate mountain complex
B4	Carbonate mountain complex
G1	Rush/grass, forb, cryptogam tundra
G2	Graminoid, prostrate dwarf-shrub, forb tundra
G3	Nontussock sedge, dwarf-shrub moss tundra
G4	Tussock-sedge, dwarf-shrub, moss tundra
P1	Prostrate dwarf-shrub, herb tundra
P2	Prostrate/Hemiprostrate dwarf-shrub tundra
S1	Erect dwarf-shrub tundra
S2	Low-shrub tundra
W1	Sedge/grass, moss wetland
W2	Sedge, moss, dwarf-shrub wetland
W3	Sedge, moss, low-shrub wetland

(54%), medium (15%), and high (31%) categories, referring to the volume of visible ice in the upper 10–20 m. Two landscape categories were mapped. Lowlands, highlands, and intra- and inter-montane depressions characterized by thick (>5–10 m) overburden (any soil or other material that lies above the bedrock horizon in a given area) cover 36% of Arctic land areas. Mountains, highlands, ridges, and plateaus characterized by thin (<5–10 m) overburden cover and exposed bedrock cover 64% of the Arctic.

Satellite data (AVHRR NDVI)

The normalized difference vegetation index (NDVI) is a measure of relative greenness calculated as: NDVI = (NIR -R) / (NIR + R*),* where NIR is the spectral reflectance in the near-infrared where reflectance from the plant canopy is dominant, and R is the reflectance in the red portion of the spectrum where chlorophyll absorbs maximally. NDVI has a theoretical maximum of 1 and its relationship to vegetation characteristics such as biomass, productivity, percent cover, and leaf area index is asymptotically nonlinear as it approaches 1. As a result, NDVI is less sensitive to ground characteristics at higher values and essentially saturates when leaf area index >1 (van Wijk & Williams 2005). This is not a severe problem in the Arctic where vegetation is often sparse and patchy; the mean NDVI for arctic land areas in the data set used in this study was 0.32, well below the saturation point (Raynolds et al. 2006).

NDVI values in the Arctic increase with the amount of vegetation as measured by leaf area index (LAI), phytomass, and productivity (Riedel et al. 2005, Shippert et al. 1995). NDVI values correlate well with ground characteristics of arctic vegetation and can be used to distinguish between vegetation types (Hope et al. 1993, Stow et al. 2004).

A 1-km-resolution maximum-NDVI data set was used for this study. These data were derived from the U.S. Geological Survey EROS AVHRR polar composite of NDVI data for 1993 and 1995 (CAVM Team 2003, Markon et al. 1995). Daily data were collected by AVHRR sensors onboard NOAA satellites for channel 1, red (0.5 to 0.68 μm) and channel 2, near-infrared (0.725–1.1 μm). Satellite measurement of NDVI is affected by a variety of conditions, especially cloud cover, viewing angle and seasonal variation, that can be compensated for by compositing data over time (Goward et al. 1991, Riedel et al. 2005). Daily NDVI values were composited into 10-day maxima. The maximum values of these composited data during two relatively cloud-free summers (11 July–31 August in 1993 and 1995) were used to create an almost cloud-free data set of maximum NDVI for the circumpolar Arctic in the early 1990s.

The vegetation map

The third data set used in this analysis was the Circumpolar Arctic Vegetation Map (CAVM Team 2003, http://www.arcticatlas.org/atlas/cavm). The map extent includes all land areas north of the northern limit of trees. The map was created at 1:7,500,000 scale with minimum polygon diameter of 8 km and is available digitally as a vector map. The integrated vegetation mapping approach used to create the vegetation map was based on the principle that a combination of environmental characteristics controls the distribution of vegetation. Vegetation-type boundaries were based on existing ground data and vegetation maps, bioclimate (Tundra Subzones A–E), floristic regions, landscape categories, elevation, percent lake cover, substrate chemistry, and surficial and bedrock geology, drawn on an AVHRR false-color infrared base map. The distribution of 15 arctic vegetation types (Table 1) was mapped and described on the CAVM, using a unifying circumpolar legend which enables analysis of the entire Arctic (CAVM Team 2003, Walker et al. 2005).

Analysis

In each of the permafrost categories the area of different vegetation types and average NDVI values were tabulated. Spatial-distribution characteristics were analyzed using GIS software. The CAVM was mapped at finer resolution than the permafrost map, so the most common permafrost category for each CAVM polygon was determined. Results of the analysis were summarized graphically, showing vegetation types occurring on different types of permafrost, using symbols proportional to area. The NDVI raster data were analyzed by calculating the average NDVI value for different categories within the permafrost map and summarizing these results using bar graphs. This analysis of over 7 million 1-km^2 pixels represents the true mean of the classes, so comparative statistical tests based on sampling were not appropriate.

General linear models (GLM) (R Development Core Team 2006) were run to determine the importance of permafrost variables in accounting for variation in NDVI in the Arctic. Attributes mapped as characteristics of the CAVM polygons, weighted by area, were used as input data. A basic model including variables known to be important in controlling NDVI (Raynolds et al. 2006) was run first, using the CAVM classes for bioclimate zone and percent lake cover. These variables accounted for the latitudinal variation in NDVI due to climate, and for the reduction in NDVI due to cover of water (NDVI of water is essentially zero). Variables from the permafrost map: extent, ice content, overburden, and the combined code (a unique number for each combination of extent, ice content, and overburden) were added to the model one at a time to evaluate their effect on the model. The amount of variation accounted for by the different variables in each model and the significance of the variable in the model were tabulated.

Interdependence of data sets

Climate and landscape characteristics including slope, elevation, geologic and glacial history have important effects on all three variables: NDVI, permafrost and vegetation. In some cases these characteristics will vary together, especially in extreme conditions. For example, steep, high elevation mountains will generally have low NDVI, continuous, low ice-content permafrost with little overburden, and barren vegetation types. In more moderate terrain the type of vegetation which will grow on a given type of permafrost varies. In these areas the vegetation map and the NDVI data provide valuable information about the distribution of vegetation on different types of permafrost.

Results

Most of the Arctic has continuous permafrost underlying 4.68 million km^2 of land surface (excluding ice and water). Arctic areas without continuous permafrost include southern Greenland, European Arctic Russia, and in Alaska the Seward Peninsula and southern parts of the Kuskokwim River Delta. Continuous permafrost in the Arctic supports a mix of vegetation types. Over 83% of areas with thick overburden commonly is vegetated by erect shrub tundras (S1, S2), graminoid-shrub tundra (G3, G4), or low-shrub wetlands (W3) (Fig. 1). All of these vegetation types have relatively high stature, high biomass, and complete cover (Walker et al. 2005). Over 65% of areas with thin overburden have barren vegetation types (B1-B4), sparse graminoid (G1, G2), or prostrate dwarf-shrub (P1, P2) vegetation types with low stature, low biomass, and partial ground cover (Walker et al. 2005). Areas with thin overburden and high ice content are likely to be vegetated with either cryptogam, herb barrens (B1), graminoid, prostrate dwarf-shrub (G2), or prostrate dwarf-shrub herb tundra (P1), with >82% of these areas vegetated by vegetation types that have low-stature, low cover, and low biomass.

In areas of discontinuous permafrost, tussock tundra (G4) and erect-shrub (S1, S2) vegetation types are common. Areas with sporadic permafrost support mostly low-shrub vegetation (S2) and sedge, moss, low-shrub wetland (W3). Areas with isolated permafrost are dominated by non-carbonate mountain vegetation complexes (B3).

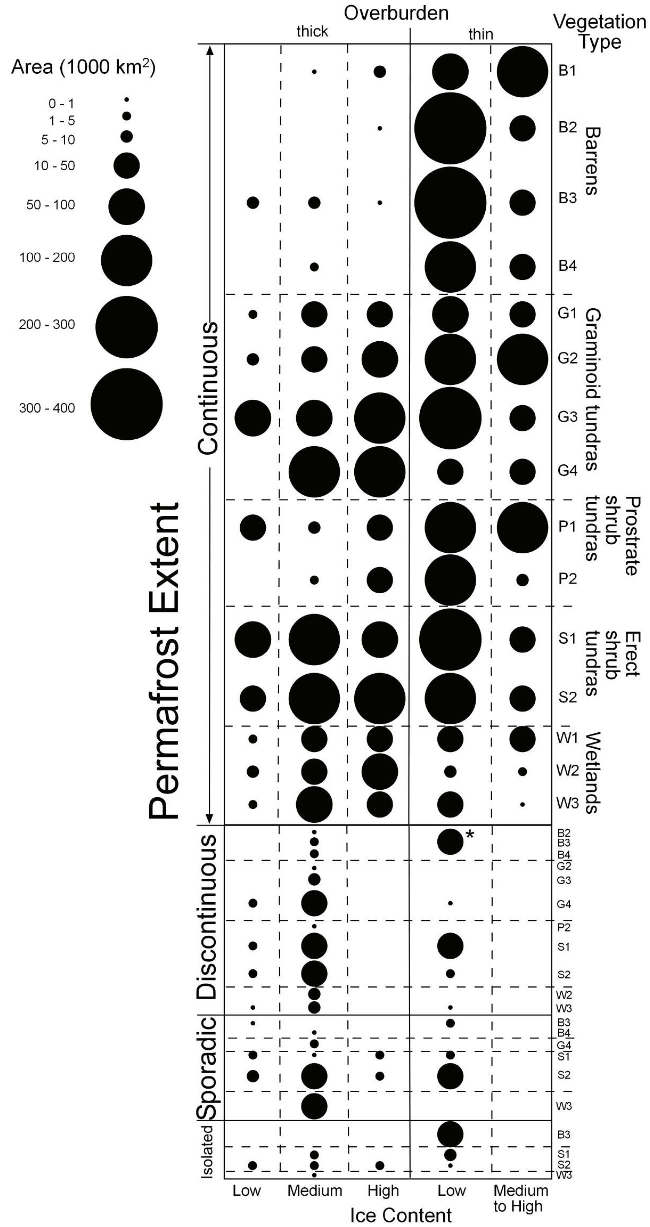

Figure 1. Area of Arctic in different types of permafrost categories (Brown et al. 1997) and different vegetation types (CAVM Team 2003). * The area represented by this symbol was all vegetation type B3.

Low ice-content permafrost is characterized by barren types (B2, B3) and shrub types (S1, S2). Medium ice-content permafrost supports graminoid- (G4) and shrub-dominated (S1, S2) vegetation, as well as wetlands (W3). High ice-content permafrost is most commonly vegetated by graminoid-dominated vegetation types (G2, G3, G4), prostrate dwarf-shrub (P1), or cryptogam barrens (B1).

Examination of the types of permafrost that characterize vegetation types reveals that only three vegetation types have <90% continuous permafrost: non-carbonate mountain complex (B3); low shrub tundra (S2); and sedge, moss, low-shrub wetland (W3). Vegetation types that occur mostly on low ice content permafrost include the barren types (B2,

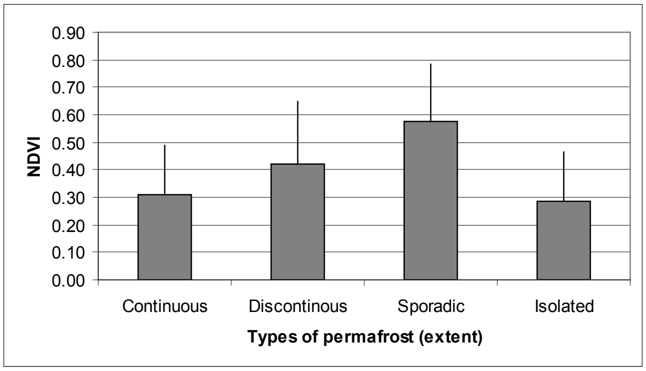

Figure 2. Average NDVI of Arctic areas with differing extent of permafrost (lines = s.d.).

B3, B4) and types common on the Canadian Shield (P2, S1). Cryptogam herb barrens (B1) characteristic of the High Arctic and wetland vegetation types (W1, W2, W3) occur mostly on medium or high ice content permafrost. Tussock sedge, dwarf-shrub, moss tundra (G4) occurs mostly on areas with thick overburden and medium or high ice content.

NDVI varied inversely with permafrost extent, increasing from continuous to discontinuous to sporadic (Fig. 2), as would be expected, following the climate gradient from colder to warmer (Raynolds et al. 2006). NDVI was lowest for isolated permafrost, which occurred mostly in the mountainous areas of southern Greenland, where steep slopes and exposed bedrock limit plant cover.

The largest differences in NDVI values occurred between overburden categories; NDVI was much greater in areas with thick overburden than with thin (Fig. 3). Thin overburden occurs in glaciated areas such as the Canadian Shield, on mountains, ridges, and plateaus. Thick overburden is less common in the Arctic and occurs at lower elevations and in depressions where sediments can accumulate. Areas with thick overburden are more commonly vegetated by graminoid (G3, G4) or erect-shrub (S1, S2) vegetation types with high NDVI values, while areas with thin overburden often have sparse vegetation with low NDVI values (B1, B2, B3, Fig. 1).

NDVI values varied less by ice content within overburden types (Fig. 3). High and medium-to-high ice-content permafrost had lower NDVI than average. Areas with thick overburden and high ice-content permafrost are largely covered with graminoid vegetation types, while medium ice-content permafrost areas are more commonly vegetated by shrub-dominated types (Fig. 1). Areas with thin overburden and medium-to-high ice-content permafrost mostly occur in high-latitude areas (such as the Canadian Arctic Islands), and have barren or sparse, prostrate vegetation (B1, P1, G2).

Permafrost characteristics accounted for 11.9% of the variation in arctic NDVI in a general linear model that included bioclimate zone, percent lake cover, and permafrost characteristics (Table 2). The CAVM variables accounted for 54.9% of the variation, with bioclimate zone responsible for 38.6% and percent lake cover for 16.3%. Permafrost ice content accounted for more of the remaining variation than either extent or depth of overburden.

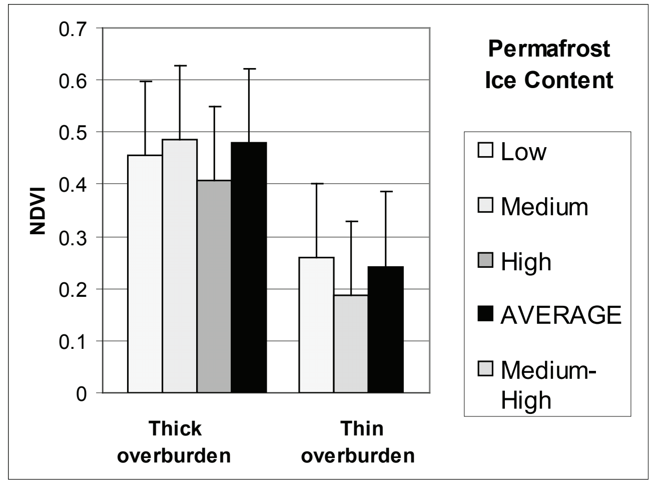

Figure 3. Average NDVI of Arctic areas with shallow vs. deep overburden over bedrock, and different levels of ice content (lines = s.d.).

Discussion

The comparison of the Circum-arctic Map of Permafrost and Ground Ice Conditions, the Circumpolar Arctic Vegetation Map, and satellite NDVI values emphasized the importance of the difference between areas with thick overburden (>5–10 m) and thin overburden (<5–10 m). The thick overburden areas had NDVI values almost twice as high as those of the thin overburden areas, indicating a much greater amount of vegetation cover (Shippert et al. 1995). NDVI would be expected to be lower in areas with thin soils, but the distinction between overburden <5 m and >5 m occurs far below the rooting depth of arctic plants. GLM models showed that once climate and percent lake cover were accounted for, overburden depth was much less important. Areas with thin overburden had more lake cover (especially on the Canadian Shield) and a more northerly distribution than areas with thick overburden, both effects reducing the average NDVI.

The model results showed that ice content correlated with variation in NDVI, and the map summaries showed that medium-high ice-content permafrost with thin overburden has especially low NDVI values. These conditions occurred mainly in the northern areas of the Arctic: the Canadian Arctic Islands and Novaya Zemlya.

About one quarter of the Arctic land area is covered by barren vegetation types. In these areas the vegetation plays a minimal role in the soil thermal regime, and the permafrost is climate-driven. The rest of the continuous permafrost in the Arctic would be considered climate–driven, ecosystem-modified permafrost, according to Shur & Jorgenson (2007). The effect of the vegetation modification is to reduce soil temperatures in summer and to increase them in winter (Kade et al. 2006). Vegetation types that have the most plant cover, thickest moss layers, and deepest organic soils insulate the soil most from summer warming (Kade et al. 2006). Types with the tallest vegetation trap the most snow in winter and

Table 2. Results of GLM analysis of variation in NDVI. Models included 3 variables, bioclimate subzone and percent lake cover plus one of the other variables. Results are from the Type 1 sums of squares, with terms added sequentially.

Model variables	% of variation in NDVI accounted for by variables	Significance (p)
Bioclimate zone	38.6	$< 2 \times 10^{-16}$
Percent lake cover	16.3	$< 2 \times 10^{-16}$
+ Permafrost ice content	6.1	$< 2 \times 10^{-16}$
+ Permafrost extent	4.2	$< 2 \times 10^{-16}$
+ Overburden	1.4	$< 2 \times 10^{-16}$
+ Permafrost combination	11.9	$< 2 \times 10^{-16}$

insulate the soils from winter cooling (Sturm et al. 2001).

The net effect of vegetation on soil thermal regimes depends largely on the thickness of the moss/peat layer and the height of the vegetation. For example, tussock tundra (G4) at Happy Valley on the North Slope of Alaska has a thick peat layer (12 cm) developed from dead tussocks and mosses, a relatively thick layer of live moss (5 cm), and also a dwarf-shrub layer (25 cm tall) (Walker et al. in press). The vegetative factors in tussock tundra decreasing absorption of summer warmth by the soil outweigh the factors warming the soil in winter, resulting in thinning of the active layer and aggradation of ice at the top of the permafrost (Shur & Jorgenson 2007). This process had been recognized by arctic researchers as paludification, a process whereby soils become progressively wetter and more acidic as reduced thaw depth restricts soil drainage (Mann et al. 2002, Walker et al. 2003). The shallower thaw and saturated soils in turn favor peat-producing species like sphagnum mosses and tussock sedges in a positively reinforcing cycle.

The vegetation types with characteristics resulting in the greatest effect on the soil thermal regime are graminoid-erect dwarf-shrub (G3, G4, W3) and erect-shrub (S1, S2) types (Walker et al. in press). These vegetation types are common in areas with thick overburden and medium or high ice-content permafrost, which occur mostly in the foothills and coastal plains of the southern Arctic. These vegetation types are also common in areas with thin overburden and low ice-content permafrost, which occur mostly on the Canadian Shield and mountainous areas.

Areas with thin overburden and low-ice content permafrost are shown as having mostly low to medium risk of subsidence due to climate change in a study that modeled IPCC climate predictions, soils, and permafrost data (Nelson et al. 2001). Risk of subsidence increases with ice-content, and areas with medium and high ice content permafrost on deep overburden are more commonly mapped as having medium or high risk of subsidence (Nelson et al. 2001).

Medium ice-content permafrost extends into discontinuous and sporadic permafrost where the permafrost is preserved by the effects of the vegetation (climate-driven, ecosystem-protected, Shur & Jorgenson 2007). Although researchers have recognized the importance of predicting the effects of climate change on permafrost in these areas because of the high risk of subsidence (Nelson et al. 2001), the complex interactions between the climate, the vegetation, and the soil are difficult to quantify. Vegetation cover varies from shrub- (42% S2, 13% S1) to graminoid-dominated (14% G4, 5% G3), and 20% of the area is wetlands (W3), in a mosaic of vegetation types with differing thermal attributes. Not surprisingly, different models project either thawing or persistence of this permafrost (Anisimov & Reneva 2006). Spatially detailed models that include vegetation data will be required to understand the effects of climate change on permafrost in these areas.

An additional complicating factor is that vegetation is not a static characteristic but will in many cases change in response to changes in permafrost. Changes in surface elevation and stability due to subsidence and erosion will change vegetation, usually to wetter types (Jorgenson et al. 2006). Increases in active layer depths in southern tundra are likely to increase shrubbiness (Schuur et al. 2007). Complete thawing of permafrost that allows previously saturated soils to drain will improve conditions for tree-line advance (Lloyd et al. 2003).

Conclusions

This study highlights both the effects of permafrost on vegetation, and conversely, the effects of vegetation on permafrost. A GLM analysis found that when added to a model that included climate and lake cover, permafrost characteristics accounted for an additional 11% of the variation in NDVI. High ice-content permafrost with shallow overburden was most strongly correlated with lower NDVI.

Over 75% of permafrost on land in the Arctic is covered by non-barren vegetation types, resulting in some degree of ecosystem-modification of the permafrost. Vegetation insulates the soil from both summer warmth and winter cold, with the net effect depending on vegetation characteristics. Thick moss layers and erect shrubs have the greatest effects on soil thermal regimes, and vegetation types with both occur in areas with medium to high ice-content permafrost and in areas of non-continuous permafrost. Including thermal characteristics of vegetation and the spatial distribution of different vegetation types, though complex, will be important for predicting the effects of climate change on permafrost in these areas.

Acknowledgments

Research for this publication was supported in part by a Univ. of Alaska International Polar Year (IPY) graduate fellowship through the Cooperative Institute for Arctic Research (CIFAR) with funds from NOAA under cooperative agreement NA17RJ1224, and NSF grants ARC-0531180 and ARC-0425517. Comments from three anonymous reviewers were very helpful in revising and focusing the paper.

Rock Glacier Distribution and the Lower Limit of Discontinuous Mountain Permafrost in the Nepal Himalaya

Dhananjay Regmi
Central Department of Geography, Tribhuvan University, Kathmandu, Nepal

Abstract

This study, by dealing with the distribution of rock glaciers as an indicator landform for mountain permafrost occurrence, estimated the existence of permafrost in five different study areas of the Nepal Himalaya (from east to west): Kangchenjunga, Khumbu, Langtang, Annapurna, and Sisne). Rock glaciers were identified by aerial photographs at all five sites, and they were checked in the field at the three sites Kangchenjunga, Khumbu, and Langtang. First, periglacial as well as glacial rock glaciers were mapped. Glacial rock glaciers were observed only in eastern Nepal, which may be attributed to the high amount of precipitation. In a second step, only periglacial rock glaciers were extracted and analyzed within a GIS by considering area, altitude, and aspect. The results show that: (1) the size of the rock glaciers tends to decrease from east to west, (2) the mean altitude of rock glaciers decreases towards the west, and (3) the aspects of the rock glaciers are variable, but southerly aspects are most common.

Keywords: glacial rock glaciers; Nepal Himalaya; periglacial rock glaciers; permafrost; rock glaciers.

Introduction

Rock glaciers, known and studied in high altitudes as well as high latitude regions, are considered to be one of the indicators of the presence of permafrost (Haeberli 1985, Barsch 1996). The spatial distribution of rock glaciers reflects climatic conditions, particularly the mean annual air temperature (MAAT) and mean annual precipitation (MAP) (Humlum 1998). The calculated critical conditions for the presence of active rock glaciers in the Central European Alps are MAAT of less than -1/-2°C and MAP of less than 2000 mm. These landforms are typical of regions with a cold, dry continental climate (Barsch 1996, King 1986).

Mountain permafrost in low and mid latitudes is considered to be sensitive to climate changes due to the fact that its temperature is close to the melting point (e.g., Haeberli 1985). Warming and degradation of permafrost have been reported in many mid latitude mountains: air and borehole temperatures have shown apparent warming trends in recent years in European mountains (Vonder Mühll et al. 1998, Harris et al. 2001, Isaksen et al. 2001, Harris et al. 2003). This may lead to an increase of natural hazards in high alpine environments. Slope failures, rockfalls, landslides and debris flows, all of which are assumed to be influenced by changes in the permafrost conditions, are known from numerous locations in high mountains, especially in the Alps (Haeberli et al. 1999, Harris et al. 2001). Therefore, proper knowledge of the permafrost distribution becomes highly significant.

Permafrost in Nepal has received very little scientific attention, despite the fact that Nepal is a country known for the Himalaya. The number of studies in the Nepal Himalaya is comparatively few and the knowledge of permafrost distribution is very limited. The distribution of permafrost was evaluated in the Nepal Himalaya initially by Fujii and Higuchi (1976) using ground temperatures. They indicated the possibility of permafrost occurrence above 4900 m in the Khumbu valley and above 5000 m in the Hidden valley. Since then, the zonation of mountain permafrost has been attempted based on the distribution of rock glaciers (Jacob 1992, Ishikawa et al. 2001), and the lower limit of discontinuous mountain permafrost zone was predicted to be at around 4800 to 5500 m.

This study examines the distribution of rock glaciers in the Nepal Himalaya in terms of size, altitude and slope orientation by focusing on five study areas. Furthermore, on the basis of active and inactive rock glaciers in these five areas of the Nepal Himalaya, the study describes the distribution of discontinuous permafrost. The relationship between the altitudinal distribution of rock glaciers and precipitation is also discussed.

Study Area

This study focuses on five study areas of the Nepal Himalaya: Kangchenjunga, Khumbu, Langtang, Annapurna, and Sisne Himal (Fig. 1). The easternmost area, Kangchenjunga, is located around 700 km from the Bay of Bengal, whereas the westernmost area, Sisne Himal, lies approximately 1100 km from Kangchenjunga. The climate in the east is strongly influenced by the southwest monsoon of the Indian sub-continent, whereas the one in the west is dominantly influenced by the mid-latitude westerlies (Asahi 2004). Hence, a substantial decrease in the MAP occurs across the Himalaya from the east to the west (Fig. 1). The selected study areas described here provide an opportunity to examine rock glaciers within different climatic and geomorphological settings. A brief description of all five study areas is given below and summarized in Table 1.

Kangchenjunga Himal (size of study area: 260 km²)

Kangchenjunga Himal, which includes peaks higher than 8000 m in altitude including the third highest peak in the world (Mount Kangchenjunga, 8586 m a.s.l.), lies in

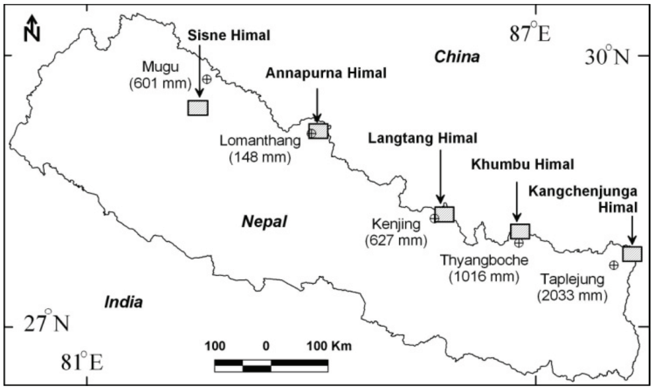

Figure 1. Location of the study area (shaded rectangles) and mean annual Precipitation (MAP) at relevant meteorological stations.

Table 1. Name and location of the five study areas, its coverage by aerial photograph interpretation and number of used aerial photographs at each site.

Name	Lat.	Long.	Area (km²)	Number of aerial phot.
Kangchenjunga Himal	27°45	88°05	260	41
Khumbu Himal	27°55	86°50	345	55
Langtang Himal	28°10	85°35	396	63
Annapurna Himal				
(a) Damodar Himal	*29°10*	*83°50*	*199*	*32*
(b) Mustang Himal	*29°10*	*84°10*	*161*	*24*
Sisne Himal	29°25	82°20	293	46
Total			1654	261

the easternmost part of the Nepal Himalaya (Fig. 1). The climate of this area is strongly influenced by maritime air masses (Ishikawa et al. 2001). The recorded MAP between 1987 and 1998, at the nearest permanent meteorological station (Taplejung: 1732 m a.s.l., about 60 km southwest of the study area), was 2033.4 mm, approximately 70% of which occurred during the summer monsoon period between June and September (DHM 1991, 1997, 2000). The study area receives less rainfall than the Taplejung area due to its leeward location further inland.

Khumbu Himal (size of study area: 345 km²)

Khumbu Himal is located in the eastern part of the Nepal Himalaya and includes Mount Everest and other peaks higher than 8000 m a.s.l. The climate in Khumbu is dominated by strong seasonality. A rainy season occurs between June and September; similar to the Kangchenjunga study area. Precipitation generally falls as snow above 5600 m a.s.l. The recorded MAP between 1967 and 1979 at the nearest permanent meteorological station (Thyangboche: 3867 m a.s.l., about 10 km southwest of the study area), was 1016 mm (DHM 1976, 1980).

Langtang Himal (size of study area: 396 km²)

Langtang Himal is located about 60 km north of Kathmandu (Fig. 1). The Langtang valley is surrounded by the high mountain ranges of Langtang Himal and Jugal Himal. Langtang Himal, with summit altitudes of about 6500 to 7200 m a.s.l., makes the northern and eastern divides, bordering Nepal and Tibet (China). Jugal Himal, with the peak altitudes of about 6800 m a.s.l., makes the southern divide. The MAP in the period 1987 to 1997 at the nearest permanent meteorological station (Kenjing: 3920 m a.s.l.) was 626 mm (DHM 1991, 1997, 2000).

Annapurna Himal - Upper Mustang area (size of study area: 360 km²)

Upper Mustang lies in the northern part of Mustang. It borders Tibet to the northeast, Dolpa District to the west. The highest peaks to the south exceed 6000 m in elevation. In 1992, Upper Mustang was included as one of the seven sectors of the Annapurna Conservation Area, the largest protected area in Nepal. The study area is subdivided into Damodar Himal to the south-east, and the Mustang Himal to the south-west of Lo Manthang, the largest settlement of Upper Mustang. The climate of Upper Mustang can be characterized as a rain shadow desert, desiccated by strong winds and high solar radiation. The region falls under the Dhaulagiri–Annapurna mountain rain-shadow zone (Asahi 2004). The recorded MAP for the neighboring station Lomanthang: 3705 m a.s.l. in the period 1976 to 1996 was only 148 mm (DHM 1980, 1986, 1991, 1997). Rainfall varies within Mustang with southern areas receiving slightly more rain than the north (Kunwar 2002).

Sisne Himal (size of study area: 293 km²)

Sisne Himal lies in the central southern part of western Nepal, with its highest peak of 5582 m a.s.l. The major parts of the mountain ridges do not exceed 5000 m in elevation and only some small glaciers exist. The recorded MAP between 1973 and 1996 at the nearest permanent meteorological station (Mugu: 3803 m a.s.l.) was 601 mm (DHM 1976, 1980, 1986, 1991, 1997).

Methodology

Permafrost, usually a subsurface phenomenon, and its presence is difficult to identify on the surface. Therefore, rock glaciers were used as a landform indicating permafrost by applying aerial photograph interpretation in all five study areas. Vertical aerial photographs of each study area in its entirety were interpreted using a stereoscope. The 1:50,000 scale aerial photographs were taken by the Survey Department, Government of Nepal in 1992 for eastern Nepal (Kangchenjunga, Khumbu, Langtang) and in 1996 for western Nepal (Annapurna and Sisne). More than 250 photographs were investigated for this study. Rock glaciers were carefully delineated on the aerial photographs and drawn onto analog topographic maps of 1:50,000 scale published by Survey Department, Government of Nepal.

Prior to the interpretation of aerial photographs, field observations were made to check the distribution of rock glaciers in three areas of Kangchenjunga, Khumbu, and

Langtang. The field observations allowed for accurate and more detailed interpretation of the aerial photographs.

The front and side slopes of rock glaciers appear "lighter" than their upper surface on aerial photographs, reflecting the exposure of "fresh" (unweathered) materials and the lack of lichen cover. Such characteristics enabled identification of the location of active and inactive rock glaciers using aerial photographs. Inactive rock glaciers having darker frontal and marginal slopes are observed and mapped in the field.

In order to delineate the discontinuous mountain permafrost zone based on rock glacier distribution, it is important to distinguish the type and origin of rock glaciers (Barsch 1978). Based on origin and geographical locations, rock glaciers are divided into two categories: glacial-origin and periglacial-origin rock glaciers (Humlum 1996). However, the terms glacier rock glacier and periglacial rock glacier are used in this study following Benn and Evans (1998). The origin of rock glaciers was identified on the basis of the rock glacier initiation line altitude (RILA) as suggested by Humlum (1988).

Based on these approaches, periglacial and glacial rock glaciers were mapped by aerial photograph interpretation with field verification. The analog maps with detail field and aerial photograph interpretation results were scanned and digitized in ArcView 3.2. After that, size, altitude, and aspect of each of the periglacial rock glaciers were analyzed using the ArcView Spatial Analyst.

Results

Distribution of periglacial and glacial rock glaciers in the five study areas

A total of 140 rock glaciers were identified by interpretation of aerial photographs in the five study areas of Nepal, covering a total area of 1654 km². Glacial rock glaciers were only found in the eastern Nepal Himalaya, i.e., Kangchenjunga and Khumbu Himal (Table 2).

A total of 22 rock glaciers were identified above 4800 m a.s.l. in Kangchenjunga Himal (Fig. 2a), covering an area of 259.6 km². Eight were recognized as glacial and 14 were periglacial rock glacier.

A total of 58 rock glaciers were identified in Khumbu Himal (Fig. 2b), covering an area of 345.4 km². Four rock glaciers were recognized as glacial and 54 were periglacial rock glacier.

Table 2. Summarized results at each of the five study areas.

Name	r.g. gla. (n)	r.g. perigl. (n)	r.g. all (n)	Total r.g. area	Mean r.g. area
Kangchenjunga Himal	8	14	22	2.45	0.11
Khumbu Himal	4	54	58	5.56	0.09
Langtang Himal	0	13	13	0.89	0.07
Annapurna Himal	0	18	18	1.32	0.07
(a) Damodar Himal	*0*	*9*	*9*	*0.63*	*0.07*
(b) Mustang Himal	*0*	*9*	*9*	*0.09*	*0.07*
Sisne Himal	0	29	29	1.35	0.04
Total	12	128	140		

In Langtang, Annapurna, and Sisne Himal with the examined area of 396.2, 359.7, and 293.1 km², a total of 13, 18, and 29 rock glaciers were identified, respectively (Figs. 2c; 2d; 2e). All rock glaciers in Langtang, Annapurna and Sisne Himal were identified to be of periglacial rock glacier.

The mean size of the rock glaciers (including glacier rock glaciers) is 0.11, 0.09, 0.07, 0.07, and 0.04 km² in Kangchenjunga, Khumbu, Langtang, Annapurna, and Sisne Himal, respectively.

Difference in the size of the periglacial rock glaciers in the Nepal Himalaya

The size comparisons show that the periglacial rock glaciers become smaller from eastern Nepal towards western Nepal although the size of the rock glaciers substantially varies among the study areas (Fig. 3).

In Kanchenjunga Himal, the size of the rock glaciers ranges between 0.03 km² and 0.19 km² with the average of 0.09 km². It ranges between 0.01 km² and 0.29 km² with the average of 0.09 km² in Khumbu Himal. Similarly, in Langtang, the size of rock glaciers ranges between 0.009 km² and 0.028 km², with the average of 0.07 km². In Annapurna, the size of the rock glaciers ranges between 0.04 km² and 0.14 km², with the average of 0.07 km² (Fig. 3). The size of the rock glaciers is substantially decreased in the western Nepal and it ranges between 0.009 km² and 0.107 km², with the average of 0.046 km² in Sisne Himal (Table 3).

Altitudinal variations in periglacial rock glacier distribution from east to west of Nepal

The mean lower limit of periglacial rock glaciers shows a decreasing trend from eastern Nepal (5239 m a.s.l) to western Nepal (4513 m a.s.l.) although the altitude of the rock glaciers significantly varies (Fig. 3). The lowest altitude of all 128 mapped periglacial rock glaciers is 5300 m a.s.l. on the south- to east-facing slopes, and 4800 m a.s.l. on the north to west-facing slopes (Fig. 2a; 3). Rock glaciers are located at the altitude ranging from 4800 m to 5640 m Kangchenjunga Himal. They are located at altitudes ranging from 4440 m to 5400 m, with the mean altitude of 4996 m in Khumbu. Similarly, in Langtang Himal they are located at altitudes ranging from 4600 m to 4920 m, with the mean altitude of 4722 m (Fig. 3). In Annapurna Himal they are

Table 3. Summarized result of altitudinal distribution and mean area of periglacial rock glaciers in five study areas.

Name	Altitudinal range (m a.s.l)	Mean altitude (m a.s.l)	Mean r.g. area
Kangchenjunga Himal	4800-5640	5239	0.09
Khumbu Himal	4440-5400	4996	0.09
Langtang Himal	4600-4920	4722	0.07
Annapurna Himal	4450-5120	4746	0.07
(a) Damodar Himal	*4480-4960*	*4681*	*0.07*
(b) Mustang Himal	*4450-5120*	*4810*	*0.07*
Sisne Himal	4200-4800	4513	0.04

located at altitudes ranging from 4450 m to 5120 m, with the mean altitude of 4746 m, whereas in Sisne Himal they are located at altitudes ranging from 4200 m to 4800 m (Table 3).

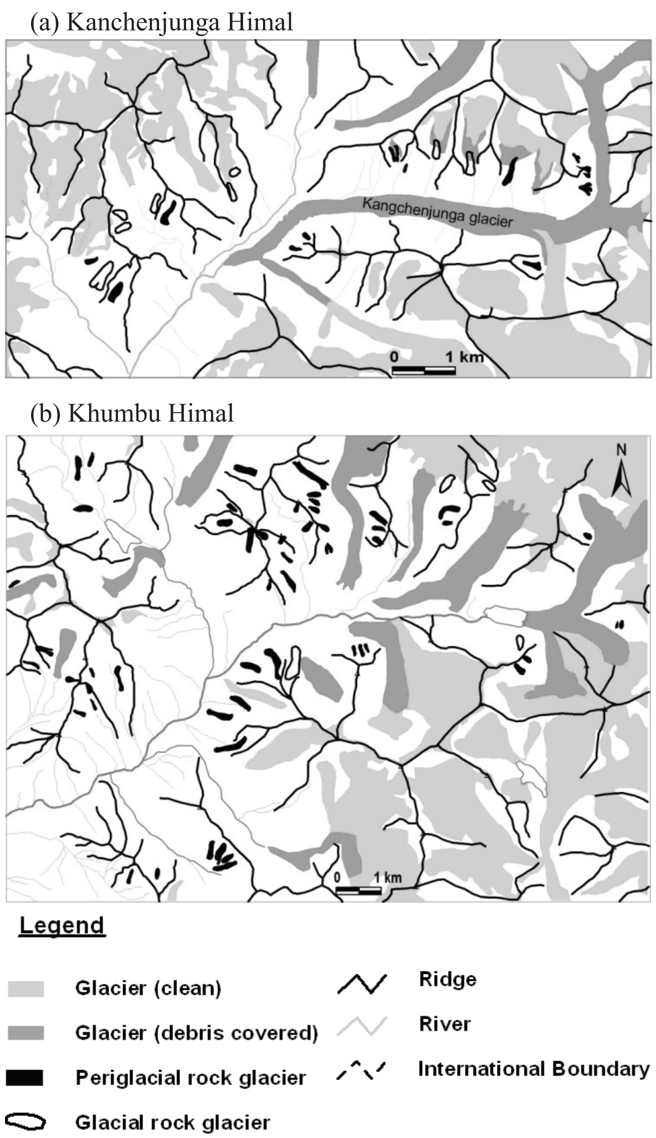
Orientational variations in periglacial rock glacier distribution from east to west of Nepal

The aspects of the periglacial rock glaciers from all Nepal Himalaya are shown in Figure 4. The rock glaciers are orientated toward the different directions, but they are mostly found on the south-, southeast-, and southwest-facing slopes.

In Kanchenjunga Himal, aspectual distribution suggests that most rock glaciers are oriented toward the east, south, and southwest directions (Fig. 2a). In Khumbu, rock glaciers are mostly found to be oriented toward the southeast, south and west directions (Fig. 2b). Similarly, rock glaciers are mostly found to be oriented toward the southwest directions in Langtang Himal (Fig. 2c). In Annapurna Himal, rock glaciers are mostly found to be oriented toward the southeast and south directions (Fig. 2d). Likewise, rock glaciers are mostly found to be oriented towards the southeast in Sisne Himal (Fig. 2e).

Discussion

King (1986) and Haeberli et al. (1993) indicated that the total amount of annual precipitation plays an important role in determining a mountain permafrost zone. The altitudinal range of the mountain permafrost zone in general decreases



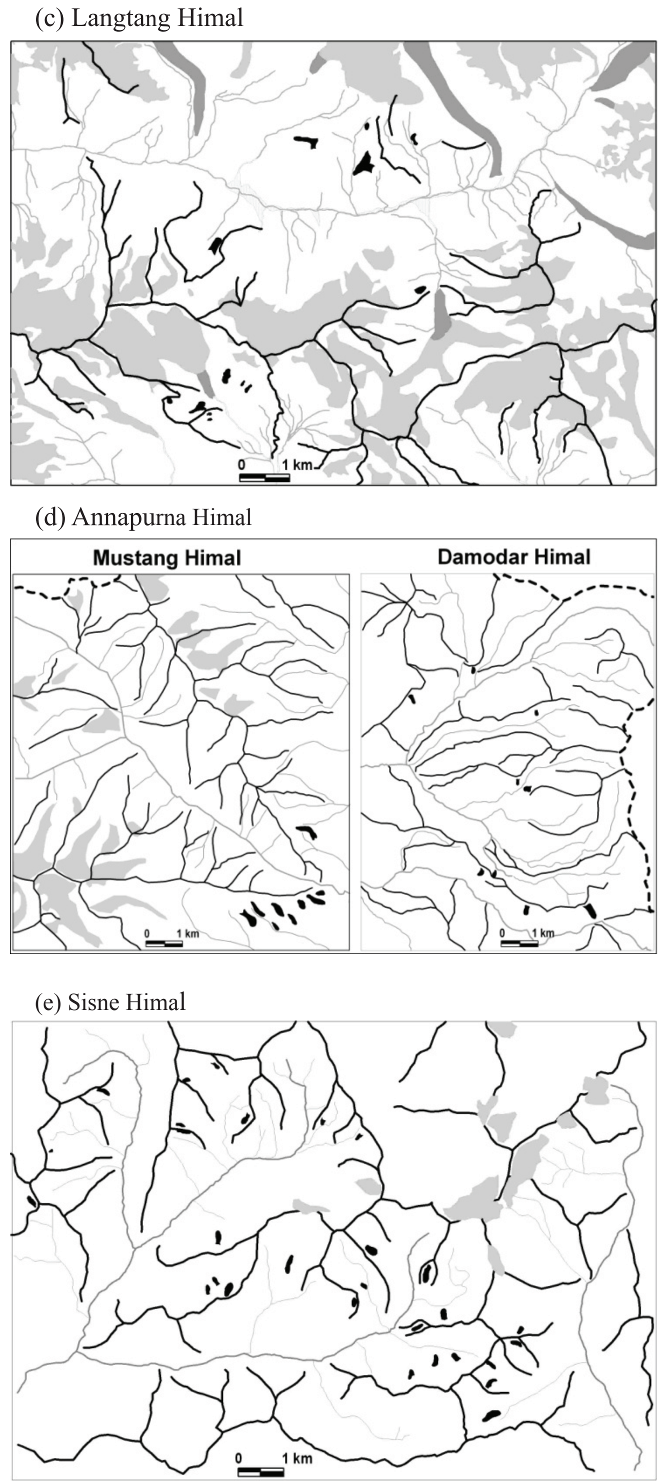


Figure 2. Rock glacier distribution and other landforms in the five study sites (a, b, c, d, and e) in the Nepal Himalaya.

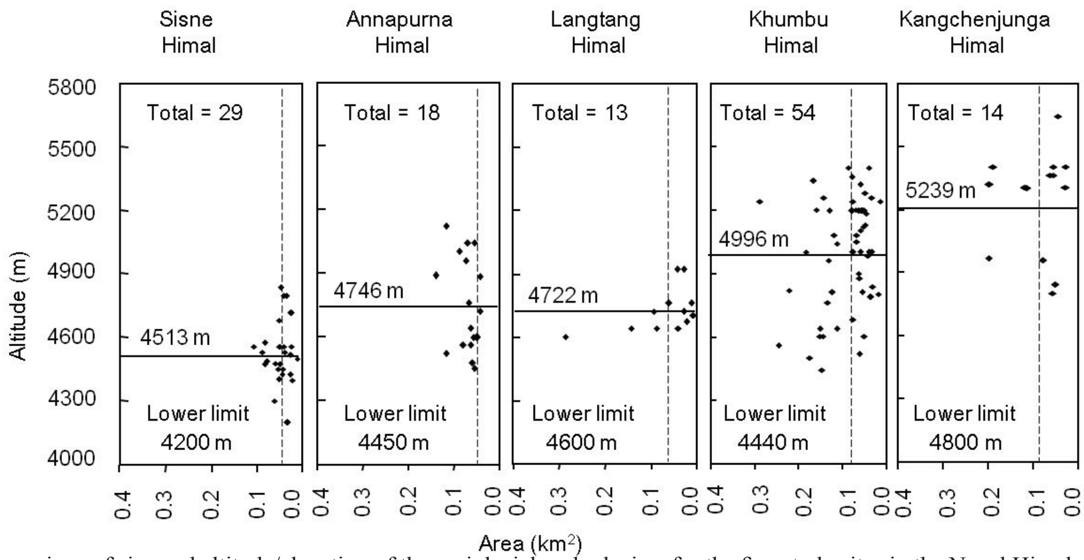

Figure 3. Comparison of size and altitude/elevation of the periglacial rock glaciers for the five study sites in the Nepal Himalaya. Horizontal line indicates the mean altitude of the rock glacier front of all rock glaciers of the given study area. Vertical dotted line indicates the mean area of each region.

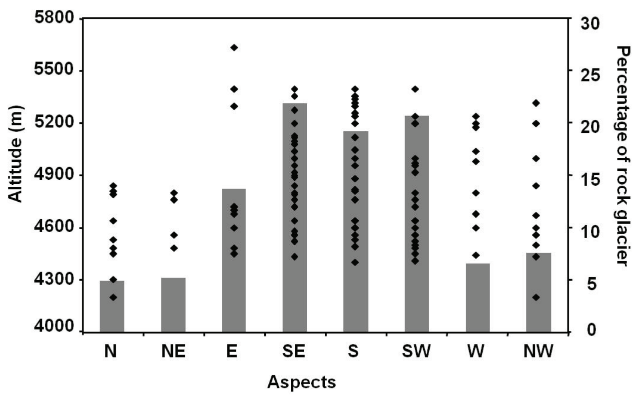

Figure 4. Altitudes and aspects of the periglacial rock glaciers in the Nepal Himalaya (n=128). Each dot shows the altitude of a rock glacier by slope aspect. The bar shows the percentage of the rock glaciers in a given aspect class.

with increasing annual precipitation. MAP substantially decreases from east to west in the Nepal Himalaya. Discussion focuses mainly on the effect of the decrease in precipitation from east to west Nepal Himalaya.

Due to its location in the easternmost part of the Nepal Himalaya, Kangchenjunga Himal is strongly influenced by monsoon winds coming from the Bay of Bengal, which provides high precipitation. MAP at the nearest meteorological station (Taplejung, 1732 m) in the Kangchenjunga region is approximately 2400 mm. Dhar and Nandargi (2000) reported a MAP of 1167 mm at Kambachen (4100 m altitude). This indicates that the permafrost in Kangchenjunga Himal belongs to an oceanic type of mountain permafrost. In contrast, the small amount of MAP in western Nepal (472 mm, in Sisne) indicates that the permafrost in Sisne belongs to a continental type.

The mean lower limit of periglacial rock glacier occurrence is 5239 m a.s.l. in Kangchenjunga Himal and 4996 m in Khumbu Himal (Fig. 3). These altitudes are considerably higher than those in the western Himalaya, which are under dry continental climatic conditions, e.g., 4513 m for Sisne Himal. Owen and England (1998) indicated that rock glaciers in the Pakistan Himalaya are restricted to regions with an MAP of less than 1000 mm and altitudes above 4000 m a.s.l. The decrease in the lower limit of rock glaciers from east to west coincides with the decrease in annual precipitation. This suggests that the MAP may cause the altitudinal difference in the lower limit of discontinuous mountain permafrost zone within the Nepal Himalaya.

Conclusions

The distribution of rock glaciers in five selected study areas in the Nepal Himalaya was mapped by applying aerial photograph interpretation and field observations. Based on this, the distribution of mountain permafrost was assessed. The following conclusions can be drawn from this study.

1. High amount of precipitation in eastern Nepal is most likely to lead to the development of glacial rock glaciers. However, further investigations are recommended considering temperature, snow cover, weathering rates, bedrock type and topography.
2. Periglacial rock glaciers in the eastern Nepal Himalaya tend to be larger than those of the western Nepal Himalaya.
3. The mean altitude of the periglacial rock glaciers decreases towards the western Nepal Himalaya.
4. Aspect of the periglacial rock glaciers is inhomogeneous, but they are mostly found in southern aspects.

Abstract

As part of the Housing Privatization Project at Elmendorf Air Force Base, Alaska, a design/build contract was implemented for the construction of 372 housing units and all associated site improvements. Adverse weather conditions including heavy rainfall with early freezing temperatures and limited snow cover during the fall and early winter period produced conditions conducive to excessive ground frost heaving. The building appurtenances adjacent to the vertical insulation and above the horizontal insulation were exhibiting excessive and unacceptable upward movement. These adverse impacts included heaving stoops, patio slabs, driveways, and uplifting of the protective perimeter vertical insulation board. A plan to repair the damaged work product was developed and implemented. The repair efforts involved removal of all damaged items. Either excavation of the silt layer or placement of additional horizontal insulation board was determined on a site-specific basis. It is important to critically assess the potential for differential movement associated with building perimeter appurtenances.

Keywords: building appurtenances; foundation insulation; frost heave.

Introduction

As part of the Housing Privatization Project at Elmendorf Air Force Base, Alaska, a design/build contract was implemented for the construction of 372 housing units and all associated site improvements. Figure 1 provides an aerial photograph of the site and completed project. The housing units consisted of 93 four-plex buildings of two-story wood frame structure constructed on frost-protected, thickened-slab shallow foundations. The project is located near the Boniface gate entrance, east of Vandenberg Avenue and immediately north and south of Provider Drive. The project owner is Aurora Military Housing, LLC, and construction was completed by Osborne Construction Company and Davis Constructors and Engineers, Inc., in a joint effort with the Hunt Building Corporation.

During the spring of 2001, "fast track" construction was initiated on the Boniface Housing Project. It continued through the following winter period and into the next 2002 full season, with the intent of allowing early occupancy as each of the four phases were completed. The first phase was completed and occupied in early fall 2001 while work continued on the remaining three phases. Adverse weather conditions including heavy rainfall with early freezing temperatures and limited snow cover during the fall and early winter period produced conditions conducive to excessive ground frost heaving. Adverse impacts to building unit perimeter entrances became visually apparent through the winter months. These impacts included heaving stoops, patio slabs, driveways, and uplifting of the protective perimeter vertical insulation board with consequent distortion of cover flashing. The authors were retained to evaluate site conditions and assist in developing remedial solutions for the contractors.

Investigation of soil conditions and perimeter appurtenances revealed frost penetration to depths of 0.9 to 1.2 m and the presence of a saturated frozen silt layer, having a variable thickness ranging from 0.3 to 1.2 m, interspersed in a sandy gravel and gravelly sand outwash deposit. It was apparent that the buildings' shallow foundation perimeter insulation was limiting frost penetration below the slabs in accordance with design requirements; however, the building appurtenances adjacent to the vertical insulation and above the horizontal insulation were exhibiting excessive and unacceptable upward movement, up to as much as 75 to 100 mm. In many instances, the larger movement resulted from a "cantilevered" lifting of the frozen material overlying the horizontal insulation board.

After review of all the conditions, a plan to repair the damaged work product was developed and implemented. The repair efforts involved removal of all damaged items. Either excavation of the silt layer or placement of additional horizontal insulation board was determined on a site-specific basis. Additional efforts were made to control roof drainage and to improve drainage away from the building perimeter. The vertical insulation board was removed and reattached in a more positive manner in those areas where excessive movement had occurred. For the 192 housing units involved, the required repairs included 111 front entry stoops, 98 patios, 92 back stoops, 80 driveways, and 82 sidewalks.

As with most structures founded on soils that are subjected to frost heave effects, it is important to critically assess the

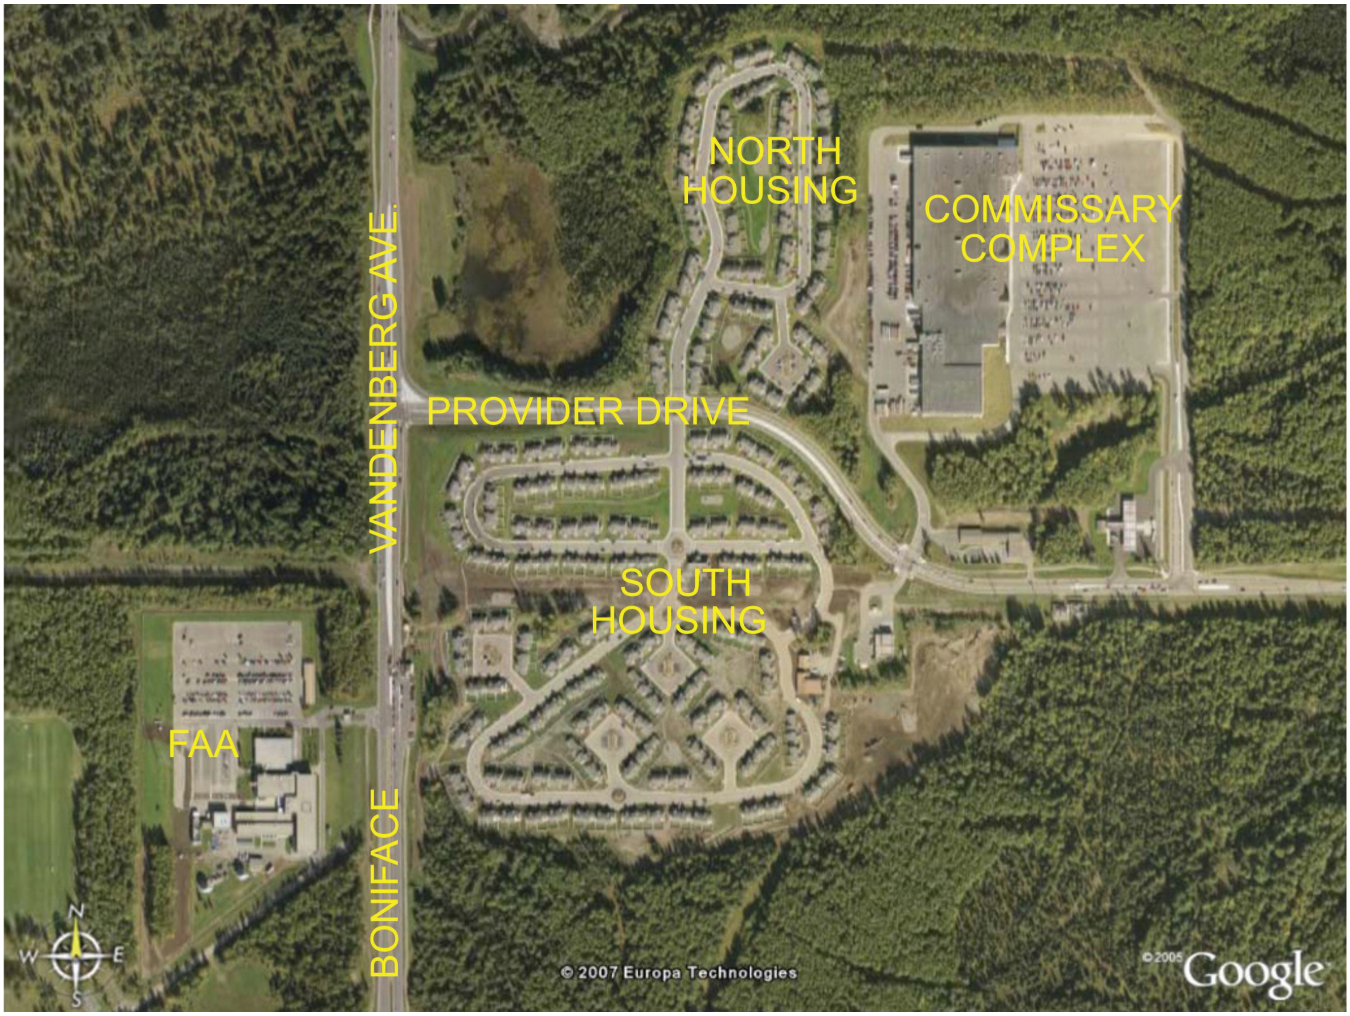

Figure 1. Aerial photograph showing Boniface Housing Project and adjacent commissary complex.

potential for differential movement associated with building perimeter appurtenances. In this case, a combination of circumstances created conditions that caused excessive differential frost heaving.

Historical Use of Frost-Protected Shallow Foundations

Some of the earliest reported work on the use of frost-protected foundations dates back to the late 1960s and early 1970s (Woodworth & Krzewinski 2002, Robinsky & Bespflug 1973, Thue 1974). Since that time, a number of technical papers have identified the effectiveness of this shallow foundation solution when appropriate design measures are implemented. It has also been utilized for remedial applications in repairing frost heave affected foundation systems such as documented in a prior case study (Woodworth & Krzewinski 2002). The Boniface Housing Project utilized the "Design Guide for Frost-Protected Shallow Foundations" (U.S. Dept. of Housing & Urban Dev. 1994). At this point in time, the principle guidelines provided in "Design of Frost-Protected Shallow Foundations" serve as an American Society of Civil Engineers (ASCE) practice standard in the United States.

While all of these documents fully address concerns with building structure foundation performance, little to no information is provided on the treatment of building perimeter appurtenances and the potential adverse effects of transitions at the outer edge of the horizontal insulation boards. This paper is presented for the purpose of identifying some of the adverse impacts that occurred when excess frost heave and unanticipated climate conditions developed during the Boniface Housing Project construction period.

Site Conditions

Elmendorf AFB is located within the Cook Inlet-Susitna Lowland physiographic province and is immediately adjacent to the northern boundary of Anchorage, Alaska. The area is characterized as a glaciated lowland containing areas of ground moraine and stagnant ice topography, drumlin fields, eskers, and outwash plains, with rugged mountains located immediately to the east. This region of Alaska is considered to be generally free of permafrost. One exception is where isolated masses of permafrost occur in lowland areas with high ground insulation, such as peat bogs and swamps. Soils at the site are interpreted as generally coarse-grained alluvial deposits of well-bedded and well-sorted gravel and sand overlying glacio-marine clay deposits of the Bootlegger Cove formation. The alluvial material is commonly overlain by 0.3 to 1.5 m of silt (R&M Engineering Consultants 2001). Bedrock was encountered at a depth of approximately 136 m in a nearby water well.

Lying between Cook Inlet and the Chugach Mountains, Elmendorf AFB has a transitional climate which may be characterized as variable, with the influence of both maritime and continental climates. Elmendorf AFB receives about 398 mm of precipitation per year. The temperature ranges from extremes of about -36ºC to 29ºC with an annual mean of 2.2ºC. The mean monthly temperature ranges from about -11ºC in January to 14ºC in July.

The undeveloped site was relatively flat, having a gentle southward slope. Much of the site was wooded with spruce and birch trees. Soil conditions within the site were defined by 20 test borings drilled to a depth of about 8.2 m by the Corps of Engineers in September 1998. The surficial soils consisted of silts and silty sand extending to a depth of 0.9 to 1.2 m, overlying sand and gravel that continued to the bottom of the test borings. Groundwater was only encountered in three test holes and was at a depth of 6 m or greater. Moisture content of the silty soil varied from 8% to 33% and averaged about 18%. Average moisture content for the granular soil was less than 4%.

Foundation Design and Building Perimeter Insulation Details

The buildings were constructed with slab-on-grade floor systems and bearing foundations consisting of a thickened perimeter edge, as shown in Figure 2. An air freezing index of 1905ºC-days, corresponding to a 100-year return period, as identified in the "Design Guide for Frost-Protected Shallow Foundations" was utilized. The insulation requirements for preventing frost heave of the thickened edge and spread footings are presented in Table 1.

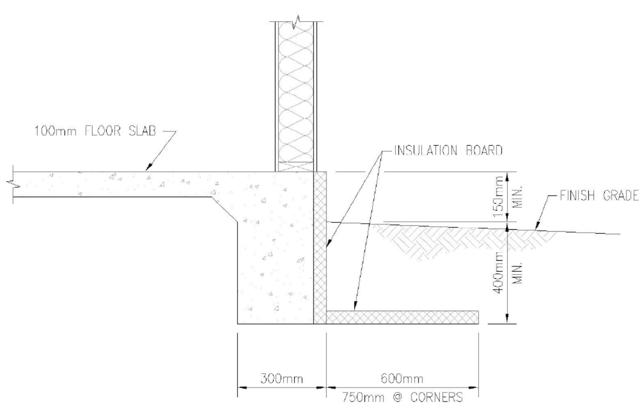

Figure 2. Thickened-slab edge foundation.

Table 1. Project insulation requirements.

Insulation	Thickness	R-Value	Required R-Value
Vertical	38 mm	1.1 k • m^2/w	1.0 k • m^2/w
Horiz. (walls)	76 mm	2.3 k • m^2/w	1.4 k • m^2/w
Horiz. (corners)	76 mm	2.3 k • m^2/w	2.0 k • m^2/w

Freezing temperatures were not observed below any of the foundation insulation board, and the building foundations have remained stable.

The design procedures were based on those required for heated buildings utilizing Anchorage, Alaska, climatic data, and assumed no insulating ground vegetation or snow cover. Since construction continued through the winter months without full building heat effects, it is likely that requirements for an unheated building would have been more appropriate. However, in either case, it seems that the adverse frost heave impacts on perimeter appurtenances would have been the same. With this in mind, an attempt has not been made to evaluate the climate and thermal conditions that actually occurred, but only to address the adverse building perimeter appurtenance impacts.

Frost Heave Impacts on Building Appurtenances

The adverse frost heave impacts resulted from both vertical and horizontal volumetric expansion of the soil, and also from a "cantilevered" lifting of the soil overlying the insulation board. Horizontal forces exerted against the vertical insulation board caused upward movement of the boards as the soil beyond the edge of horizontal board continued to heave. This resulted in sufficient vertical board movement that 1) displaced building perimeter flashing, 2) lifted stoop and patio slabs against door jambs, and 3) raised driveway pavement well above the garage door floor slab surfaces. Some of these conditions are shown in Figures 3a, 3b, 4, 5a, and 5b.

As can be seen in the test pit photograph (Fig. 6), an air gap of over 25 to 30 mm was found above the top of insulation board and the overlying soil cover. An interpretation of the forces and movements that occurred is shown in Figure 7.

When problems with the building perimeter appurtenances became visually apparent, the project contractors initiated efforts to evaluate the causes and to implement corrective

Figure 3a. Ponded water against building between driveway in insulated area that did not heave.

Figure 4. Uplifted concrete patio slab. Door sill and jambs were lifted by patio slab.

Figure 5a. Displaced vertical insulation board with flashing partially removed.

Figure 5b. View of perimeter base flashing covering vertical insulation board. Flashing has been slightly distorted by upward board movement.

actions. Such factors as project schedules, costs, and disruption of occupied building units needed to be considered in developing appropriate corrective action. The project contractors, owner/developer, and involved governmental agencies all worked together to implement necessary corrective measures.

Many driveways that had been constructed experienced significant frost heaving during the period of sub-freezing temperatures. Surface heaving of up to 63 mm was measured between the driveway surface and top of garage floor slab. Heaving of the concrete door stoops and patio slabs was also experienced to the point where door sills and jambs were distorted and impacting door swings and closures. Heaving soil conditions on the outer side of the insulation were also blocking drainage from roof snowmelt during thawing periods and, thus, compounding soil moisture and icing conditions.

Corrective actions for driveways included the following efforts and are shown in Figure 8.

• Removal of all asphalt and underlying silty soil down to gravelly soil or to a depth of 1.5 m.

• Extension of 76 mm horizontal insulation out to 1.8 m from the building edge within the driveway limits.

• Backfill excavation with F2 soil or better up to the insulation level and overlay with 450 mm of non-frost susceptible (NFS) material, 50 mm of crushed aggregate base course, and 50 mm of asphalt.

• Pave driveway to an elevation 12 mm below garage slab floor surface.

Corrective action for concrete stoops and patio slabs included the following efforts and are shown in Figure 9.

• Break up and remove concrete.

• Excavate and remove underlying soil down to the top of horizontal insulation board.

Figure 6. Test pit exposing horizontal insulation board. Air gap was found between insulation board and overlying frozen soil that was lifted by adjacent deeper frozen ground.

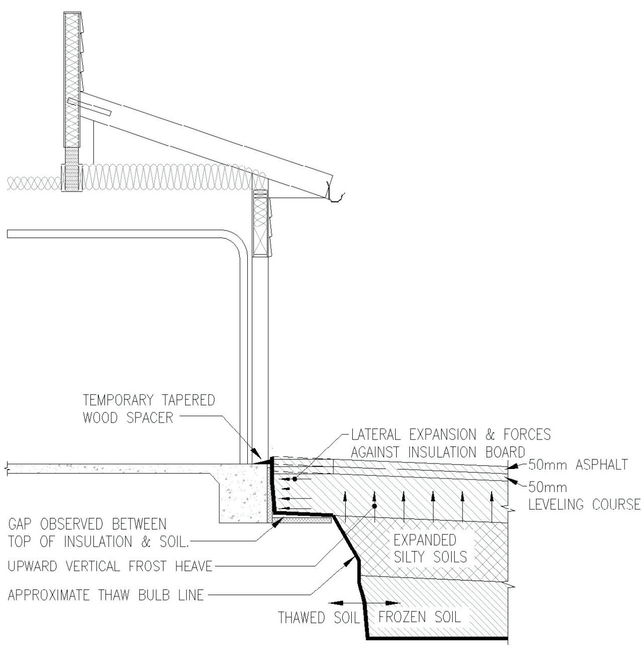

Figure 7. Interpreted ground heaving conditions and consequent expansion forces that caused vertical movement of pavement, stoops, patio slabs, and vertical insulation boards.

• Extend horizontal insulation coverage under entire slab area.

• Backfill with approximately 28 mm of NFS material.

• Remove and replace vertical base flashing using a modified flashing detail.

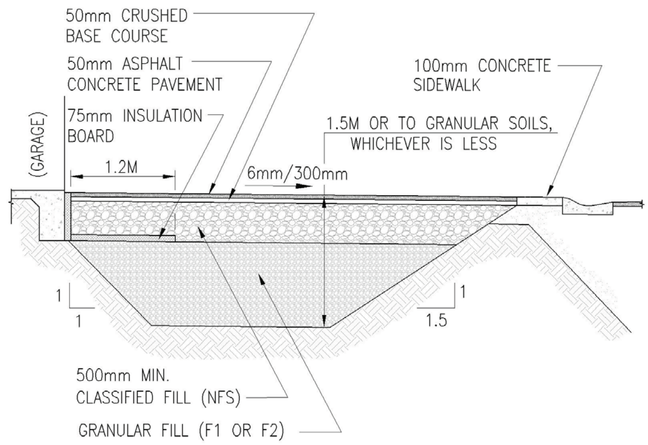

Figure 8. Profile of revised driveway improvement to reduce frost heave effects.

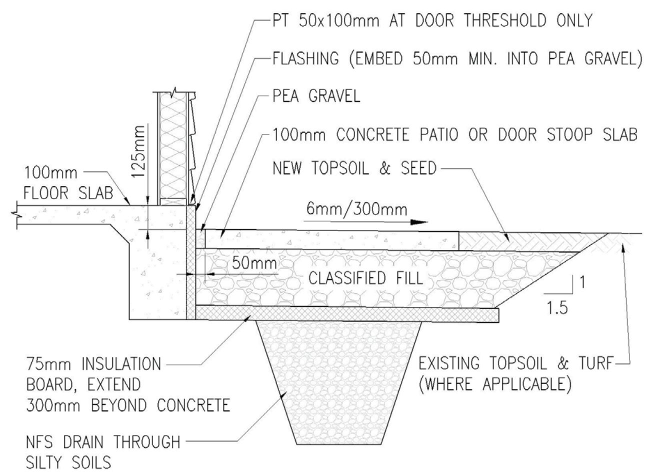

Figure 9. Profile of patio and stoop slab improvements to reduce frost heave effects.

• Re-pour new concrete patio/stoop 125 mm to 150 mm below finish floor elevation using a modified patio/stoop detail.

Corrective action for perimeter base flashing involved some limited total replacement of flashing, but in most cases consisted of cutting off existing flashing and installing new flashing using a two-piece flashing detail, as shown in Figure 10.

Roof drainage collection and disbursement modifications involved the following:

• Revising gutter location over garages to drain to center of driveways and install downspouts to improve drainage away from the building.

• Extension of gutters over front entries to reduce drainage and ice buildup on stoop.

Repairs and modifications for the project were completed by late 2002, and it is apparent that the contractor's efforts to address the frost heave-related problems were successful. Brief visual investigations have been made at those areas

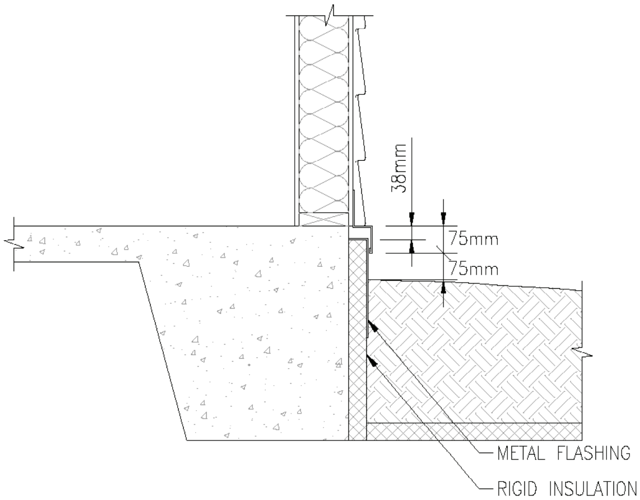

Figure 10. Foundation flashing detail modification to reduce frost jacking effects.

where the more significant frost heave impacts occurred. No evidence of adverse effects have been observed through the summer of 2007.

Closure

As with most structures founded on soils that are subjected to frost heave effects, it is important to critically assess the potential for differential movement associated with building perimeter appurtenances. In this case, a combination of circumstances created conditions that caused excessive differential frost heaving. Adverse weather conditions, including heavy rainfall with early freezing temperatures and limited snow cover during the fall and early winter period, produced conditions conducive to excessive ground frost heaving.

After review of all the conditions, a plan to repair the damaged work product was developed and implemented. The repair efforts involved removal of all damaged items. Either excavation of the silt layer or placement of additional horizontal insulation board was determined on a site-specific basis. Additional efforts were made to control roof drainage and to improve drainage away from the building perimeter.

Problems with building structure perimeter frost heave effects are not unique to just frost-protected shallow foundation structures. There are far too many examples of frost heave and jacking of driveways, decks, patios, and seasonally ponded drainage around buildings constructed on other foundation systems. This paper has been prepared for the purpose of identifying a condition that can occur with any foundation system that has the potential for vertical ground movement adjacent to the perimeter of a fixed structure. It is important for project designers to fully assess the potential for such movement and to develop details that can accommodate anticipated movements.

Estimating Active Layer and Talik Thickness from Temperature Data: Implications from Modeling Results

D. W. Riseborough
Geological Survey of Canada

Abstract

Projected permafrost warming and degradation due to climate change will make it difficult to continue with current monitoring protocols at some sites, as the top of permafrost descends to depths beyond the reach of active layer probes and thaw tubes. In this paper, thermal modeling results were used to evaluate the accuracy of active layer and talik depths estimates obtained using temperature cable data. The thermal regime of degrading permafrost was simulated using a fine-mesh 1-dimensional finite element model, while active layer and talik depths were estimated using model output at the coarse spacing typical of thermistor cable strings. Results show that estimates of annual active layer and talik depths obtained by extrapolation from above (the unfrozen side of the 0°C isotherm) were more accurate than those obtained by interpolation, or by extrapolation from below, especially where the soil thermal properties were significantly temperature-dependent. Estimates of active layer depth obtained using the annual temperature envelope were no more accurate than those obtained using individual temperature profiles, while estimates of talik depths were more accurate than estimates of active layer depth.

Keywords: active layer; ground temperature; models; talik; permafrost monitoring.

Introduction

Projected permafrost warming and degradation due to climate change will make it difficult to continue with current monitoring protocols at some sites, as the top of permafrost descends to depths beyond the reach of some methods for active layer monitoring. The standard methods for determining active layer thickness include probing, frost tubes, and estimation from soil temperature profiles (Nelson & Hinkel 2004). Probing is limited by field logistics to less than 1.5 m, while thaw tubes as currently designed are limited to about 2.4 m depth (Mark Nixon, personal communication). Estimating active layer and talik depth from temperature profiles is a common practice, but is subject to errors that are the subject of this paper.

Nelson & Hinkel (2004) suggest that the accuracy of the active layer thickness estimates from temperature profiles depends on the distance between measurement depths and the data-collection interval, and indicate that simple linear interpolation between measurements is used to determine calculate the position of the 0ºC isotherm.

Estimating the position of the 0ºC isotherm is also a problem in geothermal modeling, since most numerical models calculate changes in temperature at finite intervals along a profile, and do not calculate the position of the 0ºC isotherm directly. Calculating active layer depths by interpolation in a coarse grid usually produces a time series that follows a scalloped pattern, with slow descent before and rapid descent after the front passes points in the calculation mesh (Fig. 1). This effect depends on the interpolation method, and occurs here because linear interpolation does not account for the change in thermal properties as ice forms at 0ºC, causing an abrupt change in temperature gradient (Fig. 2). Estimating the position of the 0ºC isotherm in profiles such as in Figure 2 could be improved by using extrapolation from the grid temperatures above or below the frost front. The analysis presented in this paper is an attempt to determine whether this is generally true, by examining the magnitude of errors in 0ºC isotherm depth estimates from temperature profiles. Active layer thickness and depth of taliks were both examined, and depth estimates by extrapolation from above, by interpolation, and by extrapolation from below were compared. The effect of the distance between temperature points was also examined. This approach to error analysis could also be applied to other interpolation methods (such as cubic spline or other more sophisticated methods that account for the change in properties across the phase boundary), which are not considered here.

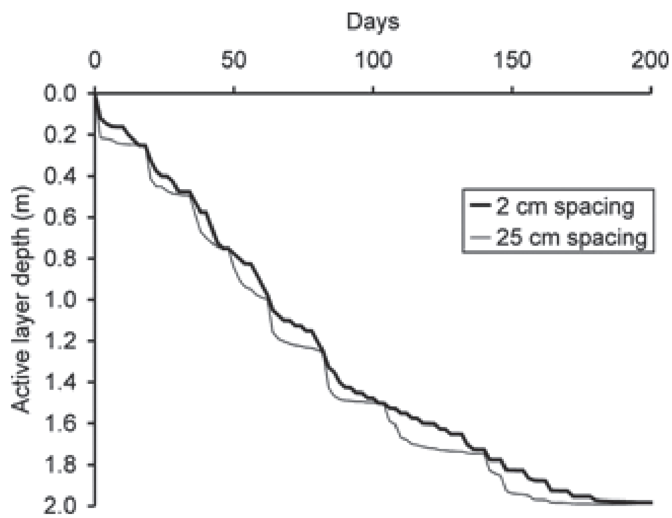

Figure 1. Example of active layer depth estimates from evenly-spaced node temperatures. Note the "scalloped" shape as node depths are approached.

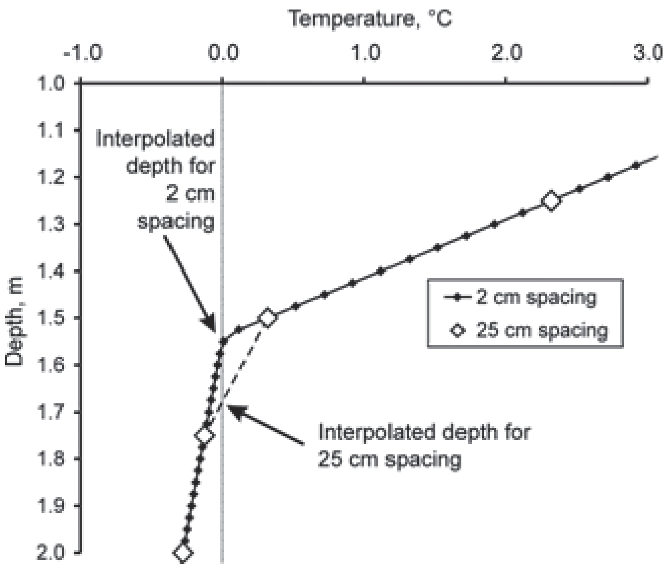

Figure 2. Typical temperature profile detail near the base of the active layer. The scalloping observed in Figure 1 is an effect of the interpolation method, as shown.

Method

Thermal modeling results were used to evaluate the accuracy of active layer and talik depth estimates obtained using temperature cable data. The multi-year thermal regime of degrading permafrost was simulated using a fine-mesh 1-dimensional finite element model, while active layer and talik depths were estimated using model output at the coarse spacing typical of thermistor cable strings. Using the fine-mesh output from the numerical model (spacings of 0.02 to 0.025 m for active layers, and 0.1 m for taliks), the "true" position of the 0ºC isotherm depth could be known to reasonable accuracy (within about 0.01m for active layers, and 0.05 m for taliks). Comparisons with active layer and talik depth estimates by extrapolation or interpolation from temperature data at coarser spacing allowed an evaluation of the relative accuracy of the estimation methods.

For active layer estimates, two different kinds of data were used. The *profile* method applied the estimation methods to instantaneous temperature profiles, allowing the tracking of seasonal progression of the active layer, as in Figure 1. The *envelope* method used annual temperature envelopes (depth profiles of the warmest and coldest ground temperatures experienced in a year) to estimate the annual maximum depth of thaw, applying the estimation methods to the profile of annual maximum temperature.

To evaluate the relationship between accuracy and sensor spacing, thermistor string data were simulated by selecting model output temperature corresponding to the depths appropriate for each spacing evaluated. For the analysis of active layer estimates, spacings of 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.75, and 1.0 m were used; for talik depth estimates, spacings of 0.2, 0.4, 0.6, 0.8, 1.0, 1.5, and 2.0 m were used.

This method was applied to simulations of similar climates, with two distinct substrates yielding somewhat different thermal regimes. The simulated surface climates included daily and inter-annual variability, with a long-term climate trend. Both simulation substrates included a 0.2-m thick saturated surface organic layer, overlying 20 m of saturated soil with 50% volumetric moisture content. For one substrate ("Bimodal"), all phase change was assumed to occur at 0ºC, with thermal properties having frozen and thawed values. The second ("Temperature dependent") substrate material had a substantial unfrozen water characteristic (using the freezing characteristic of Fairbanks silt), with phase change occurring over a broad range of freezing temperatures, resulting in temperature-dependent thermal properties at temperatures below freezing.

Model details

Simulations were made using Goodrich's discontinuous element model TONE (evaluated in Bouchard 1990 and Riseborough 2004). In each time step, the thermal conductivity and apparent heat capacity within each element were averaged based on the temperature profile, improving accounting for the total latent heat. This formulation should produce better results in soils that exhibit strong temperature dependence in thermal properties due to the freezing characteristic, as it accommodates the distribution of thermal properties across each element. Significant transitions over small temperature changes are not lost between points in the calculation mesh. However, this averaging results in a softer transition between frozen and thawed conditions in simulations where phase change is more abrupt.

Simulations

An initial 100-year simulation with a stationary climate was first performed for each substrate to establish an equilibrium initial temperature profile for subsequent simulations For each substrate, a 50-year active layer simulation and a 150-year talik simulation were performed with approximately the same surface climate (with initial mean annual temperature of -6.4, with a 1ºC per decade warming trend). Simulated climates included a 0.4-m deep annual snow cover with a parabolic accumulation function (Zhang 1993) and a density of 350 kg m^{-3}, inter-annual temperature variability (simulated by specifying standard deviations of 10% to the freezing and thawing indices, as described in Riseborough 2007), and daily variability with a standard deviation of 3ºC.

For both substrates, active layer simulations were performed with a fine mesh (0.02 and 0.025 cm spacing) in the upper 3 m (for analysis of active layer estimates) and 32 time steps per day, while talik simulations had a mesh of 0.1 m over the upper 15 m and 8 time steps per day. All simulations extended to 20 m, with a constant heat flux prescribed at the base of the mesh.

In bimodal simulations, talik depths reached 3 m depth after 68 years, and thawed to 15 m by year 118. In the simulations with temperature-dependent thermal properties, thaw depths reached 3 m by year 78, but the earliest were deep active layers, and a persistent talik did not form until year 89. Thaw depth extended to 15 m in year 137.

Analysis

Model outputs consisted of instantaneous temperature profiles at 10-day intervals and annual temperature envelopes, with results recorded for all nodes in the finite element mesh (node spacings of 0.02 and 0.025 m for active layer simulations, and 0.1 m for talik simulations). Once the simulations were complete, node temperatures (simulated "sensors") were used to construct coarser temperature profiles by sampling results at the appropriate depth intervals.

For all analyses, active layer depths were estimated in the same way, using temperature profile and temperature envelope results. Using either the instantaneous profiles or the profile of annual maximum temperature from the envelope, the node depths bounding the 0ºC isotherm were determined, and the appropriate node pairs were selected for the active layer estimate: for interpolation, the bounding nodes were used; for extrapolation, the first two nodes above or below the 0ºC position were used. Using the temperature gradients determined from these pairs, the position of the 0ºC isotherm was determined as the depth-intercept of the line defined by the sampled depth and temperature data.

Initial results showed that extrapolation methods were unreliable once freezeback had been initiated, due to the nearly isothermal conditions present between the freezing fronts bounding the unfrozen active layer. As a result, active layer estimates for instantaneous temperature profiles were not evaluated once freezeback had begun.

Talik depth estimates were obtained as for active layers, except that only one instantaneous temperature profile per year was evaluated. For the analysis of talik depths, only nodes between 3 m and 15 m were examined, in order to exclude active layers from the analysis, and to limit results to the part of the simulated profile with the smaller node spacing. For the cases with bimodal thermal properties, no active layers exceeded 3 m. In the cases with temperature dependent properties, deep active layers developed for several years before the establishment of a persistent talik.

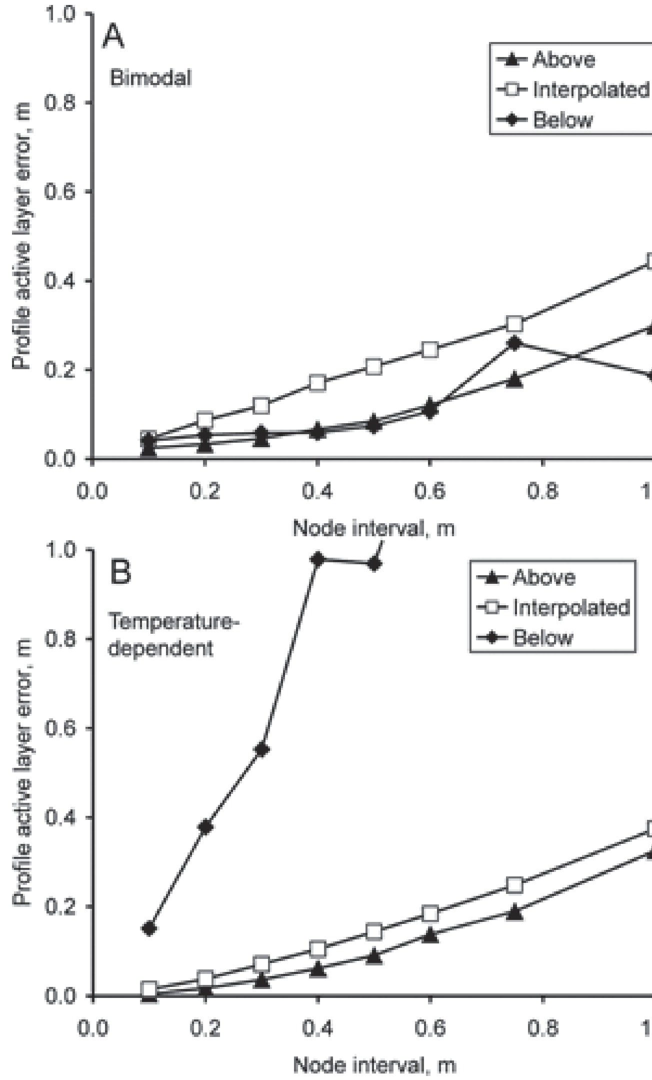

Figure 3. Average error in active layer depth estimated from instantaneous temperature profiles, as a function of selected node interval. A: simulations with bimodal (frozen/unfrozen) thermal properties and all phase change at 0ºC. B: simulations with temperature dependent thermal properties and unfrozen water.

Results and Discussion

Results for all interpolation methods were evaluated using the same procedure: for each profile or envelope, active layer or talik estimates with coarse temperature spacings were compared to estimates obtained with the fine mesh model output, and the average absolute value of all errors for each spacing calculated. Results are presented in Figures 3–5, and show that for all cases, errors increase as the node spacing increases, generally at a rate more than proportional to the increase in spacing. Errors in active layer estimates are not smooth functions of spacing, due to the variability imposed in the simulations.

Active layers from temperature profiles

Figure 3 shows the average error in active layer depth estimated from instantaneous temperature profiles. For the bimodal case, extrapolation yields more accurate active layer depth estimates, for all spacings. Up to a spacing of 0.6 m, the error in active layer depth with either extrapolation method is about half that of the error for interpolation. For the case with temperature dependent thermal properties, estimates based on extrapolation from below are very poor (exceeding the node spacing), while interpolation and extrapolation from above are better than for the bimodal case. The significant difference in errors when extrapolating from below is due to the effect of temperature dependent thermal properties on the temperature gradient, resulting in curvature in the temperature profiles that would make linear extrapolation through the frozen soil unreliable. This same effect is responsible for the improvement in the depth estimates using interpolation, as curvature in the frozen part of the temperature profiles reduces the rate of change of temperature gradient in the upper part of the frozen soil.

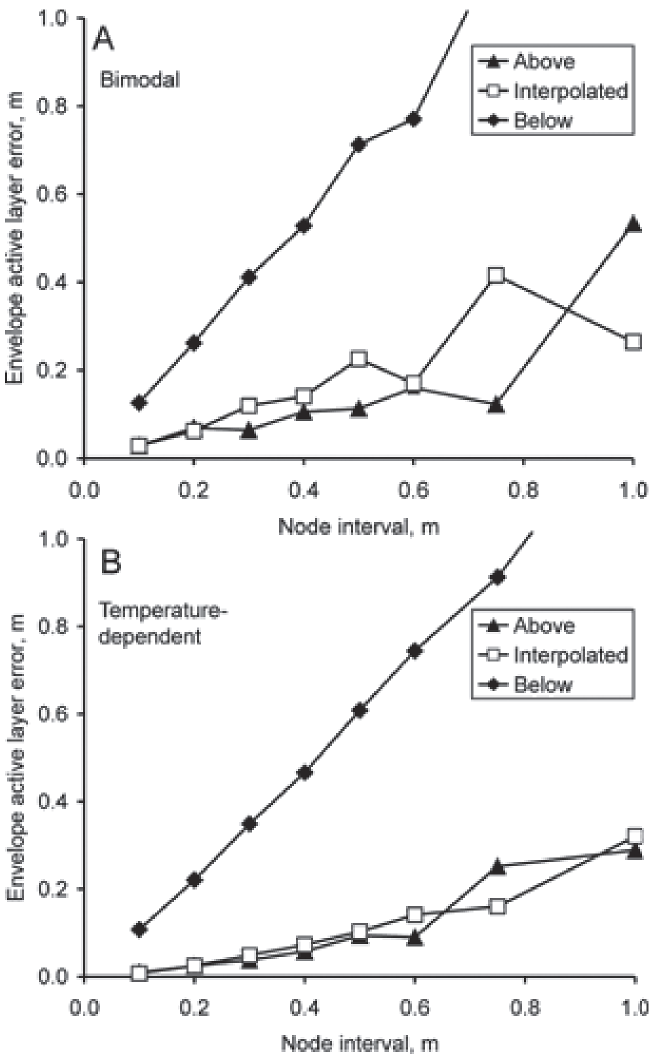

Figure 4. Average error in active layer depth estimated from annual temperature envelopes, as a function of selected node interval. A: simulations with bimodal (frozen/unfrozen) thermal properties and all phase change at 0ºC. B: simulations with temperature dependent thermal properties and unfrozen water.

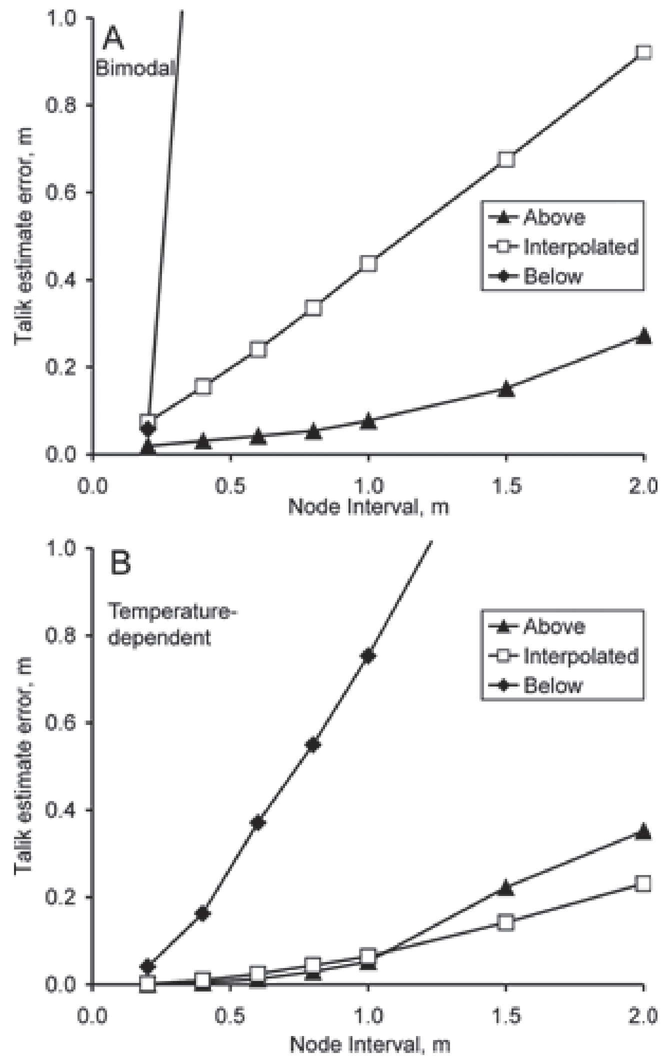

Figure 5. Average errors in estimated talik depth, as a function of selected node interval. A: simulations with bimodal (frozen/unfrozen) thermal properties and all phase change at 0ºC. B: simulations with temperature dependent thermal properties and unfrozen water.

Active layers from temperature envelopes

Figure 4 shows the average error in active layer depth estimated from annual temperature envelopes. These results represent the kinds of estimates that could be obtained using cable temperatures from a data acquisition system, from which a reliable temperature envelope could be derived. Results suggest that the errors in active layer estimates for extrapolation from above is similar to those for instantaneous profiles (Fig. 3), while estimates by extrapolation from below in soils is poor in both soil types (again exceeding the node spacing), and errors in estimates by interpolation are only slightly greater than with estimates by extrapolation from above.

Taliks

Figure 5 shows the average error in talik depth, estimated from instantaneous temperature profiles. Errors are a relatively smooth function of node spacing, due to the more steady thermal conditions within the talik compared to thermal conditions within the active layer. The accuracy of depth estimates by interpolation is similar to that for active layer estimates by instantaneous profiles (Fig. 3), while the error magnitudes when extrapolating from above are much smaller (less than half). For both soil types, extrapolation from below is unreliable, with estimation errors up to nine times the node spacing. This is due to the nearly isothermal conditions present in the permafrost degrading beneath the talik.

Conclusions

Results are summarized in Figure 6, in which the errors presented in Figures 3–5 are expressed as a proportion of the node spacing, shown as averages for all spacings:

1. Extrapolation from above is the most accurate method in all cases, and especially in cases with bimodal thermal properties.

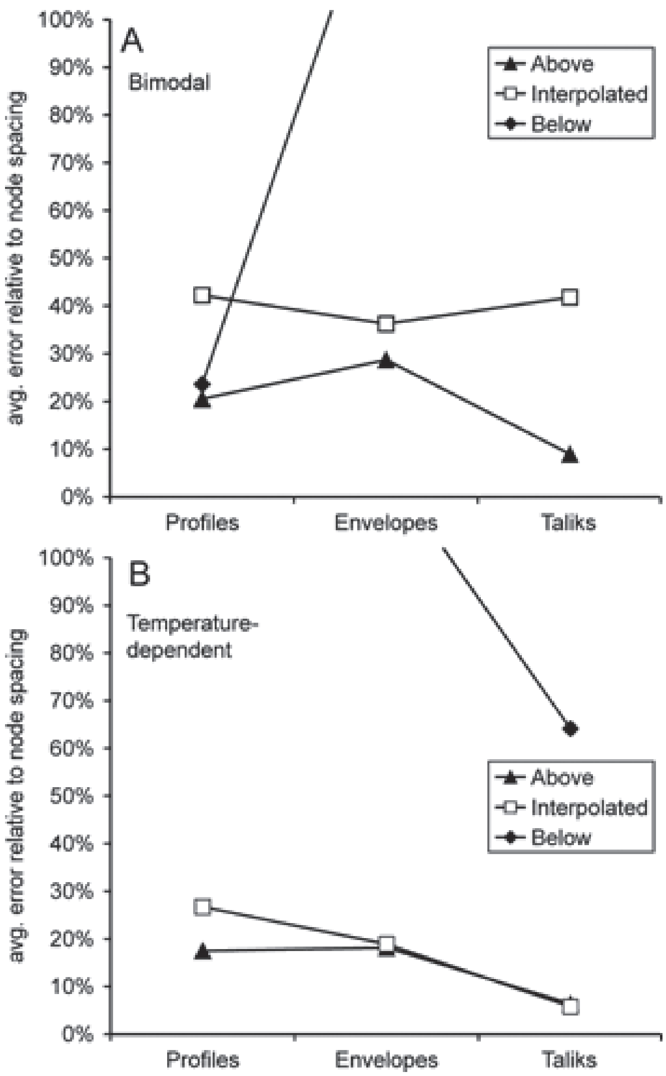

Figure 6. Average active layer/talik depth-estimate errors, expressed as a percentage of the node interval. A: simulations with bimodal (frozen/unfrozen) thermal properties and all phase change at 0ºC. B: simulations with temperature dependent thermal properties and unfrozen water. Results are truncated at 100%, as errors for extrapolation from below approached 900%.

2. For profiles, envelopes, and taliks, soils with bimodal thermal properties (and therefore an abrupt change in gradient at 0ºC), interpolation yields average errors of about 40% of the node spacing.

3. Estimation of active layer thickness from temperature envelopes is less accurate than estimates from profiles. This is likely due to the nature of the envelope data, which combines the effects of the phase transition and of diffusive extinction, yielding a profile that is not as simple to analyze as an instantaneous profile. Given that the average error for all methods exceed 25% of the node spacing when applied to envelope data in soils with bimodal thermal properties, estimates of active layer depth using temperature data from an acquisition system might be improved using sensor thawing indices (Riseborough 2003); alternately, the nearly continuous data would make it possible to select the best instantaneous profiles for estimating the active layer depth, although profiles may not capture the maximum active layer depth.

4. Except for active layer estimates from instantaneous temperature profiles in soils with bimodal thermal properties, extrapolation from below is not a reliable estimation method.

5. Talik depth can be estimated with greater relative precision than active layer depth, as deeper temperature profiles are less influenced by short term perturbations.

The extrapolation results presented here were used without a check to ensure that the 0ºC isotherm estimate was between the bounding sensors. The overall accuracy of active layer or talik estimates could be increased when used in an automated procedure by checking for this condition and reverting to estimation by interpolation where it is not met.

Results for the idealized conditions presented here may be considered a lower limit on the estimation errors investigated, since the precision of modeled temperatures exceeds that of most measurement and recording systems; Spatial and temporal variations in surface thermal conditions and in thermal properties along the soil profile will introduce additional variations not present in the smooth temperature profiles generated by the model.

While the results presented here may be applied to any temperature cable data, they also suggest a cable design strategy for optimizing 0°C isotherm depth estimates. Use of data acquisition systems typically limits the number of sensors to about 10.. Where talik depth or active layer depth is a key parameter in a monitoring program, an optimum cable design would concentrate sensors, with a relatively small spacing, close to the position of the front. A cable design with an extended lead would permit cable repositioning with the evolving thermal regime.

Acknowledgments

The ideas for the analysis presented in this paper developed from conversations with Caroline Duchesne. The comments of the anonymous reviewers were very helpful in improving the quality of the paper.

Abstract

A landscape-geocryological map is considered to be an important basic resource for comprehensive carbon budget studies under the international EU-funded CARBO-North project. The project is aimed at assessing the carbon balance at northern latitudes. The mesoscale and more detailed landscape-geocryological maps were produced for the intensive study sites using an integrated geosystem approach and landscape features indicative of permafrost conditions. The maps actually suggest a model showing spatial patterns of numerous landscape factors responsible for local and regional carbon budgets. The key issue of the mapping technique applied was the development of matrix legends arranged as tables. In general, the structure and content of such tables are variable and depend on study purposes, scale, and environmental conditions of particular areas. Under this study, a mesoscale landscape-geocryological map was produced for the Khoseda–Khard intensive site and a detailed map for the Seida intensive site, both sites located in the forest-tundra life zone.

Keywords: carbon budget; geocryological mapping; landscape; permafrost; zoning.

Introduction

Interannual climate dynamics and the ongoing rise of air temperature in the Arctic induce changes in geocryological conditions: increases in ground temperature and changes in its seasonal dynamics, increases in depth of seasonal thaw, partial degradation of thin permafrost, etc. As the permafrost is an enormous reservoir of organic matter, these changes in its upper layers bear the potential of producing a significant effect on the greenhouse gas balance at northern latitudes. Climate warming and the associated differential settlement of the soil surface can increase the thickness of the seasonally thawed (active) layer. This may substantially change conditions in the upper part of the geological section which, in turn, may lead to changes in drainage patterns and overall regional hydrology. The latter, meanwhile, is one of the major controls on regional carbon balance. In particular, the spatially differential settlement of soil surface may change the ratio of drained to wet areas. It is extremely difficult to forecast the dynamics and scope of such changes. Permafrost degradation is a complicated process associated with numerous feedbacks. Thus, it normally leads to enhancement of wet areas; however, such enhancement causes larger heat losses for the phase transition of water in a seasonal freeze-thaw cycle slowing down the progression of permafrost thaw, and, in some cases, even inducing the formation of new permafrost.

Permafrost is considered a “preserved greenhouse gases reservoir” (Samarkin et al. 1994), while the cryogenic landscapes are deemed a productive environment for this gas generation. The CARBO-North project includes as an important task the development of comprehensive landscape-geocryological maps to be used in the regional carbon budget studies for interpretation, upscaling, modeling, and forecast purposes. While developing the maps, we widely employed a technique related to the use of landscape indicators of permafrost conditions (Armand 1975). This insured common formatting of the maps of different intensive study sites and permitted the mapping of major controls on carbon budgets.

Study Area and Methods

Landscape-geocryological maps were produced for two sites, Khoseda-Khard and Seida (Fig.1).

The Khoseda-Khard site is located at 67°08′N, 59°30′E (center coordinates) and is considered in CARBO-North as a mesoscale intensive study site for assessment of the carbon budget. The site area is about 200 km^2.

Information available in achived databases, analysis of major environmental controls over geocryological conditions at the regional, landscape, and local levels, and results of a field survey we conducted earlier in this area were used for developing a map of the site.

The Seida site is located at 67°03′18″N, 62°56′06″E (center coordinates) and is considered a detailed intensive study site. The mapping area is around 4 km^2. Mapping was performed using satellite images and the results of the field surveys we conducted earlier in adjacent areas.

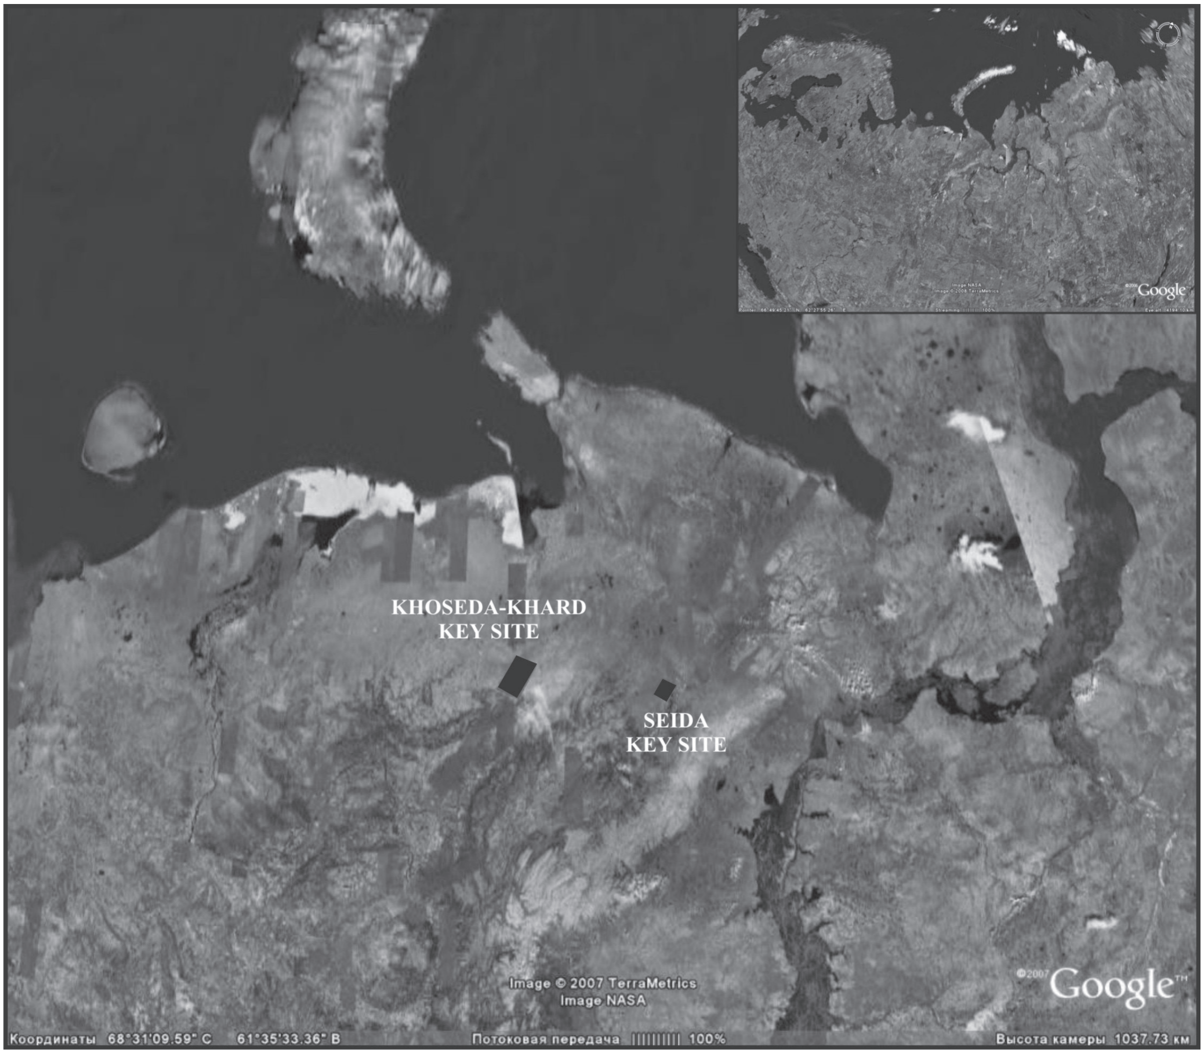

Figure 1. The location map of study sites.

The landscape-geocryological mapping technique we employed has been repeatedly used recently for compiling electronic atlases aimed at the assessment of the environment and human impacts upon it. The technique allows for mapping complex interrelations within the environment, in particular those between soil surface conditions and frozen ground distribution, or between ground lithological composition and temperature.

Accordingly, our landscape-geocryological mapping was based on revealing interrelations between the landscape features on the one hand, and the geological structure and geocryological conditions on the other. Information was summarized in matrix-format tables. Such tables are much more than just a form of data organization. They can serve for the purposes of system analysis, and at the same time they are the main component of map legends (Rivkin et al. 2004). Actually, the matrix schemes are regional geocryological classifications of an area, and accordingly, the GIS maps based on these schemes are spatial models of the classification. The combination of matrix schemes and GIS maps makes it possible to upscale rather accurately upscale point data on soil and vegetation carbon stocks and fluxes. Besides, various gradient and other spatial analyses become possible, as well as the assessment of partitioning of carbon between various landscape components, for example, active layer and permafrost, or permafrost-affected and permafrost-free soils. Moreover, the maps supplied with the matrix schemes are highly valuable for modeling changes in carbon budget induced by the climate change.

Results and Discussion

Mesoscale landscape-geocryological map of the Khoseda-Khard intensive study site

The Khoseda-Khard site is located in the southeastern part of the so-called Bolshezemelskaya Tundra and is stretched out along the Khoseda-Yu River. The vegetation represents a transition from the forest-tundra to the tundra life zone. The site altitudes vary from 60–70 m at the Khoseda-Yu water line to 130–175 m at the interfluve summits.

Most elevated parts of the interfluves represented by ridges and hills are composed of Middle Quaternary ice-marine deposits and dissected by numerous flow paths conveying surface water runoff. These flow paths are 5–100 meters wide and 0.5–3 meters deep. Away from the ridges and hills, the interfluve's surfaces are mostly represented by gentle slopes with altitudes of 90-120 m composed of Middle Quaternary lacustrine-alluvial deposits. This altitudinal level is characterized by large areas of peatlands and lakes.

The Khoseda-Yu River runs from south to north crossing the study site. The river is up to 50-60 m wide and 2–3 m deep with an average flow velocity of 0.8 m s^{-1}. The river valley is up to 30 m deep with steep (10°,-30°) slopes scarred by landslides and gullies. The I, II and III river terraces are clearly distinguishable above the flood plain. Smaller rivers are 5-20 m wide and up to 2 m deep. Their relative cut-in is 5-10 m. In the valleys of these rivers, the first and, less frequently, the second river terrace can be distinguished.

The site is rich in lakes. The lakes are mainly (except for the Neryta lake) shallow with depths of 1-3 m and small in size, less than 200 m across. They are of thermokarst origin and are located at peatlands. Many lakes are gradually draining.

The site location at the transition from tundra to forest-tundra provides for the diversity of plant associations. In a geocryological sense, the area is close to the southern boundary of the permafrost region. A characteristic feature of the area is that the permafrost distribution and temperatures are strongly controlled by landscape factors. Vegetation types and surface conditions are therefore reliable indicators of permafrost distribution. For example, in forest patches with tall understory and in shrub thickets the near-surface permafrost is typically absent, whereas in tundra it occurs at shallow depths. The high indicative value of landscape factors allowed for their use to map geocryological conditions.

The spatial analysis of environmental controls over present geocryological conditions was performed in a matrix format. The geomorphological and geological-genetic conditions of the terrain were plotted against the horizontal axis of the matrix. Identified were 8 successive geomorphological levels, within which 11 more geological-genetic complexes of deposits were distinguished, and within these complexes another 12 typical cryolithological sections were identified (Table 1). This subdivision was performed using the hierarchical approach. First of all, we identified the large geomorphological elements: interfluves and river valleys. After that we considered meso- and micro-relief, drainage, and vegetation type. Finally, the major types of cryological sections as well as exogenetic processes and associated landforms were identified.

The Middle Pleistocene ice-marine deposits of the Rogovaya suite ($gmII^{2-4}$) consist of clay loam and dark gray clay interbedded with layers and lenses of sand and sandy loam with inclusion of pebbles, gravel, and boulders. The Middle Pleistocene lacustrine-alluvial deposits of the Dozmer age ($laII^4$) are made up of loam interbedded with layers and lenses of sand and loamy sand. The Upper Pleistocene deposits of the Kazantsev age ($laIII^1$) are mainly formed by sand interbedded with layers and lenses of loamy sand and loam. All of the above deposits are classified as deposits with low ice content.

The floodplain alluvial deposits (aIV) and the deposits of the first river terrace consist mainly of gravel and pebbles, sand, and loamy sand. The alluvial deposits of the second ($aIII^{3-4}$) and the third ($aIII^{2-3}$) river terraces are made up of loam, loamy sand, and sand.

In peatland areas the bog-lacustrine deposits (lbIII-IV) with a 0.5–5 m thick peat layer overlap the ice-marine and lacustrine-alluvial deposits. When in a frozen state, peat has a high ice content, while the underlying mineral ground, frequently rich in peat admixture, has a medium to high ice content. The bog-lacustrine deposits are distributed at different geomorphological levels. They are not thick (3–7 m), and at each level there are various types of ground underlying these deposits.

On the landscape-geocryological map and in the matrix legend a specific digital code and color are assigned to each of the identified geological-genetic types of deposits and their typical cross-sections.

The landscape and geocryological conditions of the terrain are plotted along the vertical axis of the matrix. With consideration for surface topography, patterned grounds, vegetation, drainage, and depth to ground water, a total of 12 landscape sub-regions were identified:

- Spruce/birch forests and thin forests with dense understory (willow, dwarf birch) on flat plain surfaces and gentle (up to 6°) slopes, irregularly drained.
- Spruce/birch forests and thin forests with dense understory (willow, dwarf birch) on slopes more than 6° steep, well drained.
- Spruce/birch thin and sparse forests with sparse understory on flat plain surfaces and gentle (up to 6°) slopes, well drained.
- Hummocky dwarf-shrub/lichen tundra with patches of spruce/birch thin forests and shrub thickets on slopes more than 6° steep, well drained.
- Dwarf-shrub/moss/lichen tundra with low and medium hummocks on flat plain surfaces and gentle (up to 6°) slopes, well drained.
- Shrub/- and shrub/moss/lichen tundra (willow, dwarf birch up to 1 m high) on flat plain surfaces and gentle (up to 6°) slopes, irregularly drained.
- Willow, rarely dwarf birch thickets (willow up to 2 m and dwarf birch up to 1 m high) with grass/moss/sedge ground cover on flat depressed surfaces, gentle (up to 6°) slopes and along water lines, irregularly or poorly drained.
- Polygonal peatlands with hummocky dwarf-shrub/moss/lichen communities at drained polygon centers and sedge/moss communities in waterlogged dips, thermokarst depressions and subsided sites along thawing ice wedges.
- Palsa peatlands (degrading) with dwarf-shrub/moss/lichen communities on drained palsas and sedge/moss communities in waterlogged thermokarst depressions.
- Sedge/moss fens on depressed flat surfaces.
- Sedge/grass/moss meadows, in places hummocky, on large rivers flood plains, moderately drained.
- Small river and creek valleys with sedge/grass/moss communities on moderately drained flood plains and shrub/-

or dwarf- shrub/grass/moss communities on well drained terrace risers.

The map of a given scale allowed for identifying six types of permafrost sub-regions according to the degrees of permafrost spatial discontinuity:

1. discontinuous (sporadic) permafrost (covering 50%–90% of the area, of which 10%–50% has a permafrost table at 2–10 m depth);
2. massive-island permafrost (covering 20%–50% of the area, of which 10%–50% has a permafrost table at 3–10 m depth);
3. sparse island permafrost (covering <10% of the area, whereas >90% of the area is thawed grounds);
4. thawed ground underlain by the permafrost table at a depth of 3–8 m;
5. thawed ground with pereletoks and new formations of permafrost 1–3 m thick;
6. thawed ground.
7. The mean annual ground temperatures range from >0°C in the forested areas in the south of the site under survey to –1.5°C in the mineral tundra soil and polygonal peatlands in the north of the site.

Table 1. Geological-genetic complexes and cryolithological sections of Quaternary deposits at the Khoseda-Khard intensive study site.

Geomorphological level	Geological-genetic complex of deposits			Cryolithological section
Rogovskaya ice-marine plain	Bog-lacustrine	Late Pleistocene-Holocene	lb III-IV	One-to-three meters of peat underlain by loamy sand and sand. Ground is either thawed, or permanently frozen. Ice content in the frozen ground is medium or high in the upper 2-4 m layer and low in the deeper layers.
		Middle Pleistocen	gm II $^{2-4}$	Loam with layers and lenses of sand and loamy sand. Ground is either thawed, or frozen with low ice content.
Dozmer lacustrine-alluvial plain	Ice-marine	Late Pleistocene-Holocene	lb III-IV	Two-to-four meters of peat underlain by the interbedded loam, sandy loam and sand. Ground is either thawed, or permanently frozen. Ice content in the frozen ground is medium or high in the upper 3-7 m layer and low in the deeper layers.
	Bog-lacustrine	Middle Pleistocene	la II ^{4}	Loam with layers and lenses of sand and loamy sand partly overlain by a peat layer up to 0.5 m. Ground is either thawed, or permanently frozen with medium or low ice content.
Kazantsev lacustrine-alluvial plain	Lacustrine-alluvial	Late Pleistocene-Holocene	lb III-IV	Three-to five meters of peat underlain by interbedded sand, loamy sand and loam. Ground is either thawed or permanently frozen. Ice content in the frozen ground is medium to high in the upper 3-7-m layer and low in the deeper layers.
	Bog-lacustrine	Late Pleistocene	la III ^{1}	Sand with layers and lenses of sandy loam and loam partly overlain by a peat layer up to 0.5 m thick. Ground is thawed or permanently frozen with low ice content.
III river terrace	Alluvial	Late Pleistocene	a III $^{2-2}$	One-meter thick peat layer underlain by interbedded sand, loamy sand and loam. Ground is either thawed, or permanently frozen. Ice content in the frozen ground is medium in the upper 1-2 m layer and low in the deeper layers.
II river terrace	Bog-lacustrine	Late Pleistocene-Holocene	lb III-IV	One-meter thick peat layer underlain by interbedded sand, loamy sand and loam. Ground is either thawed, or permanently frozen. Ice content in the frozen ground is medium in the upper 1-2 m layer and low in the deeper layers.
	Alluvial	Late Pleistocene	a III $^{3-4}$	Sand with layers and lenses of loamy sand and loam. Ground is either thawed, or permanently frozen with low ice content.
I river terrace		Pleistocene-Holocene	a III-IV	Loam underlain by sand. Ground is either thawed, or permanently frozen with low ice content.
Floodplain and I river terrace (non-denudative)				Loam underlain by sand. Ground is either thawed, or permanently frozen with low ice content.
Floodplain	Alluvial	Holocene	a IV	Thawed sand underlain by thawed loam.

On the produced map and in the attached matrix legend, alphanumeric codes are assigned to combinations of landscape features, permafrost sub-regions, and ground temperatures; combinations are hatched differently on the map.

Within the identified permafrost sub-regions there are thus unique combinations of geological and physiographic factors: climatic, edaphic, botanical, lithologic, geomorphologic, hydrologic, hydro-geologic, and others, i.e. the entire spectrum of factors responsible for geocryological conditions. By combining the identified landscape and geocryological sub-regions (the vertical axis of the matrix) and the typical geological-genetic complexes (the horizontal axis of the matrix) we succeeded in identifying 64 typological areas at the Khoseda-Khard site.

The fact that the site is located at the transition between the tundra and the forest-tundra provides for diversity and contrast of the surface conditions, which in its turn results in spatial and temporal instability of seasonal thaw and freezing depths. The shallowest thaw depths, those of 0.3–0.8 m, are characteristic for peatlands. In mineral grounds at well drained interfluves, depths of seasonal thaw vary from 0.6 to 2.0 m depending on a ground lithological composition. Depths of seasonal thaw in loamy soils rich in peat admixture are 0.4–1.0 m, and in the loamy sand and sand deposits 0.8–2.0 m.

Cryogenic processes and landforms are highly characteristic of the area; they differ depending on the geocryological conditions of particular sites: composition, structure, physical properties, and temperature range of frozen or thawed ground. The most common are frost mounds of various shapes and sizes formed as a result of multi-annual and seasonal freezing of the ground. The seasonally thawed layer in the northern part of the site is associated with the patterned ground: non-sorted circles and hummocks. Cryogenic (frost) cracking occurs both in peatlands and mineral soils and is associated with large-block surfaces and residual polygonal relief. Ancient thermokarst lakes are numerous in peatlands. Present-day thermokarst manifests itself in the form of melting of repeatedly-wedge ice. Erosion, including thermal erosion is of limited occurrence and is confined to river valleys and thawing ice wedges with erosive gullies developing along the latter. Landslide accumulation areas can be found at the foot of steep slopes of river valleys. The ongoing paludification is limited to peatlands and wet interfluve depressions.

Detailed landscape-geocryological map of the Seida intensive study site

The site is located on the left bank of the Sediakha River, 6 km west of the Seida village. The site is the floor of a large, drained, ancient lake currently occupied by a peatland and scarred with water runoff paths and creek valleys. The perimeter of the lake basin is framed by a glacier spur with altitudes of 120–130 m. The site has a block-polygonal relief; well drained elevated blocks with shrub/moss/lichen vegetation are separated by erosive gullies differing in depth and width and overgrown by shrubs. The near-surface permafrost at the site can be subdivided into two sub-regions: discontinuous (sporadic) and massive-island. In peatlands and in the relatively elevated areas occupied by tundra with frost boils or low hummocks, the permafrost table is located directly under the active layer. In wet depressions, erosive gullies, at footslopes, and on smooth shrubby hillslopes the permafrost table is located at depths of 5 or more meters. Over 10 m deep continuous thawed ground is located under the lakes and in the large wet depressions with open water bodies.

The Seida site map indicates comprehensive information on geocryological features of the upper ground layers (down to 10 m depth). Geocryological mapping was performed on the basis of landscape subdivision of the area with the use of high-resolution satellite images.

Similarly to the mesoscale mapping of the Khoseda-Khard site, the spatial analysis of the environmental factors responsible for present-day geocryological conditions was performed in the matrix format. The structure of the detailed mapping matrix is, to a great extent, similar to that developed for the mesoscale mapping. Such consistency allows one to better correlate different types of terrain when working with maps of various scales and detail. Besides, it provides for more accurate upscaling of gas fluxes determined and estimated at various scales.

The geomorphologic and geological-genetic conditions of the area are plotted along the horizontal axis of the matrix. The whole site is located within one (non-segmented) geomorphological level (glaciofluvial lowland and II river terrace), within which are distinguished 3 geological-genetic complexes of deposits, within which another 4 typical cryolithological sections are identified (Table 2).

The landscape and geocryological conditions of the area are plotted against the vertical axis of the matrix. With consideration for surface topography, vegetation, depth to ground water, permafrost temperature and other characteristics, and thickness of seasonally frozen or seasonally thawed layers a total of 7 landscape sub-regions were identified:

- Dwarf-shrub/moss/lichen tundra, moderately drained, with small hummocks, occasionally with frost boils, groundwater at a depth of 1–3 m, discontinuous permafrost (occurs at 50%–90% of the area, and at 10%–50% of the area the permafrost table is at a depth of 3–5 m);
- Shrub/moss/lichen tundra, shrubs up to 1 m high, medium and large hummocks, irregularly drained, ground water at 0–1 m, permafrost surface at a depth of 3–6 m;
- Peatland, irregularly drained, with dwarf-shrub/moss/lichen communities on mounds and moss/sedge in hollows, ground water at 0–0.5 m, discontinuous permafrost (occurs at 70%–90% of the area, and at 10%–30% of the area the permafrost table is at a depth of 2–5 m);
- Palsa peatland, strongly eroded, with dwarf-shrub/moss/lichen tundra on palsas and sedge/moss communities in inter-palsa depressions, ground water at 0–0.5 m, massive-island permafrost (covering 50% of the area and within 50% of that area the permafrost surface is at a depth of 2–10 m);
- Sedge/moss mire with residual palsas occupied with dwarf shrub/moss/lichen communities, ground water at 0–0.3

Table 2.Geological-genetic complex of deposits and cryolithological sections of Quaternary deposits at the Seida intensive study site.

Geomorphological level	Glaciofluvial lowland and II river terrace			
Geological-genetic complex of deposits and their age	alluvial, glaciofluvial	bog-lacustrine		alluvial deposits of river channels and small water channels
	late Pleistocene	late Pleistocene-Holocene		Holocene
	a,fg III^2	lbIII-IV		alV
Cryolithological section	thawed or frozen sand and loamy sand with pebble interbeds and low ice content	peat layer up to 1 m thick underlain by interbedded sand, loamy sand, and loam, thawed grounds or frozen grounds with a low ice content below a depth of 1-3 m	peat later from 1 to 4 m thick underlain by interbedded sand and loamy sand, rarely loam, frozen with medium or high ice content below a depth of 4 m	peat layer up to 1 m thick underlain by interbedded sand, loamy sand, and pebble

m, island permafrost (covering 20%–30% of the area and within area 70%–80% the depth of the permafrost table is 5–10 m);

- Water lines and bogged depressions with herb/sedge/moss and shrubs of varying coverage up to 2 m high, poorly drained, ground water at 0–1 m, thawed ground with possible pereletoks and new formations of permafrost;
- Creek valleys, irregularly drained, herb/sedge/moss communities, occasionally willow thickets up to 2 m high, ground water at 0–1 m, thawed grounds.

By combining the identified landscape sub-regions and the typical sections of geological-genetic complexes (the horizontal axis of the matrix) we managed to identify 8 typological areas at the Seida site, which in its turn allows for mapping the whole spectrum of the existing geocryological and landscape conditions.

The landscape-geocryological maps of the two intensive sites differ in the degree of detail. Variability within map polygons in permafrost conditions, ground temperatures, soil, vegetation, and degree of drainage is much higher on the Khoseda-Khard than on the Seida map. Attribution of a polygon to the particular typological area on the Khoseda-Khard map is based on generalization, so that for the local-level carbon budget assessment further detailization of the map is needed. The latter, in a large degree, can be done using the typological units defined and deliniated on the mesoscale map. On the contrary, on the detailed map of the Seida site, characteristics of the ground including ground temperatures, as well as degrees of drainage, soil and plant communities defined in the legend precisely correspond to each polygon shown on the map. This makes it possible to accurately enough determine landscape-geocryological features necessary to estimate and interprete local carbon budgets.

It should be stressed once again that the landscape-geocryological units identified during the mesoscale mapping, if necessary for carbon studies, can be subjected to further sequential detailization in the course of detailed field mapping. From the technical viewpoint it can be done in a form of sequential detailization of the spatial analysis matrix. It is important to keep the detailed-scale matrix in compliance with the medium-scale matrix, so that the detailed-scale matrix r would suggest more detail within the mapping units and, correspondingly, map polygons which were defined on the medium-scale map.

Conclusions

The matrix schemes of landscape-geocryological subdivision developed under the CARBO-North project represent regional classifications of landscape and geocryological conditions. They reflect the system of environmental controls over the geocryological situation, as well as major controls over carbon budget components at the studied areas. On the one hand, sequential detailed geocryological mapping of an area allows for sequential detailed assessment of the carbon budget components and, on the other hand, makes it possible to integrate and upscale the detailed carbon data to assess a regional carbon budget using mesoscale cartographic models.

Abstract

The data on methane content and pattern of its distribution across permafrost of different age and origin on late Cenozoic permafrost of Northeastern Arctic are summarized. We have found that methane is present in the epycryogenic Holocene and early Pleistocene layers and is absent in the syncryogenic late Pleistocene ice complex. Incubation under anaerobic conditions triggered the process of methane formation in Holocene and early Pleistocene layers and did not initiate it in the ice complex sediments. Based on the analysis of microbial community, organic matter, and potential for methane formation in various genetic types of permafrost sediments, we concluded that ice complex sediments, and to a lesser extent than epycryogenic ones, have the potential to produce methane in consequence of permafrost degradation.

Keywords*:* permafrost; methane production; methanogenic arhaea; isotopic composition.

Introduction

In the framework of global change studies in the last decades, attention has been given to CO_2 and CH_4 emission from high-latitude ecosystems (Whalen & Reeburgh 1990, Christensen, 1993, Fyodorov-Davydov 1998, Reeburgh et al. 1998, Worthy et al. 2000, Zamolodchikov & Fyodorov-Davydov 2004, Wagner et al. 2003, van Huissteden et al. 2005). However, significant amounts of these greenhouse gases have been isolated from biogeochemical cycling and conserved in permafrost (Rivkina et al. 1992,) together with organic matter (Schirrmeister et al. 2002, Kholodov et al. 2004) and viable anaerobic microorganisms (Rivkina et al. 1998, Gilichinsky 2002). Thus, permafrost is a huge deposit and potentially, a large source of old organic carbon. It is important to assess the consequences of permafrost degradation because at least four pathways of carbon moblilization are influenced by permafrost thaw:

1. The reservoir of carbon dioxide and methane bound in upper permafrost horizons that, unlike the deep high-pressure gas hydrates, could be easily liberated in the case of thawing in the polar regions.

2. The paleomicrobial community of viable methanogens expected to retain activity and be anew involved in biogeochemical processes, including generation of greenhouse gases (Rivkina et al. 2006).

3. Labile organic matter conserved in permafrost will be consumed by these microorganisms as an energy source for greenhouse gas production.

4. Increased production of methane in the active zone. This is in fact observed on northeastern Arctic exposures under present conditions with associated release methane, which is of similar magnitude to the direct production in Arctic tundra (Rivkina et al. 2001).

Recent studies have provided a new impetus to such discussion, as they forecast high gas emission in response to permafrost degradation (Walter et al. 2006, Zimov et al. 2006). These papers, describing the flux of greenhouse gases from thermokarst ponds, have stimulated significant public and scientific interest. Quantification of methane release from thawing permafrost is of prime importance in climate research.

Our objective is to clearly recognize the concentration and features of distribution of carbon sources in permafrost, based on its history (Sher 1974, Schiermeister et al. 2002). The present paper, based on the analysis of microbial community, organic matter and content of CO_2 and CH_4, as well as on the possibility of methane formation and oxidation in various genetic types of permafrost sediments, will discuss the potential of greenhouse gases emission to the atmosphere in response to permafrost degradation and specifically, the late Pleistocene Icy Complex thawing upon which most activities are now focused.

Study Area and Object of Investigation

Investigations were carried out in continuous permafrost area in tundra and forest tundra zone landscapes on north-eastern Arctic coastal lowlands (125–162°E, 68–72°N), located between the Lena and Kolyma River deltas (Fig. 1). Sites were located outside the oil and gas basins, and were characterized by different Quaternary deposits (early Pleistocene to Holocene) and permafrost of both syn- and epicryogenic origin (Kaplina et al. 1984, Schirrmeister et al. 2002). Permafrost here had begun to form 3 million years ago and until now has not been deeply affected by global thawing.

Studies were carried out down to 100 m depths on fine dispersed late Cenozoic stratotypes, which have been well described by many authors (Kaplina et al. 1981, 1988, Sher et al. 2005) on the bases of radiocarbon, palynological, paleontological, paleomagnetic, cryolithological, and physicochemical data.

Distribution, thickness and area of the following strata

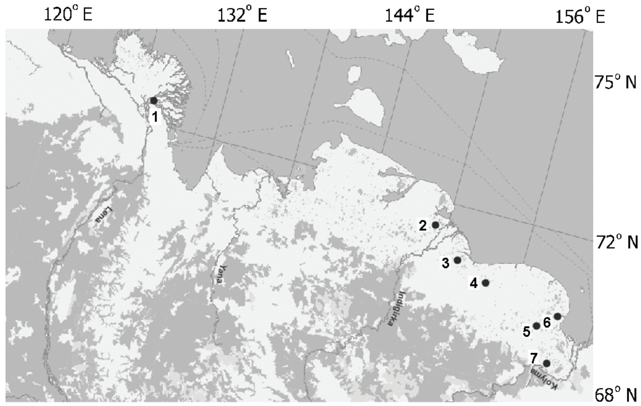

Figure 1. Arctic study sites: 1–Bykovskii Peninsula, Lena River; 2–Low basin of Indigirka River; 3– Khomus-Yuryakh River; 4–Alazeya River; 5–Chukochya River; 6– East Siberian Sea coast; 7–Khalarchinskaya tundra sandy plain.

were calculated, tested for microorganisms, organic matter, CO_2, and CH_4 presence:

- Thomus-Yar Suite, the lowermost (15–20 m below sea level) sediments in the middle Chukochya and Alazeya Rivers (Kolyma lowland) dated back to the second half of the Pliocene, 2–3 million years.
- Overlying Olerian Suite, the stratotype of late Pliocene.
- Early Pleistocene age (1.8–0.6 million years). The upper part of the suite is represented by epicryogenic horizons with pseudomorphoses, and the lower one, by syncryogenic layers.
- Middle Pleistocene syncryogenic sediments and ice wedges belong to buried Icy Complex, named as Jukagir Suite on Cape Svyatoy Nos (Laptev Sea coast), Allaikha Suite on the left channel inflow of Indigirka River, and Maastakh Suite on the right bank of the middle Chukochya River.
- Predominantly syncryogenic middle to upper Pleistocene cross-sections on Bolshoy Homus-Yuryah River (Kolyma lowland): three Ice Complex units with interbedded epicryogenic horizons. Age of deposits varied from >50 ka in the late Pleistocene Ice Complex to 200–600 ka in the middle Pleistocene.
- Marine sediments of Kon'kovaya Suite (East Siberian Sea coast), frozen after sea level dropped at the end of the middle Pleistocene 120 ka ago.
- Late Pleistocene (10–60 ka old) syncryogenic Ice Complex deposits known as Edoma Suite that compose the upper part of cross sections of remains of a late Pleistocene accumulative plane between Lena and Kolyma Rivers.
- Late Pleistocene epigenetically frozen river bed sands of Khalerchinskaya tundra region on the left bank of lower Kolyma River, overlain by Holocene eolian sands.
- Holocene (6–8 ka) syncryogenic alluvial deposits of water meadows on the modern flood-lands and epicryogenic alas horizon and "covering" layer on the top of the Icy Complex, formed by refreezing of the sediments that have melted and drained.

Methods

The data presented are based on 2000 tested samples. Thirty cm-long permafrost cores (diameter 68–107mm) were sampled from boreholes (step-interval 1 m). The strict protocols for drilling and the subsequent handling of cores are designed to ensure uncontaminated material. For microbiological studies the cores were split into c. 5-cm long segments, placed into sterile boxes or bags, stored in the field within a hole in the permafrost at a natural temperature of -10°C, and transported frozen to the laboratory.

Gas samples were collected in the field by degassing 50 g of frozen cores in a 150-mL syringe under a nitrogen atmosphere (Alperin & Reeburgh 1985). The gas mixture was then transferred through a needle to the rubber septa sealed vials filled with salt water. At that point, brine was substituted by gas with the excess water flowing out through the second needle. Gas samples were kept in the vials until further analysis in the lab. CH_4 and CO_2 concentrations were measured using KhPM gas chromatograph (Russia) equipped with katharometer (for carbon dioxide) and hydrogen-flame ionization detector (for methane). Hydrogen was used as a carrier gas in both cases. The same samples were analyzed for $\delta^{13}C$ methane and carbon dioxide using GC Combustion Thermo Finnigan interface and Delta XL mass spectrometer (Germany). To estimate methanogenesis, samples were incubated for 3 weeks at temperatures -16.5, -10, -5, -1.8, and 5°C as described by Rivkina et al. (2007). At the end of the incubation, newly formed radioactive CH_4 was removed from the experimental vials by an air flow (50 ml/min). It was passed through a drexel bottle with a solution of 200 g/l NaCl and 1N KOH and combusted to $^{14}CO_2$ at 700–800°C with cobalt oxide as a catalyst. At the final stage $^{14}CH_4$, oxidized to $^{14}CO_2$, was absorbed in the vial with a mixture of 2 ml β-phenylethylamine and 10 ml of Universal LSC cocktail (Sigma). Vials were counted on an LS 5000 TD liquid scintillation counter (Beckman). Archaea were cultivated according the Hungate anaerobic technique (1969).

The total organic matter was estimated by wet and dry incineration methods. Redox potential was measured in the field immediately after melting, using an "Ecotest-120" (Russia) potentiometer with a platinum electrode and a silver chloride electrode as reference.

Results

Methane and carbon dioxide content and distribution

Unlike CO_2, which is found in all layers below the permafrost table (in various concentrations up to 20 ml of gas per 1 kg of frozen ground), CH_4 shows a distinct and alternating pattern with depth. In a generalized geological cross-section, in which all the geological layers exist in chronological order, CH_4-containing layers would be sandwiched between layers free of methane (Fig. 2). The CH_4 concentration (0.4 to 30.0 ml/kg) does not appear to be correlated to any textural or chemical characteristics of the sediments, age, or the depth of burial. Methane is found primarily on a present-day floodplain bog, in the "covering" layer, alas horizons, marine deposits, late Pliocene-early Pleistocene and Pliocene suites. The lowest concentrations of CH_4 (<0.01 ml/kg) are present in modern alluvial plains in virtually all the river valleys of the area, in Holocene eolian and late Pleistocene river-bed sands, and in the mid and late Pleistocene Icy Complexes in different locations in the region.

For at least several hundreds of thousands years, methane has not diffused from the methane-rich layers into adjacent layers, which are devoid of methane, which implies that there is negligible diffusion of methane in the permafrost under both present and past conditions. We can estimate an upper limit on the diffusion of methane by using the profile shown in Fig. 2 (sites 4 and 5). The methane profile in sediments that are 0.6 to 3 million years old retain structure over length scales of about 3 m. The relationship between time (T), and distance diffused (x), is given by $T = x^2/D$, where D is the diffusion coefficient. From this relationship we calculate that D must be less than 10^{-13} m^2/s; i.e., the upper limit on the diffusion of methane through permafrost is surprisingly low.

Evidence from the West Siberian natural gas fields and gas-hydrate bearing fields in Mackenzie Delta (Dallimore & Colett 1995) further supports the conclusion that methane is in a bound form and not able to diffuse through the near-surface fine dispersed frozen sediments with negligible lithostatic pressure. It suggests that the methane is held in a clathrate form within the sediments (Rivkina et al. 2001).

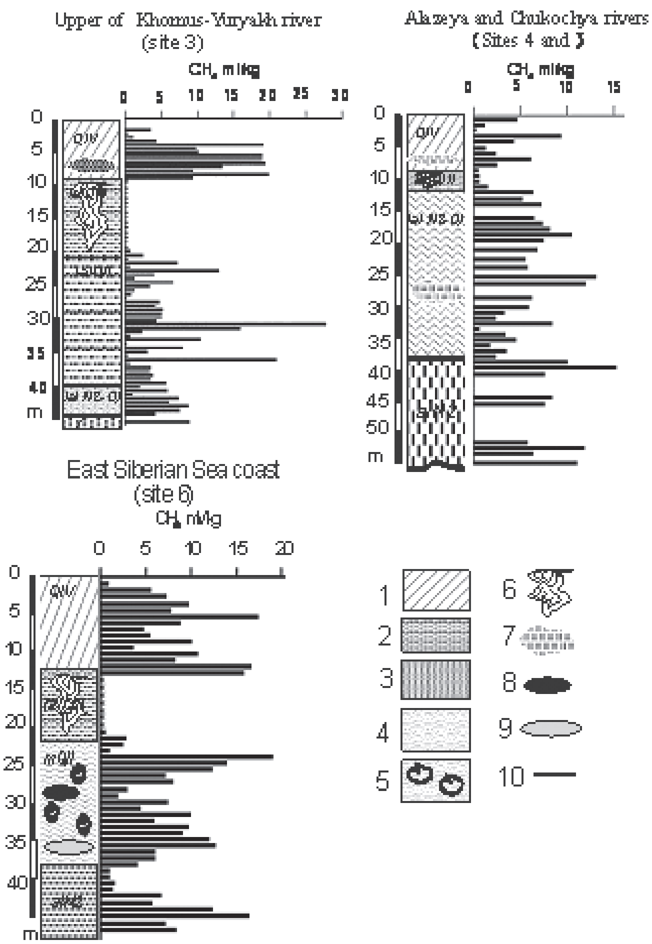

Figure 2. Methane content in permafrost: 1–loam, 2–sandy loam, 3–sand, 4–loamy sands, 5–marine sediments, 6–ice wedges, 7–peat, 8–methane hydrate, 9–lenses of cryopegs, and 10–methane concentration.

One possible way to reconcile the methane hydrate formation at low pressures with the theoretical requirement for stability only at high pressures is to assume that, within the pore spaces of the permafrost, high pressures are created by the freezing process and that it is within these zones of high pressure that the methane hydrate is located. The matrix formed by the sediment grains in permafrost may be crucial to the formation of these intrapore high-pressure zones. In the pore spaces, methane concentration is possibly much higher than it was measured in these samples. The possibility that methane-hydrate may exist in fine-grained sediments of the upper permafrost horizons was confirmed experimentally (Ershov et al. 1991, Chuvilin et al. 2005).

However, strong diffusion of methane from below was observed if the borehole crossed the fine dispersed sediments and reached the pebbles horizon (Fig. 3). Despite the fact that methane content in fine dispersed sands and sandy loams did not differ from typical value, the methane concentration in the borehole gas phase reached 90%. It means that methane in the borehole came from a different source (e.g., from a deeper strata). The same situation is often obtained if the borehole reached CH_4-lenses buried in near surface marine sediments (Fig. 2, site 6).

From the isotopic composition of C-CH_4 (Fig. 4) CH_4-containing layers can be separated into two groups: a main group containing horizons of different origin and age, late Pliocene to Holocene, with $\delta^{13}C$ values ranging -64 to -80 per mil and a minor group represented by mid Pleistocene epicryogenic soils with $\delta\,^{13}C$ value varying 90 to 100 per mil.

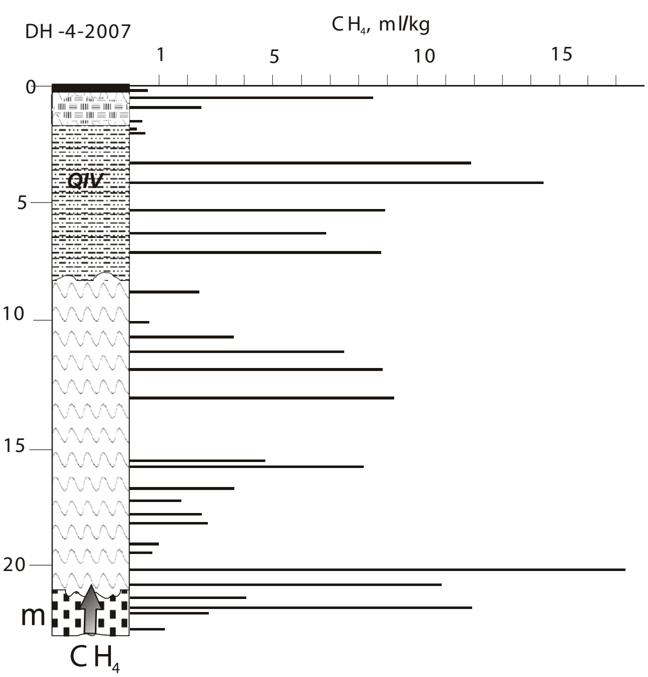

Figure 3. Methane entry in borehole from pebble horizon.

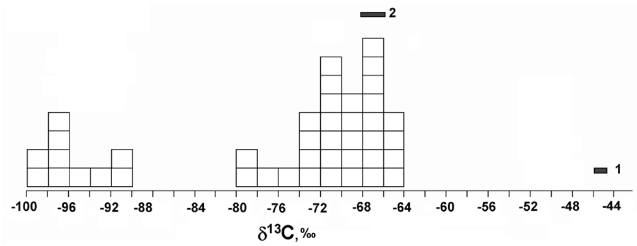

Figure 4. δ [13]C of methane from permafrost. 1–atmospheric methane, 2–methane from gas fields, 3–methane hydrate from permafrost, Mackenzie River delta (Dallimore et al. 1995)

The isotopic composition of methane produced by methanogenic bacteria in natural ecosystems ranges from -50 to -70‰, while abiogenic methane is substantially more enriched in ^{13}C, with values ranging from -45 to -50‰ (Fig. 4). The isotopic composition of CH_4 carbon in permafrost (δ ^{13}C -64 to -99‰) confirms its biological origin and, along with discrete bedding, suggests *in situ* formation of this biogenic gas. The extremely low value of δ ^{13}C methane in some samples (-90 to -99‰) allows us to conclude that CH_4 mainly formed as a result of CO_2 reduction, and a portion of this methane could be formed at subzero temperatures, which was accompanied by significant fractionating of carbon isotopes.

Permafrost also contains viable methanogenic bacteria, but only in epigenetically frozen sediments, and not in the eastern Arctic sincryogenic Icy Complexes. In contrast, viable methanotrophic (methane-oxidizing) psychrophilic bacteria are present in both, epi- and syngenetically frozen layers (Khmelenina et al. 2002).

Incubation of thawed permafrost samples in anaerobic conditions with CO_2+ H_2 showed methanogenic activity in Holocene and late Pliocene-early Pleistocene epicryogenic sediments only. In the samples of Icy Complex this process was not observed (Fig. 5). At the same time, methanotrophic bacteria were able to oxidize and assimilate methane in samples from both, epi- and syncryogenic horizons with the maximum rate of methane oxidation was observed at permafrost table (Khmelenina et al. 2002).

The content of total organic carbon in epicryogenic layers and Icy Complex is similar and varied 1.5–2 to 5% (Fig. 6). But for all that the Icy Complex contains more labile organic matter than epicryogenic sediments: range of ulmification is 15 and 20%, respectively (Kholodov et al. 2006).

Discussion

Greenhouse gases of biological origin excluded during frozen state from biogeochemical turnover are a variety of geogases inherent to cryolithosphere only. Unlike the deep high-pressure gas hydrates, this reservoir of ancient biogeogases in the upper horizons of the cryolithosphere could be easily liberated into the atmosphere and reinvolved in the present-day turnover, should the permafrost degrade as a result of warming. However, this reservoir of organic carbon and methane has been very poorly quantified. Recent research has shown that considerable variation exists in the

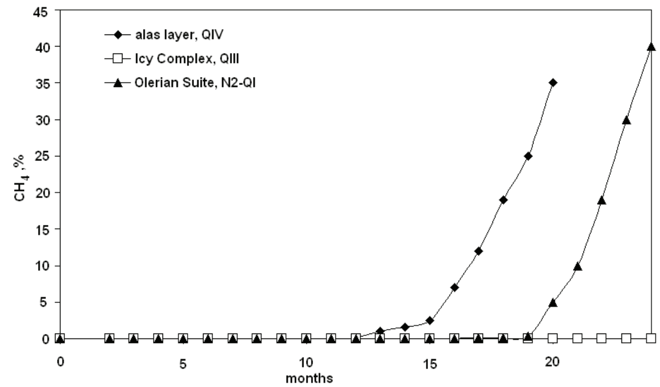

Figure 5. Increase of methane concentration (percentage by volume) in headspace of jars with different permafrost sediments incubated at 22°C in anaerobic condition

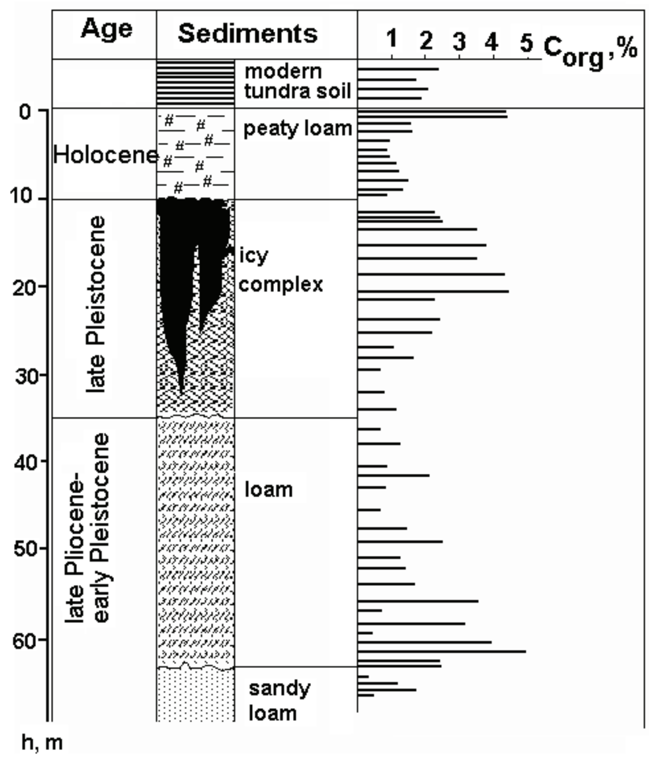

Figure 6. Content of organic carbon in late Cenozoic frozen suites (sites 4 and 5, Figs.1, 2).

amount of methane stored in frozen deposits (Rivkina et al. 2007). This strongly affects estimates of the amount of greenhouse gases that may be released from these deposits upon warming, and forecasting the contribution of these gases to atmosphere. To answer the question, does the release of bound methane and carbon dioxide and activation of CH_4 and CO_2 formation lead to dramatic effects on climate, it is necessary to understand the response of permafrost to climate warming in the past. The Holocene optimum, which was accompanied by widespread permafrost degradation, can be used as models of future warming.

Methane content in the Earth's atmosphere during the Pleistocene and Holocene was affected by the climate changes, varying between 0.35 to 0.7 ppm, reaching the maximum concentrations during optima and minimum in cryochrones. This could be demonstrated by the high methane content in alas layers, formed during the Holocene optimum. Nevertheless, permafrost thawing during the Holocene optimum, which destroyed at least half of the Icy Complex in the eastern Arctic, did not lead to dramatic warming of air temperatures, probably because methane generation took place simultaneously with methane oxidation, and smoothly gave way to new cooling and refreezing of thawed sediments. Anthropogenic effects became more prominent during the last 270 years. During this time, atmospheric methane content has increased sharply to 1.8 ppm, independently of century cryo- and thermochrones.

Our data established several important findings:

1. Methane is present in the epicryogenic Holocene and late Pliocene-early Pleistocene sediments and is absent in the late Pleistocene Icy Complex.

2. Incubated under anaerobic conditions, Holocene and late Pliocene-early Pleistocene sediments, but not sediments of the Icy Complex, exhibited methane formation.

3. Permafrost contains viable paleomicroorganisms, including methane-producing archaea. Nevertheless, viable methanogenic bacteria were isolated from epicryogenic layers only, and never found in Icy Complexes.

4. The isotopic composition of CH_4 carbon in permafrost confirms its biological origin as a result of CO_2 reduction.

On the basis of these findings we can conclude that climate warming and, as a consequence, permafrost thawing, undoubtedly trigger biological activity, including the microorganisms of the carbon cycle. In this case the methane content, microbial community, organic matter, and methane production, show that Icy Complex have less potential as a methane producer than epicryogenic sediments. Thawing of the Icy Complex will not add methane to the atmosphere because 1) the Icy Complex does not contain bound methane, and 2) the Icy Complex does not contain methanogenic bacteria. An additional CH_4 flux is possible also in cases when the talik zone under thermokarst lakes penetrates through the Icy Complex and reaches the underlying methane-containing horizons (as shown on Fig. 3).

We calculated the possible additional greenhouse gases flux to atmosphere in the case of thawing 50-m thick CO_2 and CH_4-containing epicriogenic sediments under square 1 km^2. The sum of C (CO_2+CH_4) store in such volume is ~ 150 tons (without calculation of possible methane oxidation or production). Even the amount is not very significant; this flux of biogeogases bound in permafrost to atmosphere has to be taken into consideration even now. For example, the average abrasion rate of the Arctic coast consisting of frozen sediments is 3 m/year. Destruction of each kilometer of coast 25 m high is accompanied by the release of 3 tons of methane and carbon dioxide. Given the minimal length of the Arctic coastline, the total quantity of C (CO_2+CH_4) being annually released into the atmosphere today is 12 thousand tons. The same order of gases, likely due to the coastal abrasion, came from the river-banks and lakesides in the cryolithozone.

The other way is emission to atmosphere of the gases newly formed in thawed permafrost. In recent years, methanogenic archaea have been isolated from permanently cold lake and marine sediments (Franzmann et al. 1997; Von Klein et al. 2002; Kendall et al. 2007), as well as culture-independent methods, and have demonstrated that the active layer of arctic soils is a natural habitat of a diverse archaeal community (Ganzert et al. 2007). Even though there is limited data regarding microbial processes in thawed permafrost sediments, we can forecast that microbial activity in thawed layers and themokarst lakes is increasing, but not more than in the existing lakes and seasonally thawing soils.

Conclusion

One can expect that due to permafrost thawing and the accessibility of organic matter, the paleomicrobial community would become involved in the biogeochemical processes, including production of greenhouse gases. The ultimate goal of the current investigation is to estimate the sum effect of these processes, taking into account their outcomes in the past optima.

Abstract

In many high mountain regions, warming of perennially frozen ground in both coarse debris and rock walls has a major influence on slope stability. In this context, indications of destabilizing active rock glaciers, such as high horizontal velocities (up to 4 ma^{-1}), front advance rates of up to 4 ma^{-1}, and development of crevasse-like cracks (up to 14 m deep), have been documented and monitored in the Alps for a few years. Beside the limited knowledge of rock glacier dynamics, our principle hypothesis is that the primary factors controlling the development of cracks and the destabilization of rock glacier tongues are the rheological properties of warming ice. In addition, we postulate that hydrological effects of unfrozen water within the active layer, the permafrost body, or at its base may contribute to the initiation of the slide-like mass wasting.

Keywords: European Alps; kinematics; rock glacier; slope destabilization.

Introduction

In the context of recent climatic changes and their impact on the cryosphere, high-mountain environments play a key role due to their sensitivity to thermal changes. The indicative role of rock glaciers in these geosystems was emphasized only recently (e.g., Harris & Haeberli 2003, Haeberli et al. 2006), but was up to now mainly restricted to temperature variations within the permafrost body and variations in active layer thickness. Within the last decade, an increasing number of studies monitored and quantified the creep behavior of rock glaciers in the European Alps and observed increasing surface displacements since the 1990s (Schneider & Schneider 2001, Ikeda et al. 2003, Lambiel & Delaloye 2004, Kääb et al. 2007, Roer 2007). In this context it is described that the Alpine rock glaciers show a rather synchronous behavior and respond sensitively to recent temperature increase (Roer et al. 2005a, Roer et al. 2005b, Kääb et al. 2007, Delaloye et al. 2008). In 2003, Kääb et al. stated that the correlation between the velocity field (e.g., speed, creep direction, strain rates) and the present day three-dimensional geometry indicates that most active rock glaciers have not undergone significant dynamic changes in the past. But recently, distinct changes in surface topography are described for a number of active rock glaciers in the Alps, indicating the landslide-like behavior and destabilization of these landforms.

Based on these observations, the study aims at identifying primary factors controlling the development of cracks and causing the landslide-like behavior of the landforms. Furthermore, possible natural hazards due to rock glacier instabilities are discussed.

Observations

The destabilization of active rock glaciers is indicated by distinct changes in their kinematics, geometry and strongly modified topography. These phenomena are investigated qualitatively by field inspection and by interpretation of terrestrial and aerial photographs. In addition, horizontal velocities, advance rates of the rock glacier front, as well as the growth and depth of cracks, are measured and quantified by the use of digital othophotos and by differential GPS measurements in the field. Also, recently the remote sensing technique InSAR (Interferometric Synthetic Aperture Radar) has been applied to detect landform changes (Delaloye et al. in prep., Lambiel et al. 2008). Once indications for destabilizations are detected, the rock glaciers have been surveyed regularly and monitored in detail. Examples are provided from different regions of the European Alps:

(1) rock glacier Hinteres Langtalkar, Carinthia, Austria
(2) rock glacier Grueo1, Valais, Switzerland
(3) rock glacier Furggwanghorn, Valais, Switzerland
(4) rock glacier Petit-Vélan, Valais, Switzerland
(5) rock glacier Tsaté-Moiry, Valais, Switzerland

First, observations on variations in velocity fields accompanied by the development of transverse cracks were described for the rock glaciers Äusseres Hochebenkar and Hinteres Langtalkar, both situated in Austria (Kaufmann &

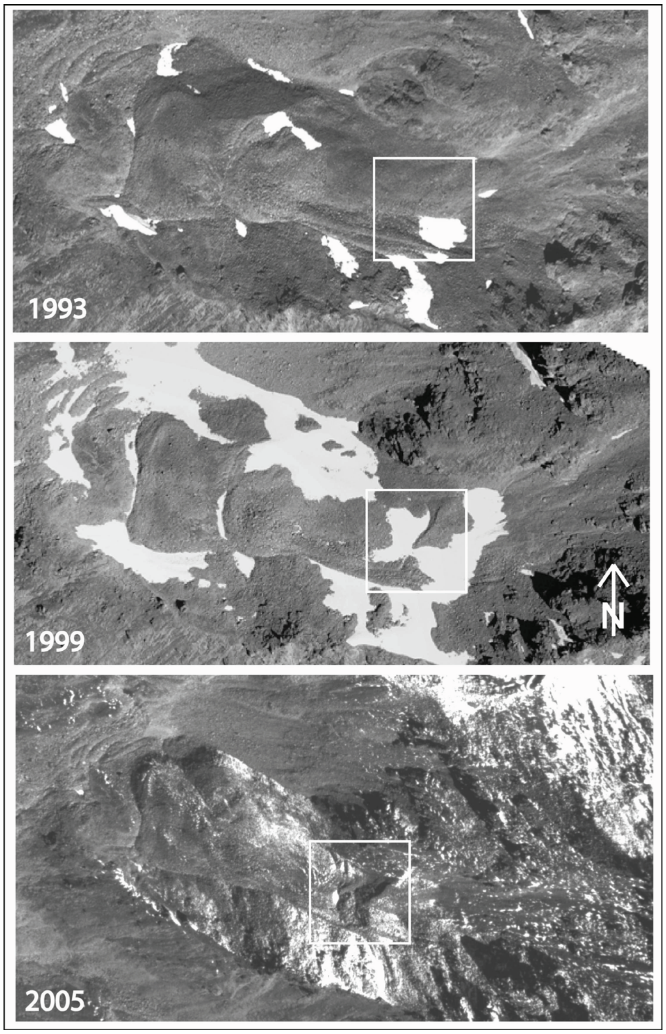

Figure 1. Development of cracks cracks phenologically similar to crevasses occurring on glaciers, in the rooting zone of rock glacier Furggwanghorn (Valais, Switzerland). A small crack started to grow between 1993 and 1999 and evolved into two 14 m deep cracks until 2005. In parallel, the former stable front of the rock glacier advanced about 1.55 ma^{-1} during this time. Orthoimages of 1993, 1999, and 2005 © Swiss Federal Office of Topography (Swisstopo).

Ladstädter 2003, Avian et al. 2005). The strong deformation of the lowest part of the rock glacier Hinteres Langtalkar was interpreted as expression of enhanced strain due to movement of the landform over a terrain ridge into steeper terrain. Thus, the sudden change in slope inclination seemed to cause this specific dynamic response. Later, further rock glaciers showing similar creep instabilities accompanied by the formation of surface ruptures were detected in the Valais, Switzerland.

Rock glacier topography

At the scale of an entire rock glacier, its typical topography is characterized by a relatively smooth and unstructured surface in the upper part (with sometimes longitudinal ridges) and a distinct pattern of ridges and furrows in the lower part, indicating compressive flow. Thus, the surface structure of a rock glacier depicts the complex strain history

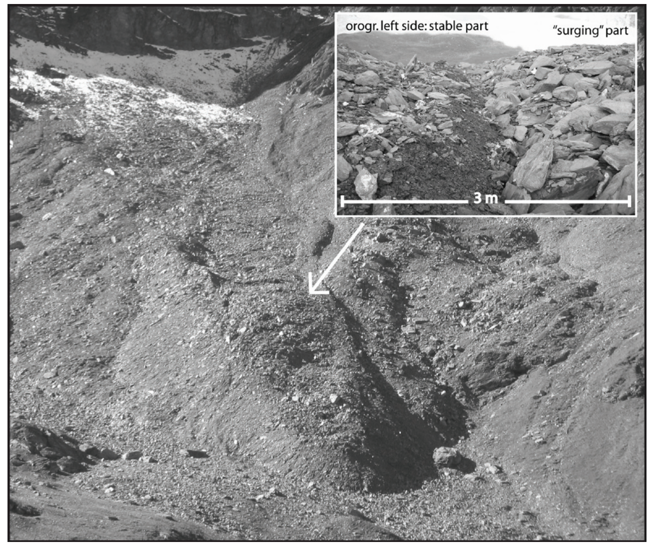

Figure 2. Rock glacier Tsaté-Moiry, Valais, Switzerland. Several scars, developing since the 1980s, are found all over the landform. Velocities at the front were about 7 ma^{-1} between 2006 and 2007. In the field, stable and surging parts can easily be differentiated due to stability (wedged or loose blocks) as well as sorting of the material at the rock glacier surface (Photos: C. Lambiel, 2007).

of the landform (Haeberli 1985, Kääb & Weber 2004). Normally, even if the horizontal velocities are high, the geometric change of the creeping permafrost body is very small (Kääb & Vollmer 2000, Roer 2007).

Most of the rock glaciers investigated here show a smooth morphology prior to the sliding behavior (e.g., rock glacier Furggwanghorn 1993, Fig. 1). In addition, those landforms featuring failures at the front in parallel, indicate smooth surfaces with continuous horizontal displacements in their rooting zones (Kaufmann & Ladstädter 2003, Roer 2007). In the case of rock glacier Tsaté-Moiry, indications for destabilization are not restricted to one part, but affect the whole landform (Fig. 2). Most of the rock glaciers show a collapse behavior in the lowermost part of their tongue. Such failures are indicated by the rugged topography due to the crack formation and by the strong advance of the tongue which is accompanied by a lowering of the surface.

Horizontal velocities and advance rates

As mentioned before, the morphological change of the rock glaciers studied here is caused by distinct high horizontal velocities over the entire landforms, between 1.00–3.76 ma^{-1} (Table 1). These velocities indicate strong spatial variations. In general, deformation rates of the investigated rock glaciers are very small in the rooting zone and at the margins of the landform; the highest movement rates are found in the central flow field. On most of the destabilizing rock glaciers, highest velocities are measured at the front, where most of the morphological changes occur (e.g., Fig. 3). For some of these rock glaciers, measurements of velocities were even inhibited on the destabilized parts of the tongue, due to a loss in corresponding features in the repeated orthophotos. In such cases, the surface is not slowly changing anymore,

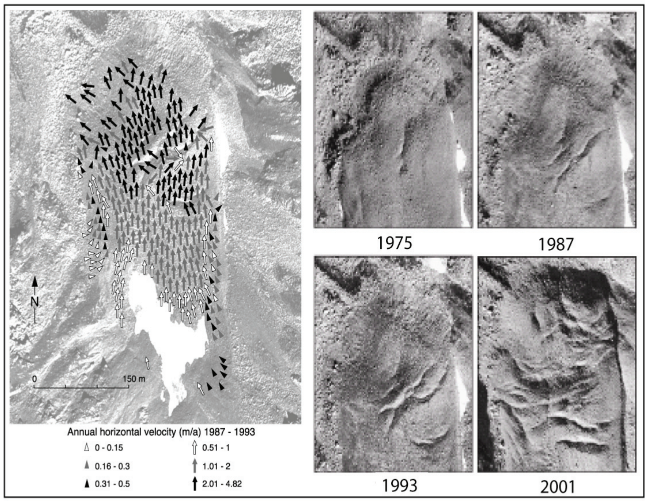

Figure 3. Collapsing tongue and development of deep cracks of rock glacier Grueo1 (Valais, Switzerland) between 1975 and 2001. The cracks started to develop on the orographic right side, while later (between 1993 and 2001) the landslide-like failure extended over the entire tongue. Between 1975 and 2001 the rock glacier advanced about 60 m (~ 2.3 ma^{-1}). (See also Roer 2007, Kääb et al. 2007). Orthoimages of 1975, 1987, and 1993 © Swiss Federal Office of Topography (Swisstopo). Orthoimage of 2001 © RTG 437, Department of Geography, University of Bonn.

but is rather characterized by tilting and toppling of blocks into the forming cracks.

In addition to the high displacement rates, all rock glaciers considered here indicate extraordinary changes at their fronts. Regarding typical rock glaciers, even if different advance mechanisms occur (Kääb & Reichmuth 2005), the annual rates are very small (0.1- 0.4 ma^{-1} in the Alps (Roer 2007)). In contrast, rock glaciers showing a landslide-like behavior, feature extraordinary advances of several meters per year (see Table 1, Fig. 5). Due to that fact, the shape of the terminal fronts changed significantly. Hence, they are not stable anymore, and often show a high rockfall frequency.

Formation of cracks

Caused by the high horizontal velocities and the pronounced advance of the fronts, cracks that are –phenologically similar to crevasses which occur on glaciers –developed on all rock glaciers in this study. These cracks are mostly found in the lower part of the tongues; rock glacier Furggwanghorn is the only one with cracks in the rooting zone after 1993 (Fig. 1). They are up to 14 m deep and feature lengths of 150 meters and more. An interesting fact is that, on most of the rock glaciers investigated, first indications of the existence and growth of cracks go back for over 20 years (Table 1). The formation of cracks on the rock glaciers Grueo1 (Fig. 3) and Hinteres Langtalkar (Fig. 4), expanded and accelerated in the 1990s. This is in accordance with observations on rock glacier Furggwanghorn, which show a more recent crack formation (between 1993 and 1999, Fig. 1). In the case of rock glacier Tsaté-Moiry, the phenomena is instead described by the occurrence of scars (which are less deep than cracks, and therefore seem to affect the active layer only) occurring all over the landform.

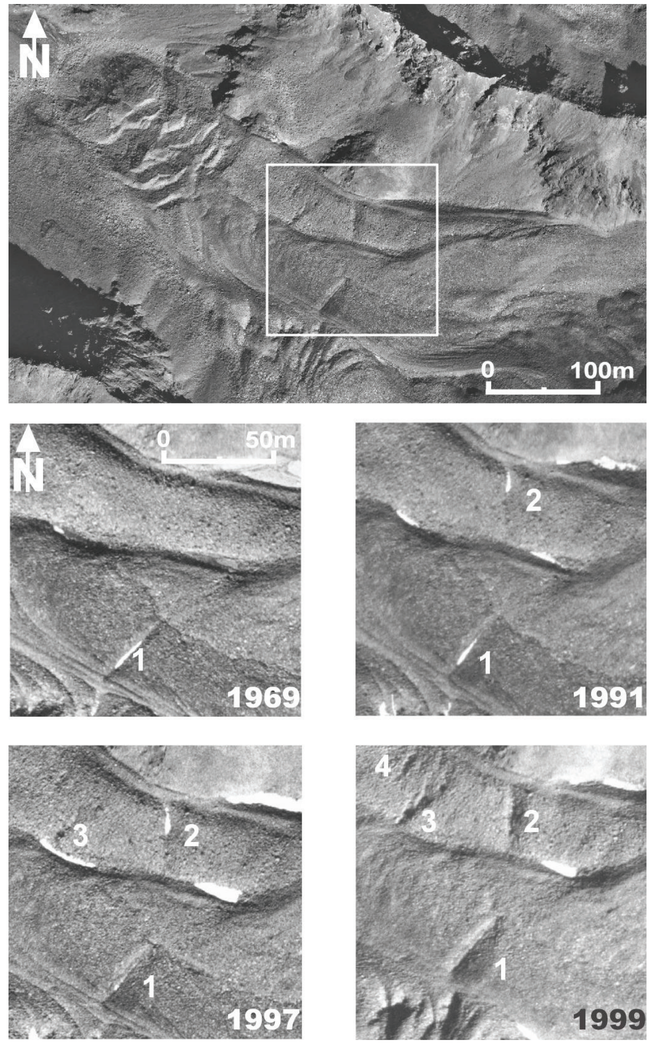

Figure 4. Rock glacier Hinteres Langtalkar (Carinthia, Austria): formation of cracks (1–4) between 1969 and 1999 in the middle part of the landform (square in uppermost image). Aerial photographs of rock glacier Hinteres Langtalkar for 1969, 1991, 1997, and 1999 © Austrian Federal Office of Metrology and Survey (BEV), Vienna, 2001.

Inspections and investigations of these cracks in the field offered more questions than answers. In most of the cracks, neither ice nor evidence of water was found during the summer months, hinting at a well-developed drainage through and/or underneath the creeping permafrost bodies. However, on rock glacier Hinteres Langtalkar (Fig. 4), two of the cracks were filled with water during summer.

Destabilization of rock glacier tongues

A destabilization of the rock glacier tongues happens in those cases where deep cracks form in the lower part of the landforms (i.e., rock glaciers Hinteres Langtalkar, Grueo1, and Tsaté-Moiry). The cracks indicate deep shear-zones similar to those known for rotational landslides (Dikau et al. 1996). Also, the movement of the tongue, which is characterized by a massive downslope displacement of the mass accompanied by a distinct lowering of the surface (see Fig. 5), is analagous to sliding processes. Hence, a change

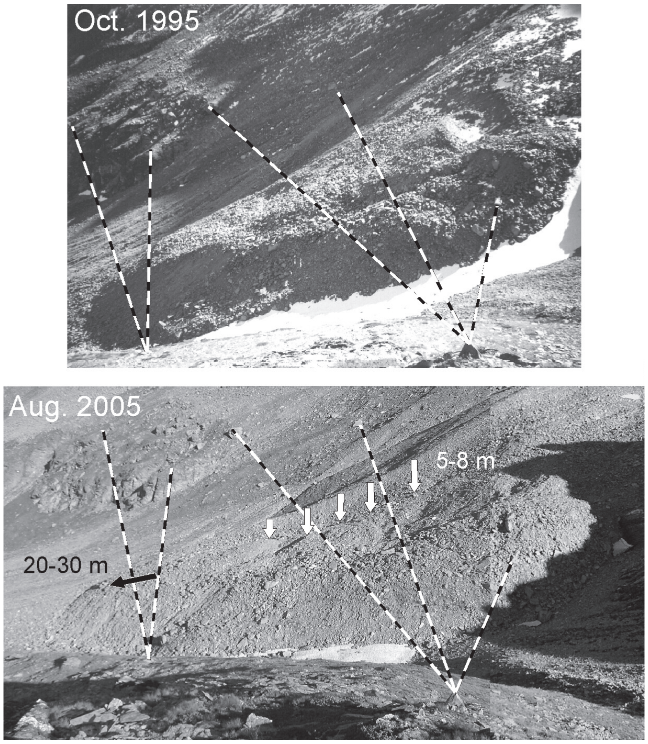

Figure 5. Instability of the tongue of rock glacier Petit-Vélan (Valais, Switzerland). The dashed lines connect the fixed points in stable terrain outside the rock glacier and provide the basis for the photo analysis. Between October 1995 and August 2005, this landform advanced about 20–30 m (approx. 2.5 m per year). Due to that shift of mass, vertical lowering of 5–8 m occurred (Photos: R. Delaloye)

in process regime is indicated. Related to the landslide-like mass wasting, the lowermost part of the tongues changed from a formerly convex to a more concave morphology.

Hazards

The changes described before can affect all parts of rock glaciers: the active layer, the permafrost body, the rooting zone, or the front. Arenson (2002) stated that instabilities within the active layer seem to be most probable due to the effect of unfrozen water during summer. The accelerated horizontal velocities, as well as the sliding processes, strongly influence the stability of the rock glacier front. Here, enhanced rockfall activity (frequency and magnitude) was recognized on several rock glaciers. In general, the position of the landform (especially the slope angle) is decisive for its hazard potential.

Considerations

The interpretation of the presented observations is, up to now, strongly limited due to the complexity of the phenomenon and the lack of information on the thermal state and internal structure of the rock glaciers considered here. Borehole data (internal deformation, temperatures) or data delivered by geophysical soundings from adjacent landforms can not be consulted, since the dynamics of individual rock glaciers cannot be readily compared. Therefore, only the given information on rock glacier kinematics can be analysed. Since these data provide a cumulative signal reflecting all components of the creep process (internal deformation, sliding in shear horizons, and deformation at the base), the processes below the surface can be considered to some degree. The key question is which of the creep components increased by certain changes, i.e., whether the internal deformation, the sliding in shear horizons, or the basal sliding increased significantly (Fig. 6).

Table 1. Summary of characteristics of the investigated rock glaciers. The numbers refer to the rock glaciers listed on page 1.

rockgl.	mean annual velocity (ma^{-1})	front advance (ma^{-1})	crevasses in lower part	crevasses in rooting zone	beginning of crevasse formation
1	2.80 (mean 1997 - 1998)	-	x	-	before 1954
2	2.79 (mean 1993 - 2001)	2.30 (1975-2001)	x	-	before 1975
3	1.46 (mean 1993 - 2001)	1.55 (1975-2001)	-	x	between 1993 and 1999
4	1.24 (mean 2005 - 2007)	2.50 (1995-2005)	x	-	between 1988 and 1995
5	1.50 (mean 2005 - 2007)	4.00 (1999-2005)	x	x	before 1988

Under constant temperatures, stresses, and strain rates, rock glaciers show long-term steady-state (secondary) creep behaviour (Haeberli 1985). The flow results from the plastic deformation of the ice inside the supersaturated permafrost body in response to gravity and is controlled mainly by its internal structure (Barsch 1992). Sliding in shear horizons, where reduction in viscosity enables higher deformations, plays an additional role (Wagner 1992, Arenson et al. 2002). Hence, different factors or a combination thereof, may lead to the observed geomorphic changes: changes in ice content or ice characteristics; changes in the shear horizons (e.g., number, position, frictional behaviour, occurrence of unfrozen water); or changes in the internal structure of the permafrost body leading to changes in deformation. Another creep component, which could have led to the observed changes, might be the deformation of subpermafrost sediments (Fig. 6).

All those effects may result from a change in ground temperature regime. The significance of a rise in air temperature for a change in the strength of ice-rock mixtures has been demonstrated by Davies et al. (2001) in laboratory tests. They proved that a rise in air–and consequently ground–temperature leads to a reduction in shear strength of ice-bonded discontinuities and thus may induce slope failures. In addition, Kääb et al. (2007) conclude from modeling and field investigations, that the creep of perennially frozen granular material close to 0°C is significantly more sensitive to climate forcing than the creep of colder material. Their modeling results also stress the importance of a deeper understanding of shear horizons in rock glaciers, since they appear to be the most sensitive parts in the response of the permafrost bodies to atmospheric and ground warming.

The analysis of the observed development of cracks indicates that strain rates increased significantly. It is not clear whether this formation is a gradual process (as indicated by the slow growth of most of the cracks, Figs. 3, 4) or sudden exceeding of a threshold (as given by the acceleration of crack formation in the 1990s). In addition, this development may differ between rock glaciers. The related changes at the rock glacier surface (e.g., thinning of the protecting debris cover) might enhance the process by positive

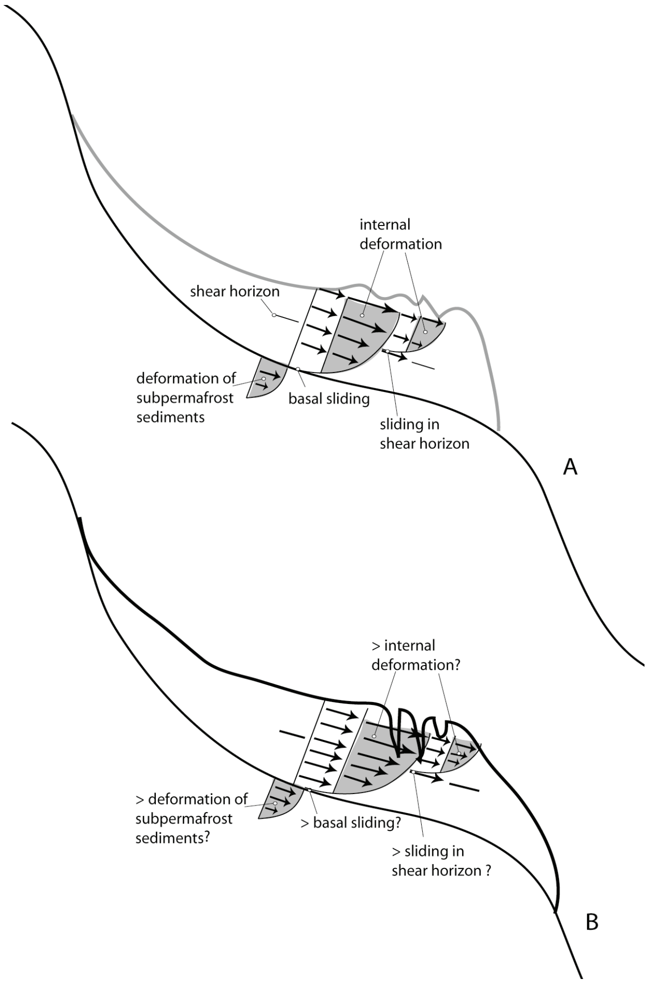

Figure 6. Schematic profile of a typical rock glacier for steady-state conditions (A), and a destabilized rock glacier with crack formation in the lower part of the tongue (B). A deformation profile showing the single creep components is depicted for both cases; it is not clear which component is decisive for the destabilization of the tongue

feedback mechanisms (Kääb et al. 2007). Due to the cracks, latent heat can easily penetrate into the permafrost body, and thus may lead to a warming of the ice (thermokarst phenomena).

The observed changes at the front of the rock glaciers' are probably not exclusively related to permafrost creep processes alone. The analysis of the morphological changes indicates a mass wasting similar to landslides.

Conclusions and Perspectives

Our principle hypotheses are that the primary factors controlling the development of cracks and the destabilization of rock glacier tongues are the rheological properties of warming ice and the resulting changes in the stress-strain relation. In addition, and related to the before mentioned, hydrological effects (unfrozen water) within the permafrost body or at its base may contribute to the initiation of rapid flow acceleration into tertiary creep. Unfrozen water ponding on the permafrost surface could lead to surface instabilities and trigger landslides (Arenson 2002). Another component in this context might be the deformation of subpermafrost sediments. In some cases, topographic influences due to movement onto steep slopes (>25-30°) and/or convex terrain can initiate the destabilization of the landform. Generally, the interpretation of those exceptional rock glaciers is limited, due to the little knowledge of rock glacier dynamics.

The challenge in the investigation of destabilized active rock glaciers lies in the ongoing monitoring of these landforms, for research purpose as well as for hazard assessments. In addition, more data related to internal characteristics are needed in order to develop a process model that couples creep and sliding mechanisms. The coupled analysis will allow for an assessment of how changes in subsurface characteristics will be translated into a rheological response. These goals fit into the key questions of future permafrost research addressing spatio-temporal changes of surface and subsurface processes in response to atmospheric forcing.

Acknowledgments

The photogrammetric analyses of Furggwanghorn rock glacier were conducted in collaboration with Patrick Thee, Swiss Federal Institute for Forest, Snow, and Landscape Research. We gratefully acknowledge the valuable comments of two anonymous reviewers.

Abstract

To characterize the thermal state of permafrost, the International Permafrost Association launched its International Polar Year Project #50, Thermal State of Permafrost (TSP). Ground temperatures are measured in existing and new boreholes within the global permafrost domain over a fixed time period in order to develop a snapshot of permafrost temperatures in both time and space. This data set will serve as a baseline against which to measure changes of near-surface permafrost temperatures and permafrost boundaries, to validate climate model scenarios, and for temperature reanalysis. The first results of the project based on data obtained from Russia are presented. Most of the observatories show a substantial warming during the last 20 to 30 years. The magnitude of warming varied with location, but was typically from 0.5 to 2°C at the depth of zero annual amplitude. Thawing of Little Ice Age permafrost is ongoing at many locations. There are some indications that Late Holocene permafrost has begun to thaw at some undisturbed locations in northeastern Europe and in northwest Siberia. Projections of future changes in permafrost suggest that by the end of the 21st century, Late Holocene permafrost in Russia may be actively thawing at all locations and some Late Pleistocene permafrost could start to thaw as well.

Keywords: dynamics of permafrost; long-term thaw; modeling; temperature regime.

Introduction

Permafrost has received much attention recently because surface temperatures are rising in most permafrost areas of the Earth, which may lead to permafrost thaw. Thawing of permafrost has been observed at the southern limits of the permafrost zone; thawing can lead to changes in ecosystems, in water and carbon cycles, and in infrastructure performance. If the current trends in climate continue, warming of permafrost will eventually lead to widespread permafrost thawing in the colder permafrost zones. There is, however, uncertainty concerning where this thawing will occur first, the rate of thaw, and the consequences for arctic, subarctic, and global natural systems. Hence, it is critically important to organize and sustain continuous observations of the thermal state of permafrost in various locations and for various natural settings within the entire Earth permafrost domain. To characterize the thermal state of permafrost, the International Permafrost Association launched its International Polar Year Project #50, Thermal State of Permafrost (TSP). Ground temperatures are measured in existing and new boreholes within the global permafrost domain over a fixed time period in order to develop a snapshot of permafrost temperatures in both time and space (Brown & Christiansen 2006). The resulting data set will serve as a baseline against which to measure changes of near-surface permafrost temperatures and permafrost boundaries, to validate climate model scenarios, and for temperature reanalysis.

More than half of Russia is occupied by permafrost, constituting a significant portion of the entire Northern Hemisphere permafrost area. Hence, without comprehensive understanding of permafrost dynamics in Russia it will be very difficult to draw any general conclusions about the state and fate of permafrost in the Northern Hemisphere. Permafrost research in Russia has a long, rich history. Many historically active institutions are still active in permafrost research today, though there is a strong need to develop an integrated network of permafrost research stations to improve the efficiency and sustainability of these efforts. The Russian-US TSP project funded by the US National Science Foundation (NSF) was established to initiate the process of collaborating and integrating US (mainly Alaskan) and Russian permafrost observing stations into an International Network of Permafrost Observatories (INPO) within the framework of the International Polar Year (IPY). Several institutions from the universities and the US Geological Survey and more than ten Russian institutions and organizations are involved in this project. This project is open to new participants, both individual and institutional. The first results of this project based on both currently measured and historical data from several permafrost regions in Russia (Fig. 1) are presented in this paper.

Examination of past trends in permafrost conditions and

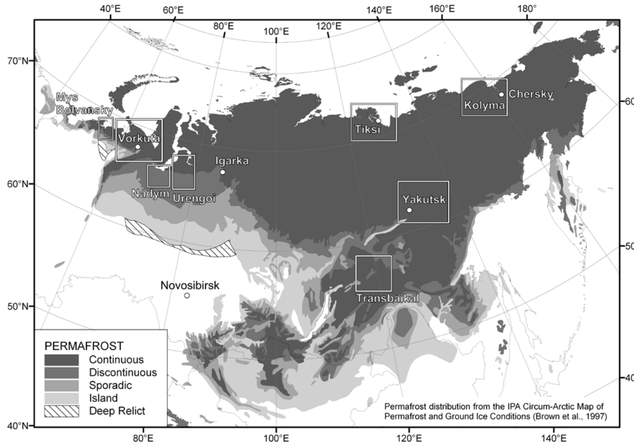

Figure 1. Location of selected Russian TSP research areas discussed in this paper.

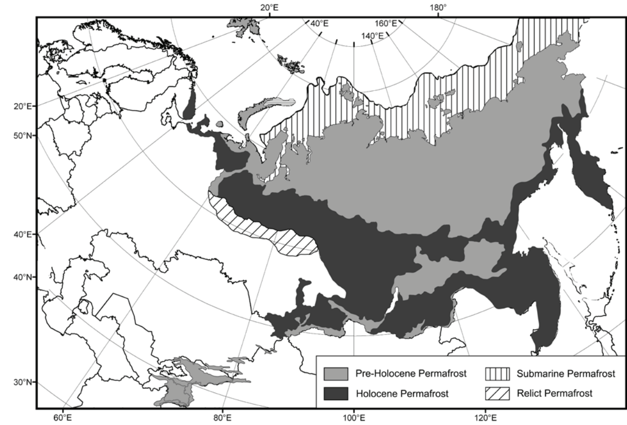

Figure 2. Present-day distribution of permafrost of different ages in Russia (after Lisitsyna & Romanovskii 1998).

distribution (especially during the last glacial-interglacial cycle) can also facilitate better understanding of the possible rates and pathways of permafrost degradation in the future. The primary reasons for this are: 1) many present-day features in permafrost distribution both vertically and laterally were formed during the last 100,000 years, and 2) we can expect that with persistent future climate warming, the first permafrost to thaw will be the youngest Little Ice Age permafrost, followed by Mid and Late Holocene permafrost, and last to thaw will be the Late Pleistocene permafrost. Thawing of the Little Ice Age permafrost is ongoing at many locations. There are some indications that Late Holocene permafrost has started to thaw at some specific undisturbed locations in northeastern Europe, in northwestern Siberia, and in Alaska. In this paper we will briefly describe our knowledge of permafrost development in Russia during the last glacial-interglacial cycle and provide currently available information about recent long-term permafrost thawing in this region.

Permafrost History in Russia During the Last Glacial-Interglacial Cycle

Permafrost distribution changed during the last glacial-interglacial cycle in response to changes in climate. During the last glacial maximum (ca. 20ky BP), permafrost underlay more land area than today. Significant portions of non-glaciated territory of Europe, northern Eurasia, and North America were affected by permafrost. With the termination of the last glacial epoch during the transition from glacial to interglacial climate, permafrost started to thaw rapidly both from the top and from the bottom at the southernmost limits of its Late Pleistocene maximum distribution. With climate warming in progress, more and more permafrost in this area became involved in rapid degradation. As a result, by the time of the Holocene Optimum (5-9 ky BP), permafrost had completely disappeared from most of the territory of deglaciated Europe, from northern Kazakhstan, and from a significant portion of West Siberia in northern Eurasia (Yershov 1998). In areas where the upper several hundred meters of permafrost was ice-rich, such as in the Pechora River basin and in the northern and central parts of West Siberia, permafrost had not disappeared completely; it is still present at greater depths (200 m and deeper). Permafrost on land was generally stable and did not experience any widespread thaw during the Holocene Optimum within the northern part of Central Siberia and within the entire continuous permafrost zone in East Siberia and in the Russian Far East (Fig. 2). However, numerous thermokarst lakes have rapidly developed during this period causing localized thawing of permafrost under lakes that were sufficiently deep.

Climate cooling during the Middle and Late Holocene resulted in a reappearance of permafrost in many areas of the present-day discontinuous permafrost zones (Fig. 2). In some areas, permafrost aggradation was accompanied by an accumulation of new sediments resulting in so-called syngenetic permafrost formation. More commonly, this new Holocene permafrost was formed by refreezing of already existing sediments and bedrock (termed epigenetic permafrost). In the areas where the Late Pleistocene permafrost was still in existence at some depth, two-layered permafrost was formed. The number of newly formed thermokarst lakes significantly declined within the continuous permafrost area.

Generally, Holocene climate has been much more stable than during the Late Pleistocene. However, several relatively warm and cold several-centuries-long intervals can be traced in the Middle and Late Holocene (Velichko & Nechaev 2005). During these intervals, new, fairly shallow, short-lived permafrost appeared and disappeared several times in some specific landscape types found within the sporadic and discontinuous permafrost zones near the southern boundary of present-day permafrost distribution. The last and probably the coldest of such intervals was the Little Ice Age, which dominated most of the Northern Hemisphere climate between ca. 1600 and 1850. During this period, shallow permafrost (15 to 25 m, e.g. Romanovsky et al. 1992) was established within the sediments that were predominantly unfrozen during most of the Holocene. Present-day warming initiated the Little Ice Age permafrost thawing that has been documented for several regions in North America (Jorgensen et al. 2001, Payette et al. 2004).

A Short Description of Selected Research Areas and Methods of Measurements

A large number of borehole temperature measurements at different depths were obtained for the Eurasian permafrost regions starting in the 1960s. Only a small fraction of these data became available for analysis during the initial implementation stage of the Russian TSP project. Comparing retrospective data with results of modern observation allows estimation of the trends in thermal state of permafrost during the last few decades. During the first year of this project (2007), some data from the European North of Russia, north of the western Siberia and Yakutia regions were collected. New temperature monitoring instruments were installed in more than 100 already existing and newly drilled boreholes at various locations within the Russian permafrost domain. This instrumentation allows automatic continuous collection of temperature data with sub-daily time resolution.

The longest permafrost temperature time series from Russia in our records are from northeast European Russia and from northwest Siberia. Permafrost temperatures at various depths have been measured since the early 1970s in the Nadym and Urengoy research areas, since the late 1970s in the Vorkuta research area, and since the early 1980s near the Mys Bolvansky meteorological station located near the shore of the Barents Sea (Fig. 1). At each location the specially designed temperature-monitoring boreholes were established in different natural landscape settings within these research areas.

Permafrost temperatures in more than 200 boreholes were measured in the mid-1980s in the Transbaykal Chara research area (Romanovskiy et al. 1991). This area is characterized by extremely high variability in landscape and permafrost conditions. Temperature measurements were re-established in the 2000s in a very limited number of selected boreholes as a part of the Russian TSP activities.

Temperatures in permafrost boreholes have been measured in the Yakutsk research area (Fig. 1) since the 1960s; however, most collected data are not readily available. In this paper we present permafrost temperature data for 1990–2006 collected by scientists from the Melnikov Permafrost Institute at their long-term monitoring station in Yakutsk. A permafrost temperature time series similar in length was obtained from the Tiksi research station as a collaborative effort between the Melnikov Permafrost Institute and Hokkaido University, Japan (Prof M. Fukuda).

Since the 1970s, the researchers from the Institute of Physical-Chemical and Biological Problems of Soil Science (Russian Academy of Science, RAS) have obtained occasional temperature measurements within the network of boreholes on the Kolyma lowland (Fig. 1). However, many of these boreholes are abandoned now and only a few are still available for further observations. Recently, temperatures in four boreholes established in the 1990s were re-measured. During the 2007 field season, as a part of the Russian TSP project, three boreholes were reconstructed by drilling new boreholes next to the old ones for continuity of temperature measurements. The first results of these activities will be presented in this paper.

Most of the boreholes at the Russian permafrost research stations were equipped with permanently installed thermistor strings and temperatures were measured periodically. In some boreholes thermistor strings were inserted into the boreholes only for the short period during which measurements were performed (but long enough to equilibrate thermistor temperature with ambient borehole temperature). The accuracy of the measurements using calibrated thermistors was typically at or better than 0.1°C. In the Vorkuta region temperatures were monitored using mercury thermometers with a scale factor from 0.05 to 0.1°C. The thermometers were placed in cases filled with an inert material such as, for example, grease. The frequency of measurements varied at different locations from once per year to monthly measurements. Starting in 2006, boreholes are being equipped with HOBO U-12-008 temperature data loggers and TMC-HD temperature sensors (www.onsetcomp.com/products/data-loggers/u12-008). Ice bath testing of these sensors and loggers always shows an accuracy of 0.1°C or better. Time resolution of these measurements is typically at four-hour intervals.

The diversity of past measuring techniques could lead to uncertainty when comparing data obtained using these different sensors. Special field experiments were performed during the 2007 field season to address this concern. Temperatures were measured simultaneously with mercury thermometers and data loggers in a borehole within the Vorkuta research area (Oberman 2008). In the Urengoy research area, data logger and thermistor string measurements were performed simultaneously in the same borehole. Readings in both cases differed on average by 0.05°C. These experiments assure the comparability of all measurement techniques at an overall accuracy of 0.1°C. The high temporal resolution of data obtained by the newly installed sensors and data loggers also demonstrates that the depths of zero annual amplitude at the Urengoy, Nadym, Vorkuta, and Mys Bolvansky research areas are relatively shallow, not exceeding 7 to 8 m.

Long-Term Changes in Permafrost Temperatures

At the Urengoy research area in northwest Siberia (Fig. 1) permafrost temperature at the depth of zero seasonal amplitude increased during 1974–2007 in all landscape units (Fig. 3A). An increase of up to 2°C was measured at colder permafrost sites (e.g., borehole UR1503, Fig. 3A). Up to 1°C warming for the same period was observed in warmer permafrost. A 2°C warming was observed in warm permafrost in a borehole that was situated in deciduous forest (not shown). A similar increase was characteristic of marshes with standing water at the surface (borehole

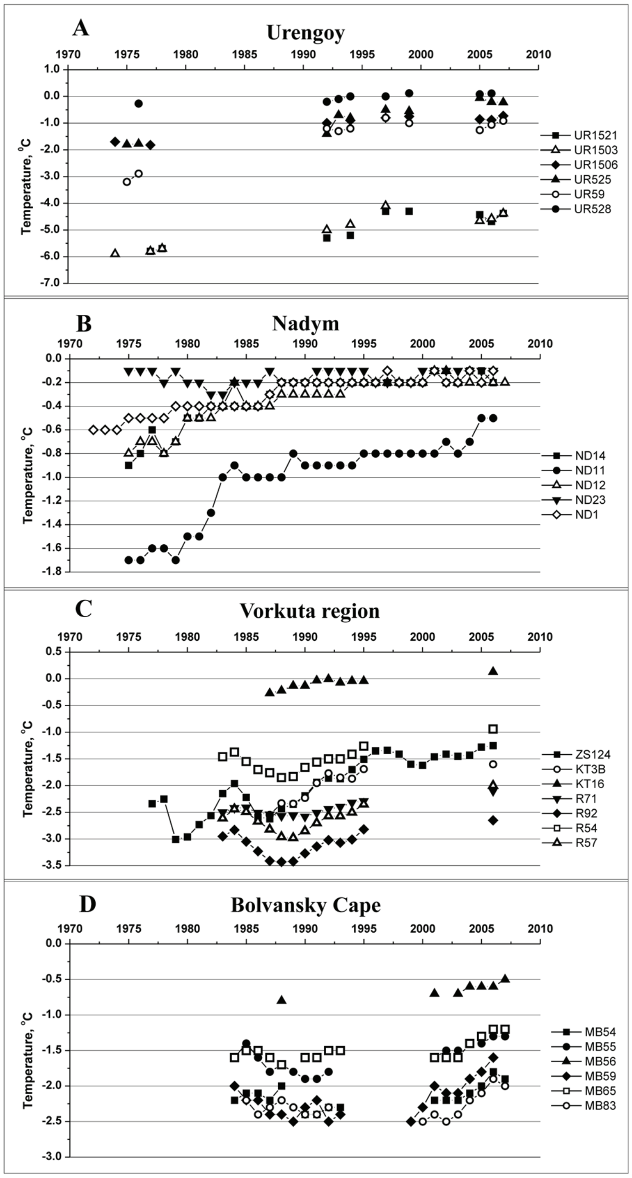

Figure 3. Decadal trends in permafrost temperatures at selected sites in Russia.

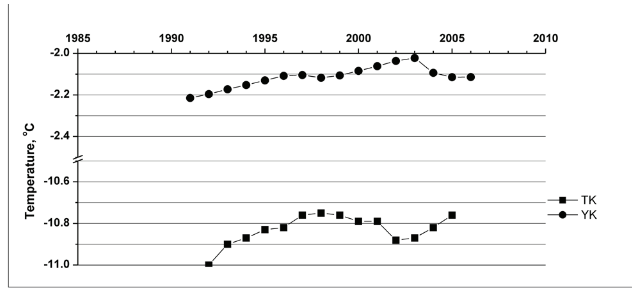

Figure 4. Time series of mean annual permafrost temperatures at 30 m depth at the Yakutsk (YK; circles) and Tiksi (TK; squares) sites.

UR59, Fig. 3A) Generally, the most significant changes in permafrost were measured in the forested and shrubby areas; often the formation of taliks up to 10 m thick were observed. In undisturbed tundra, permafrost is still generally stable (Drozdov et al. 2008). It was also observed that most warming occurred between 1974 and 1997. At the majority of locations permafrost temperatures did not change, or even cooled between 1997 and 2005. A slight warming has occurred since then at sites characterized by temperatures colder than -0.5°C (Fig. 3A).

In the Nadym research area (Fig. 3B) the most significant permafrost warming occurred before 1990, by about 1°C at a colder site and by up to 0.5°C at the warmer sites (Moskalenko 2008). At the warmest site (borehole ND23) permafrost temperature was -0.1 to -0.2°C and did not change for the entire measurement period (1975–2007). Since the temperature reached the same values at the rest of the warm sites in the late-1980s or early-1990s, it appears that permafrost temperature has not changed at the depth of zero annual amplitude at these sites (boreholes ND14, ND 12, and ND1, Fig. 3B). High temporal resolution data obtained with new data loggers show that all annual variations in temperature have occurred in the upper 2 meters of soil, indicating that permafrost has already begun to thaw internally at these sites.

Relative cooling occurred in the Vorkuta region in the late 1970s, mid to late 1980s, and in the late 1990s (Fig. 3C). The most significant warming occurred between the late 1980s and late 1990s. The total warming since 1980 was almost 2°C at the Vorkuta site (Oberman 2008).

At the Bolvansky station in northwest Russia the warming trend in air temperature for the last 25 years is 0.04°C/yr; observed trends in mean annual permafrost temperatures vary from 0.003 to 0.02°C/yr in various natural landscapes (Malkova 2008). For the last 10 years, an increase in climatic variability and alternation of extremely cold and extremely warm years has been observed. These changes initially led to a considerable increase in permafrost temperature, followed in 2007 by a small decrease in temperature in most boreholes (Fig. 3D).

Continuous 15-year permafrost temperature time series were obtained in Tiksi and Yakutsk by researchers from the Melnikov Permafrost Institute in collaboration with scientists from Hokkaido University in Japan. Permafrost temperatures at 30 m depth show a slight positive trend for the 1990–2005 time period (Fig. 4). In contrast, permafrost temperatures apparently did not change significantly in the Kolyma research area (Fig. 1) in the eastern Siberian Arctic during the last 10 to 20 years (Kraev et al. 2008). However, further study is needed to test this conclusion, which was based on recent temperature measurements in or near the historical boreholes that were recently re-occupied as a part of the TSP program.

Permafrost temperatures obtained from the Transbaikal research area (Fig. 1) generally increased during the last 20 years. Borehole #6 was established in the mid-1980s by researchers from Moscow State University and is located in the upper belt of the Udokan Range; temperatures re-measured at this site show a 0.9°C increase between 1987 and 2005 at 20 m depth (Fig. 5). Since 2006, temperatures in this borehole have been recorded at 4-hour time intervals.

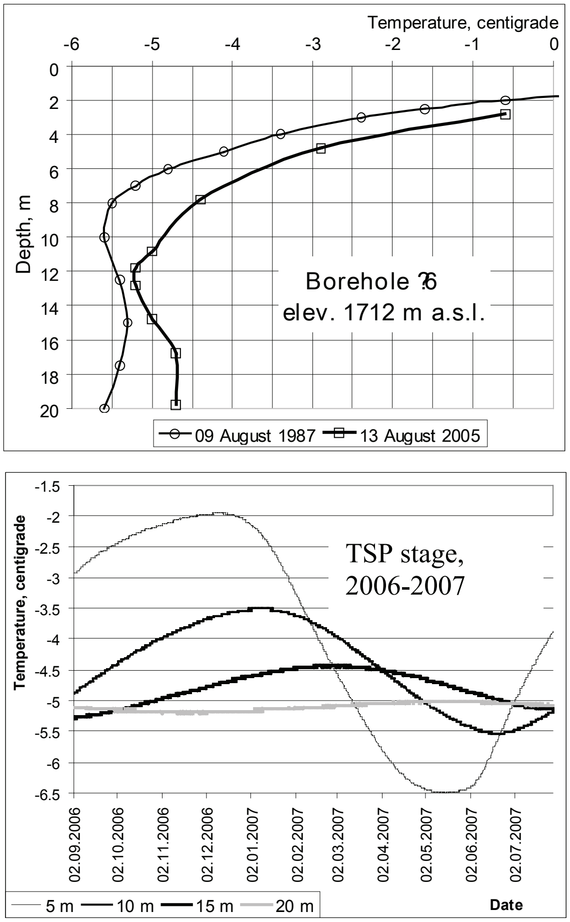

Figure 5. Upper graph: Temperature profiles from the Transbaikal research area obtained in 1987 and 2005. Lower graph: Continuous temperature records at four different depths.

Evidence of Long-Term Thawing of Permafrost

Recently observed warming in permafrost temperatures have resulted in thawing of natural, undisturbed permafrost in areas close to the southern boundary of the permafrost zone. Most observed thawing of long-term permafrost has occurred in the Vorkuta and Nadym research areas. At several locations in the Vorkuta area, long-term thawing of permafrost has led to the development of new closed taliks (Oberman 2008). At one of these locations, the permafrost table lowered to 8.6 m in 30 years. It lowered even more, to almost 16 m, in an area where a newly developed closed talik coalesced with an already existing lateral talik. Permafrost thawing during the last 30 years also resulted in the deepening of previously existing closed taliks. The total increase in depth of the closed taliks developed here ranged from 0.6 to 6.7 m depending on the geographical location, genetic type of a particular talik, ice content and lithological characteristics of the bearing sediments, hydrological, hydrogeological, and other factors.

As a result of recent climatic warming, permafrost patches 10 to 15 m thick thawed out completely in this area (Oberman 2008). In deposits perennially frozen to a depth of about 35 m, the permafrost base has been slowly rising. Comparing small-scale maps based on 1950–1960 data with maps based on 1970–1995 data shows a shift of the southern limit of permafrost by several tens of kilometers northwards (Oberman 2001). This also indicates that permafrost is mostly degrading in the southernmost part of the region.

Permafrost is also degrading in the Nadym and Urengoy research areas. Temperature records from five of a total of seven boreholes in the Nadym area show that cold winter temperatures do not penetrate deeper than 2 m into the ground and that permafrost became thermally disconnected from seasonal variations in air temperature. This also indicates that the constituent ice is already actively thawing in the upper permafrost although the permafrost table (based on the formal 0°C definition of permafrost) is still located just below the active layer. In Urengoy, permafrost is thawing in the forested and shrubby areas, developing closed taliks (Drozdov et al. 2008).

Permafrost degradation in natural undisturbed conditions not associated with surface water bodies has not been reported from the other research areas discussed in this paper. There are numerous occasions of long-term permafrost thawing in Central Yakutian areas around the city of Yakutsk, but all are directly related to natural (forest fire) or anthropogenic (agricultural activities, construction sites) disturbances (Fedorov 1996, Fedorov & Konstantinov 2003).

Permafrost Temperature Reanalysis and Modeling of Past and Future Changes in Permafrost Temperatures

Two levels of permafrost modeling are implemented in our research: a "permafrost temperature reanalysis" and spatially-distributed physically based permafrost modeling. The first level of modeling is the "permafrost temperature reanalysis" approach (Romanovsky et al. 2002). At this level, a sophisticated numerical model (Sergueev et al. 2003, Marchenko et al. 2008), which takes into account the temperature-dependent latent heat effects, is used to reproduce active layer and permafrost temperature field dynamics at the chosen sites. The input data are prescribed specifically for each site and include a detailed description of soil thermal properties and moisture for each distinct layer, surface vegetation, snow cover depth and density, and air temperature. In this modeling approach variations in air temperature and snow cover thickness and properties are the driving forces of permafrost temperature dynamics. The second level of permafrost modeling involves the application of a spatially distributed physically based model that was recently developed in the University of Alaska Fairbanks (UAF) Geophysical Institute Permafrost Lab (GIPL, Sazonova & Romanovsky 2003).

Permafrost temperature reanalysis was successfully applied to several locations within the Russian permafrost domain (Marchenko & Romanovsky 2007, Romanovsky et al. 2007). The model has been calibrated (Nicolsky et al. 2007) for each specific site using several years of measured

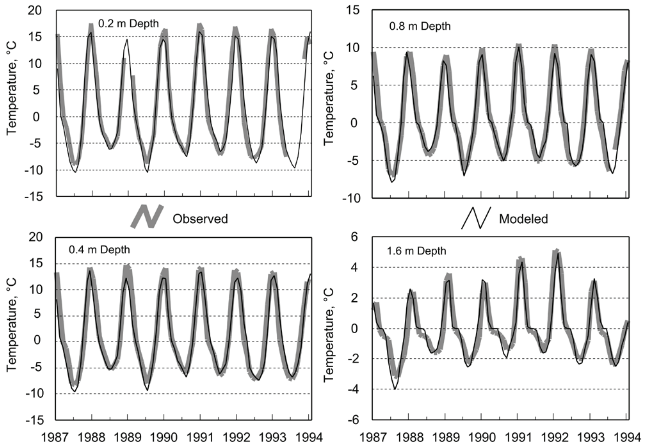

Figure 6. Observed (thick gray line) and calculated (thin black line) ground temperatures at the Yakutsk meteorological station at several depths.

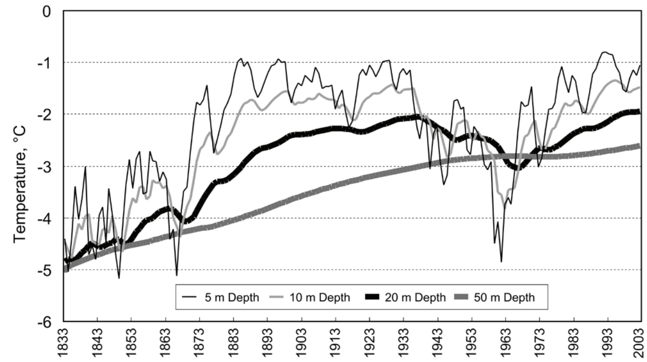

Figure 7. Calculated permafrost temperature time series at several depths for a specific location at the Yakutsk meteorological station.

permafrost and active layer temperature data and climatic data from the closest meteorological station for the same time interval. After validation on measured data that were not involved in the calibration process, the calibrated model can then be applied to the entire period of meteorological records at each station, producing a time series of permafrost temperature changes at various depths. Figure 6 shows the results of calibration of the permafrost model using climate and soil temperature data from the meteorological station in Yakutsk. The differences between measured and modeled temperatures are typically less than 0.5°C and rarely exceed 1°C. Deviation of modeled from measured temperatures decreases with depth (Fig. 6).

The calibrated model was then used to calculate the permafrost temperature dynamics during the transition period from the Little Ice Age up to the present (Fig. 7). Climate forcing includes the air temperature and snow cover dynamics for the period 1833–2003. Air temperature was reconstructed by using observed temperature records from 1834–1853 and 1887–2003 and a spectral analysis technique (Shender et al. 1999). It was also assumed that there were no long-term trends in the snow cover characteristics.

The initial (1833) temperature profile was derived from permafrost temperatures observed by Prof. Middendorf in 1844–1846 in the Shergin's mine in Yakutsk (Sumgin et al. 1939). All measurements were made in narrow horizontal holes in the walls of the mine. The length of each hole was about 2 m. Independent boreholes near Shergin's mine confirmed the characteristic permafrost temperature. Another independent method to test the choice of initial conditions is comparing calculated with measured temperatures for the time intervals when both are available. Such a comparison shows a satisfactory agreement (e.g., compare Figs. 4 and 7).

The results of calculations shown in Figure 7 indicate that the most rapid permafrost warming in the Yakutsk area occurred during the second half of the 19th century. Mean annual temperatures at the shallow depths (5 and 10 m) were already at the present-day level by the 1880s and 1890s, while deeper temperatures continued to increase up to the 1930s. A colder period in the 1940s and especially in the 1960s interrupted this warming trend. Only by the year 2000, permafrost temperatures at the 20 m depth had returned to the pre-cooling level. However, permafrost temperature at greater depths (e.g., 50 m in Fig. 7) continued to increase, although at a slower rate.

The spatially distributed permafrost model GIPL1 that was developed at the Permafrost Lab of the Geophysical Institute, UAF (Sazonova and Romanovsky 2003, Sazonova at al. 2004) was applied for the entire permafrost domain of northern Eurasia (Fig. 8). For present-day climatic conditions, the CRU2 data set with 0.5° x 0.5° latitude/longitude resolution (Mitchel & Jones 2005) was used. The future climate scenario was derived from the MIT 2D climate model output for the 21st century (Sokolov & Stone 1998).

Due to this model's spatial resolution (0.5 x 0.5 latitude/longitude) it is practically impossible to reflect the discontinuous character of permafrost in the southern permafrost zones. That is why we choose the ground surface and soil properties for each cell that will produce the coldest possible mean annual ground temperatures within the cell. This choice means that all results produced by this model reflect permafrost temperatures only in the coldest landscape types within this area. It also means that if our results show thawing permafrost somewhere within the domain, we should interpret this to mean that permafrost is thawing in practically all locations within the area. It also means that in the stable permafrost area identified in Figure 8, partial thawing of permafrost may occur at some specific locations.

According to this model, by the end of the 21st century permafrost that is presently discontinuous with temperatures between 0 and -2.5° C will have crossed the threshold and will be actively thawing. In Russia, the most severe permafrost degradation is projected for northwest Siberia and the European North. This model also shows that by the mid-21st century most of the Late Holocene permafrost will be actively thawing everywhere except for the south of East Siberia and the Far East of Russia.

By the end of 21st century, practically all Late Holocene permafrost will be thawing and some Late Pleistocene permafrost will begin to thaw in the European North and in Siberia (compare Figs. 2 and 8).

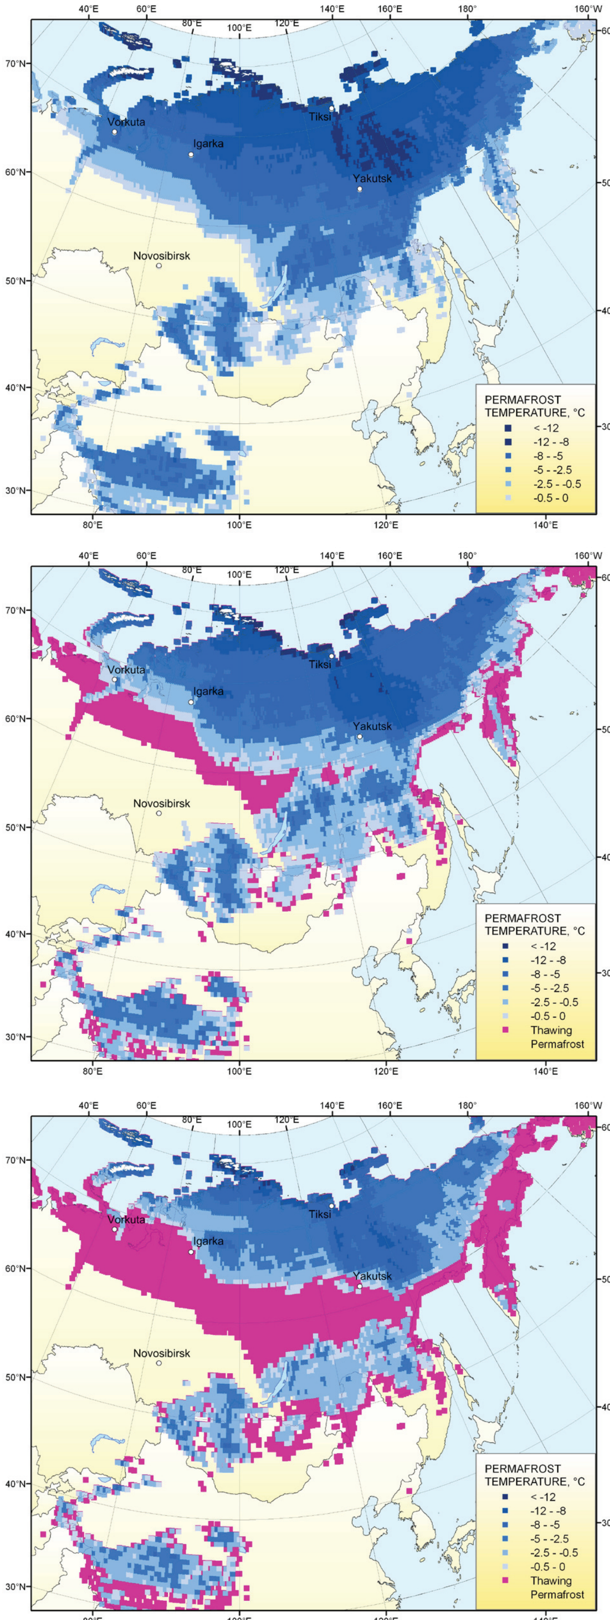

Figure 8. Calculated distribution of mean annual ground temperatures at the bottom of the active layer in Northern Eurasia averaged for three time intervals: 1990-2000 (upper graph), 2040-2050 (middle graph), and 2090-2100 (lower graph). The area with widespread permafrost thawing from the top down is shown in pink.

Conclusions

- Most of the permafrost observatories in Russia show substantial warming of permafrost during the last 20 to 30 years. The magnitude of warming varied with location, but was typically from 0.5 to 2°C at the depth of zero annual amplitude.
- This warming occurred predominantly between the 1970s and 1990s. There was no significant observed warming in permafrost temperatures in the 2000s in most of the research areas; some sites even show a slight cooling during the late-1990s and early-2000s. Warming has resumed during the last one to two years at some locations.
- Considerably less or no warming was observed during the same period in the north of East Siberia.
- Permafrost is already thawing in specific landscape settings within the southern part of the permafrost domain in the European North and in northwest Siberia. Formation of new closed taliks and an increase in depth of pre-existing taliks has been observed in this area during the last 20 to 30 years.
- Permafrost temperature reanalysis provides a valuable tool to study past changes in permafrost temperature, which helps to place recent changes into a long-term perspective.
- An implemented spatially-distributed permafrost model shows that if warming in air temperatures continues to occur, as predicted by most climate models, widespread thaw of Late Holocene permafrost may be in progress by the mid-21st century. If warming continues, some Late Pleistocene permafrost will begin to thaw by the end of the 21st century.

Acknowledgments

This research was funded by the Polar Earth Science Program, Office of Polar Programs, U.S. National Science Foundation (ARC-0632400, ARC-0520578), by the Russian Foundation for Basic Research, by the Russian Federal Agency for Mineral Resources Management (№AM-18/35 pr, 30.01.2006), by a NASA Water and Energy Cycle grant, by the State of Alaska, and in cooperation with several earlier and on-going Russian activities. We would like to thank Drs. Jerry Brown, Kenneth Hinkel, and Candace O'Connor for their valuable suggestions, which improved the quality of this paper.

Abstract

Soil climate data were collected during a recent biocomplexity study along a bioclimatic gradient in the North American Arctic tundra. The measurements were made from south to north at Happy Valley, Sagwon Hills, Franklin Bluffs, Deadhorse, West Dock, Howe Island, Green Cabin, Mould Bay, and Isachsen research sites. Mean annual air temperature changes from around -10°C at the Happy Valley and Sagwon Hills sites to -16°C at Mould Bay and Isachsen. Mean annual ground surface temperature has an even larger range, changing from -2°C to -15.5°C in the same direction. Mean annual ground temperature at the permafrost table changes from -3.5°C at Happy Valley to -15.5°C at Mould Bay and -14.7°C at Isachsen. Snow depth generally decreases from south to north, and snow density generally increases in the same direction. Measured maximal frost heave within the nonsorted circles in patterned ground vary between 18–20 cm at the Deadhorse and Franklin Bluffs sites and less than 1 cm at West Dock.

Keywords: active layer; frost heave; patterned ground; permafrost; snow cover; temperature regime; thermal offset.

Introduction

Recent warming in permafrost temperatures has been reported from many locations in the Circumpolar North (Harris & Haeberli 2003, Isaksen et al. 2000, Pavlov & Moskalenko 2002, Oberman & Mazhitova 2001, Osterkamp 2003a, Osterkamp & Romanovsky 1999, Romanovsky et al. 2002, Romanovsky et al. 2007b, Smith et al. 2005). At some of these locations that lay near the southern boundary of permafrost, this warming has already triggered long-term permafrost thawing. These changes in permafrost inevitably affect northern ecosystems, making them evolve rapidly. Some of these changes could be advantageous, but most of them have negative consequences for the natural and anthropogenic systems. Because of a wide variety in permafrost conditions in the Arctic and Subarctic, different regions experience different rates or even different directions of this change during the same time period. To document the temporal changes and spatial variability of permafrost in Alaska, a number of permafrost observatories were established in the late 1970s and early 1980s by the Geophysical Institute, University of Alaska Fairbanks, along the International Geosphere-Biosphere Program (IGBP) Alaska Transect, which spans the entire permafrost zone in Alaska (Osterkamp 1986, Osterkamp & Romanovsky 1999, Romanovsky & Osterkamp 2001, McGuire et al. 2002, Osterkamp 2003a, b, Romanovsky et al. 2003).

The recent Biocomplexity Project of the University of Alaska Fairbanks, which investigates small pattern-ground features that occur along a North American Arctic Transect (NAAT), has been funded by the National Science Foundation, USA, and is now in the final stage of its accomplishment (Walker et al. 2004, 2008). This project made it possible to extend the IGBP Alaska Transect into low- and high-Arctic regions in western Canada (Fig. 1). This extension was a valuable addition to the Transect because it adds sites where permafrost temperatures are some of the coldest in the Northern Hemisphere. Also, a reduced vegetative cover and high ice content make permafrost in this region extremely vulnerable to recently observed and projected changes in climate.

There are two types of natural gradients that will be discussed in this paper. One is the regional north to south gradient in air and soil temperatures, snow, and active layer thickness. Another is the local gradient in soil moisture and temperature, active layer thickness, and ground surface heave that is governed mostly by the surface vegetation distribution. The local gradients are the cause and, at the same time, affected by nonsorted circle formation and evolution. The regional gradients in the atmospheric climate, soil climate, and vegetation also modulate the formation and development of patterned ground and are responsible for the specific morphological features of the patterned ground in the arctic landscapes. The morphology and origination of these features have been discussed in the scientific literature for many years (e.g., Washburn 1980). Soil and permafrost climate data, together with air temperature, snow depth, and seasonal frost heave data collected at the sites along the Permafrost/Ecological North American Arctic Transect during the lifetime of the Biocomplexity Project, together with some previously collected temperature data, will be discussed in this paper. First, we will provide a brief description of natural settings at the research sites and provide some information on measuring technique and the equipment used. Further, using long-term data from several sites, we will show how relatively short records from the

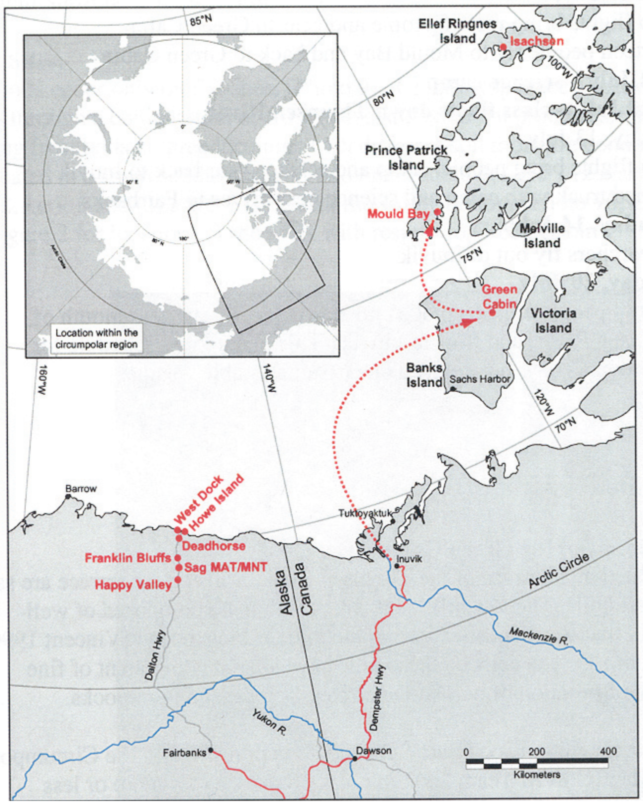

Figure 1. Location of research sites along the Permafrost/Ecological North American Arctic Transect.

biocomplexity project (2001–2006) fit a more general picture of temperature changes during the last 20 years. Then we will present data on soil climate and seasonal frost heave for the entire transect during the years of 2004–2006. Discussions based on these data lead to several important conclusions.

A Short Sites Description

Temperature, moisture, and snow measurement stations were installed from south to north at: Happy Valley, Sagwon Hills, Franklin Bluffs, Deadhorse, West Dock, Howe Island, Green Cabin (Banks Island), Mould Bay, and Isachsen (Fig. 1). All these sites are located in the continuous permafrost zone with a relatively cold climate. Climatic conditions determine type of vegetation along this transect. All sites are within the tundra biome and represent all types of tundra from subzone A (or arctic desert) at Isachsen to subzone E (or southern tundra) at Happy Valley. The specific locations were chosen as representative of zonal conditions within each of five Arctic bioclimate subzones (A through E) (Walker et al. 2005). All the studies were located on fine-grained sediments conducive to the formation of nonsorted patterned-ground features and zonal vegetation. The Sagwon MAT and Happy Valley locations had acidic soils (pH < 5.5), and all the others had nonacidic soils. Several sites (Howe Island, Green Cabin, Deadhorse, Franklin Bluffs) had soil pH values exceeding 8.0. The zonal vegetation varied from nearly barren surfaces with scattered mosses, lichens, and very small forbs in subzone A to knee-high shrub-dominated

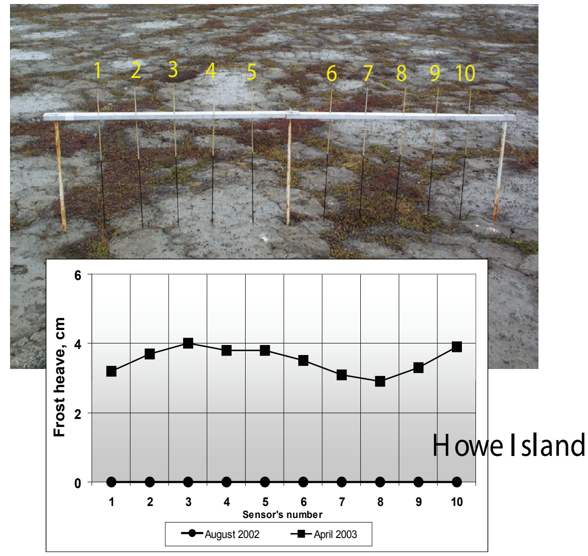

Figure 2. Frost heave measurements across a nonsorted circle at the Howe Island site.

tundra with thick moss carpets in subzone E. A more comprehensive description of natural settings at the study sites can be found in (Walker et al. 2008).

Methods of Measurements

Small climate stations were established at each location. The air and ground-surface temperatures at each location were recorded using standard Campbell Scientific L107 thermistors. Two ground surface thermistors and two 1-m long arrays of thermistors (with approximately 10 cm distance between thermistors) were located about six meters apart: one in an unsorted circle and the other between the circles. After pre-installation calibration, the precision of the sensors is better than 0.04°C. All measurements were made with one-hour time interval. The stations were operated and data were stored by Campbell Scientific CR10-X data loggers. A 20-watt regulated solar panel coupled with a 12-volt battery was used for power supply. The installations are also part of the Permafrost Observatory Network (Osterkamp 2003, Osterkamp & Romanovsky 1999, Romanovsky & Osterkamp 2001, Romanovsky et al. 2003). Snow depth was measured continuously with one-hour resolution at most of the sites using a Campbell Scientific SR50 Sonic Ranging Sensor that was connected to the Campbell data logger at the climate stations. Also, the maximum snow depth was measured every year manually at the Alaskan sites during spring (late April) field trips. At the Canadian sites, maximum snow depth was measured manually once in early May 2006. The ground moisture (including the unfrozen water content in winter) was measured at two depths within the unsorted circle and at two depths in the inter-circle space. SDI-12 volumetric water content sensors (http://www.stevenswater.com/catalog/stevensProduct.aspx?SKU=%2793640%27) were used. Each of the sensors was pared with an additional L107 temperature probe. Moisture content was recorded hourly during the entire year.

Frost heave was monitored on and off the unsorted circles at all sites using two types of specially designed heave meters. Along the Alaskan portion of the NAAT, a ten-pin heave instrument described in (Walker et al. 2004) was used (Fig. 2). In the High Arctic, heave scribers were used. Each of these instruments consisted of a 2-m x 1.5-cm solid copper grounding rod that was driven 1.5 m into the ground, anchoring it in the permafrost. A steel plate and sleeve with an attached sharp steel scriber was placed on the rod, with the plate resting on the ground. The steel plate and scriber slid freely on the rod, rising with the frost heave in the winter and allowing the scriber to scratch a line on the copper rod. The length of the scratched line above a reference scribe determined the amount of heave.

Long-Term Changes in the Air, Active Layer, and Permafrost Temperatures

When we describe atmosphere and soil climatic conditions for some period of time, it is always important to have information on how this period looks compared to longer-term patterns of these parameters. It is especially important now when the climate experiences significant changes within short time intervals. Fortunately, we have long-term (more than 20 years) continuous temperature records for three sites within the NAAT: West Dock, Deadhorse, and Franklin Bluffs. Data from the West Dock site are shown in Figure 3. This figure clearly shows a significant long-term warming trend in mean annual temperatures at all levels: air, ground surface, and permafrost at 20 m depth. A linear trend in air and ground surface temperatures was 3°C for the last 20 years, and an increase in permafrost temperature at 20 m depth was 2°C. This figure also shows that during the period of the Biocomplexity Project (2001–2006), soil climate was the warmest on average for the last 20 years. Also, during this period the soil climate was relatively stable except for an anomalously warm year, 2003.

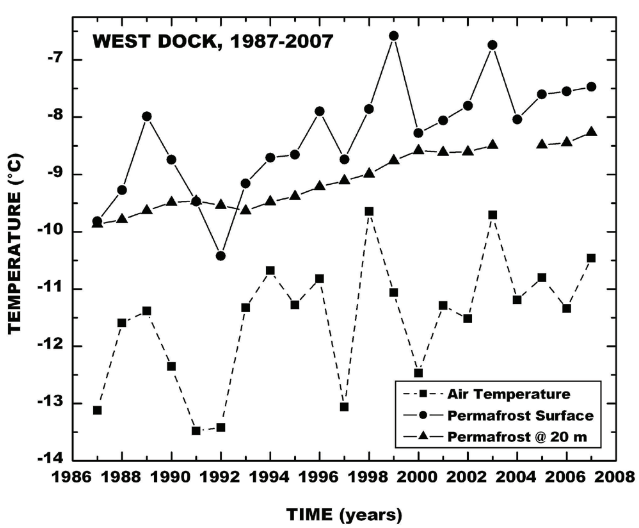

Figure 3. Time series of mean annual air (squares), permafrost surface (circles), and permafrost at 20 m depth (triangles) temperatures at the West Dock site.

Figure 3 also shows that the interannual variations in the surface temperature can differ significantly from the interannual changes in the air temperature. However, on a longer time scale (five years and longer), the match in these trends is very good. Similar results were obtained from the Deadhorse and Franklin Bluffs sites. We came to similar conclusion analyzing long-term data from the East Siberian Transect (Romanovsky et al. 2007b).

Snow Conditions and Air and Soil Temperatures Along the NAAT Transect

All our sites are within the continuous permafrost area. However, there is a significant range of air and soil temperatures along this transect. Mean annual air temperature (MAAT) changes from around -10°C at the Happy Valley and Sagwon Hills sites to -16°C at Mould Bay and Isachsen (Fig. 4), while mean July air temperatures vary in the range from 10°C at Happy Valley to 3°C at Isachsen (not shown). Elevated temperatures at Isachsen are an artifact, because only temperatures for 2005–2006 were available for this station (it was established in the summer of 2005) and the 2005–2006 year was substantially warmer in this region than 2004–2005. Data from the Mould Bay station show that MAAT in 2005–2006 was warmer by almost 2°C than in 2004–2005. Mean annual ground surface temperature (MAGST) was by more than 1°C warmer as well.

All Alaskan sites show very similar MAAT in the range between -9.7°C (Sagwon MNT) and -11.3°C (Franklin Bluffs). All Canadian sites are much colder with MAAT at or colder than -16°C. The spatial variability in MAGST is much more pronounced along NAAT. The warmest sites are all located in the inland part of the transect, with temperatures as warm as -2°C (Happy Valley) and just below -4°C (Deadhorse and Franklin Bluffs). Relatively colder temperatures were observed at Sagwon Hills (-5°C and -6°C). All coastal sites in Alaska have lower MAGST with -7.2°C at West Dock and -8.8°C at Howe Island. The coldest MAGST were observed in the Canadian Arctic with MAGST typically at or below -14°C. It was shown in previous publications (Kade et al. 2006, Walker et al. in review) that summer temperatures at the ground surface within the unsorted circles are significantly warmer than in inter-circle areas. As it can be seen from Figure 4, it is not true for the mean annual surface temperatures, which are generally very similar for both circle and inter-circle areas. A possible explanation is that differential frost heave within the circles decreases snow depth here and decreases surface temperatures during the winter. Colder winter temperatures compensate summer warmer temperatures within the circles with a net effect close to zero.

Snow cover is the major factor that determines the difference between MAGST and MAAT. Our data show that this difference is much larger at the inland sites than at the sites close to the Arctic coasts. Snow depth is generally decreasing from the south to the north, and snow density is generally increasing in the same direction. The maximum

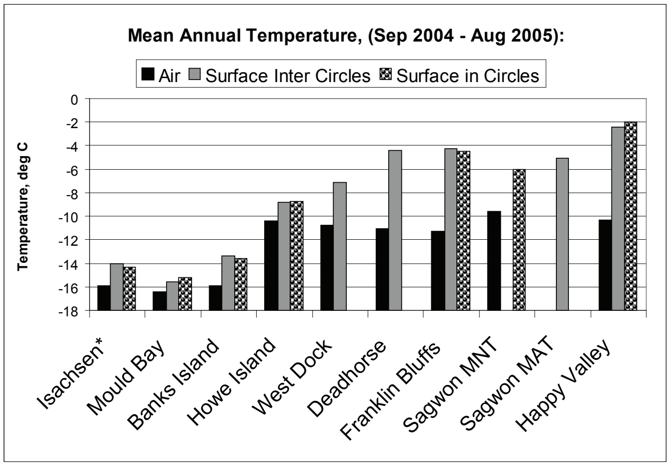

Figure 4. Mean annual temperatures (September 2004–August 2005, except for Isachsen where temperatures were measured in 2005–2006) in the air (black) and at the ground surface within inter-circles (gray) and circles (polka-dot) along NAAT.

snow thickness decreases from 60–70 cm at Happy Valley to 20 cm and less at the Banks Island and Mould Bay sites (Fig. 5). Accordingly, the warming effect of snow on MAGST is decreasing from 8°C at Happy Valley to only 1°C at the Mould Bay site (Fig. 4). Mean annual soil temperature near the permafrost table changes from -3.5°C at Happy Valley to -15.3°C at Mould Bay (Fig. 6). There is no noticeable difference in this parameter between circle and inter-circle areas.

Comparing Figures 4 and 6 we can see that the mean annual temperatures at the permafrost table are always colder than MAGST. This effect is very well-known as a "thermal offset" (Burn & Smith 1988, Romanovsky & Osterkamp 1995). Thermal offset for most of the sites along NAAT in 2004–2005 was less than -1°C, with the smallest number for Mold Bay (-0.1°C) and Banks Island (-0.15°C). For Isachsen, West Dock, Deadhorse, Franklin Bluffs, and Sagwon MNT, the thermal offset was in the range between -0.3 and -0.75°C. Significantly larger thermal offset was measured at the Howe Island site (-1°C), and for the acidic tundra sites Sagwon MAT (-1.3°C) and Happy Valley (-1.2°C). Increased thermal offset at the acidic tundra sites directly related to increased thickness of the organic soil layer that has a significantly larger ratio of the thermal conductivities in the frozen and thawed states. This ratio is the most important parameter responsible for thermal offset (Romanovsky & Osterkamp 1995).

Active Layer Depth

Active layer depth does not have a pronounced latitudinal trend and has a significant local variability, depending on the soil type and on the structure and density of the surface vegetation cover (Fig. 7). At the localities with dense vegetation, the active layer depth could be from 20 to 40% less than within the nonsorted circles with much less or no vegetation. For example, the mean depth of thaw at the end of August 2005 in the vegetated tundra between the nonsorted

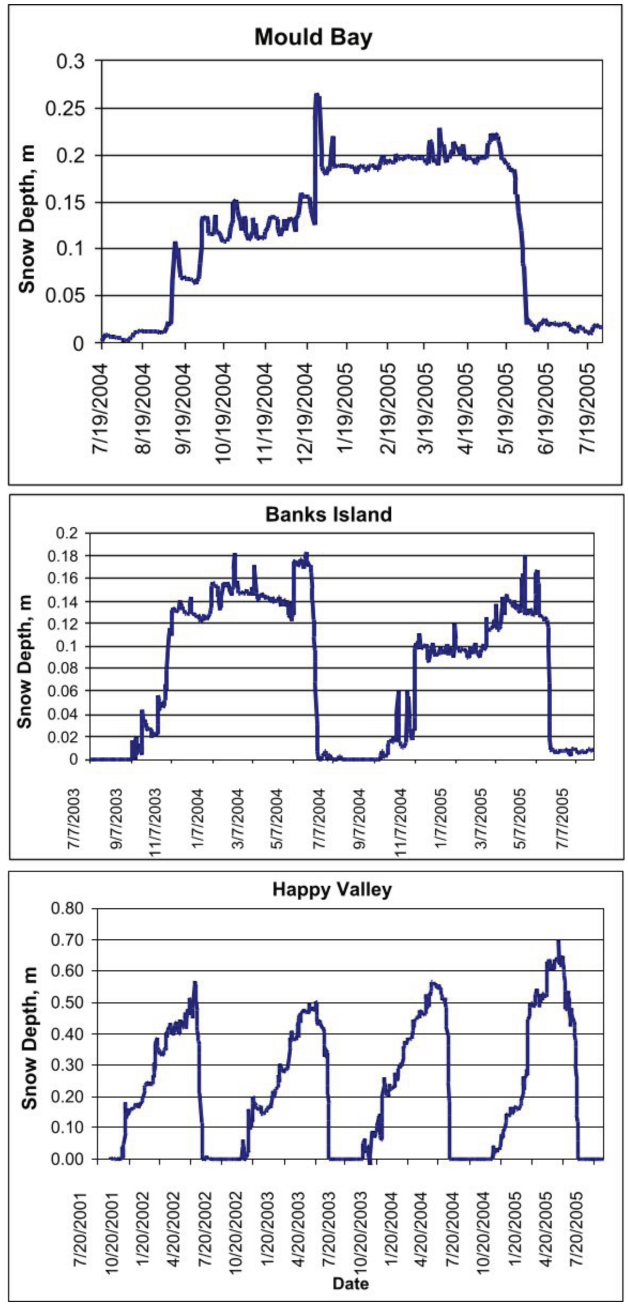

Figure 5. Hourly recorded snow cover depth at three sites: Mould Bay (A), Banks Island (B), and Happy Valley (C).

circle features was less at Happy Valley, the site with the warmest soil-surface temperatures (active layer = 30 cm), than it was at Isachsen, the coldest site (almost 50 cm). Maximum active layer thickness was observed in the middle part of the transect at the sites Franklin Bluffs, Deadhorse, Howe Island, and Banks Island.

A large difference in the active layer thickness between the nonsorted circles and inter-circle areas was observed in better vegetated sites Franklin Bluffs, Sagwon Hills, Happy Valley (Fig. 7), and Deadhorse (not shown). This difference was much less at the sites with less vegetation (Howe Island, Banks Island, Mould Bay, and Isachsen). Because of this local variability in the active layer thickness and because of

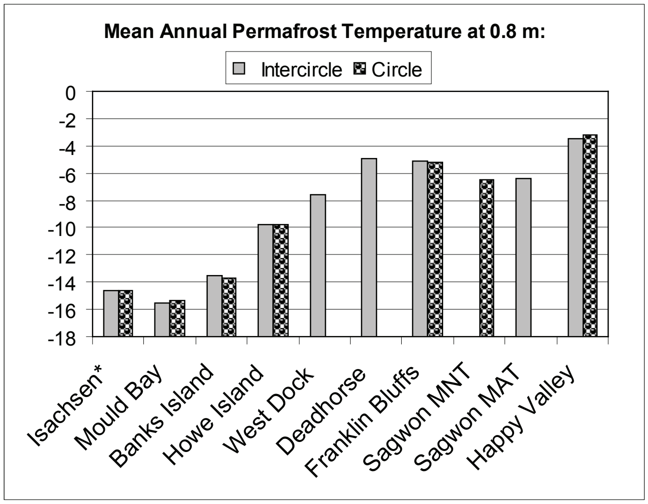

Figure 6. Mean annual soil temperatures (September 2004–August 2005, except for Isachsen, where temperatures were measured in 2005–2006) at 0.8 m depth at different sites along NAAT.

the differences in the timing of freezing, the ground surface experiences a significant differential frost heave, which is mostly responsible for nonsorted circle development.

Frost heave

Measured maximum frost heave within the circles vary between 18–20 cm at the Deadhorse and Franklin Bluffs sites and less than 3 cm at the Green Cabin site on Banks Island (Fig. 8). Frost heave in inter-circle areas was typically less than 3 cm and very seldom reached 5 cm. Frost heave was greatest in the centers of nonsorted circles on silty loess soils at Deadhorse, Franklin Bluffs, and Sagwon MNT (20, 19, and 15 cm, respectively) (Fig. 8). Intermediate amounts of heave occurred on the clay soils at Isachsen, and the acidic tundra sites at Sagwon MAT (9 cm) and Happy Valley (9.5 cm). Heave was least at West Dock (0.4 cm), where there was a thick organic soil layer and no patterned ground. Differential heave (difference in the heave on the circles and between circles) was also greatest at Deadhorse and Franklin Bluffs (17 cm), where there was strong contrast in the vegetation on and between the patterned ground features. Differential heave was least (0 cm) at Isachsen, where the zones between patterned ground features are very narrow. Generally low amounts of heave occurred in the sandier soils at Mould Bay, Howe Island (Fig. 2), and Green Cabin on Banks Island. Measured heave also varies significantly along the local topographical gradients illustrating the dependence of this process on local water availability. More information on governing physical processes responsible for frost heave and nonsorted circles formation and on numerical modeling of these processes can be found in (Nicolsky et al. 2008).

Conclusions

• A strong regional gradient exists in the air and soil temperatures along the North American Arctic Transect. Mean annual air temperature ranges between -10°C and

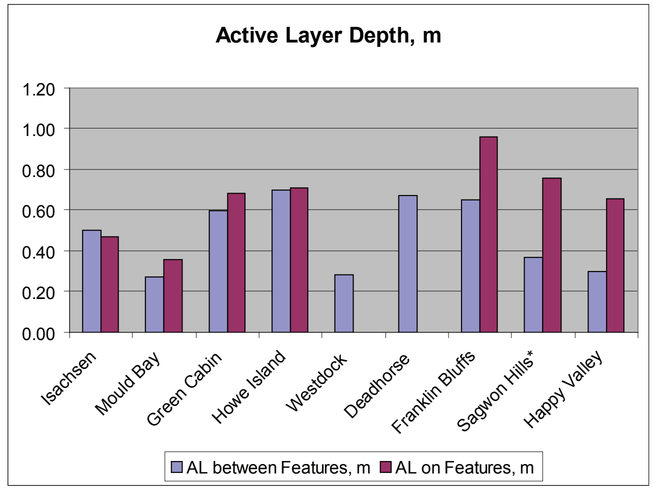

Figure 7. Maximum summer thaw (active layer depth) at the sites along NAAT.

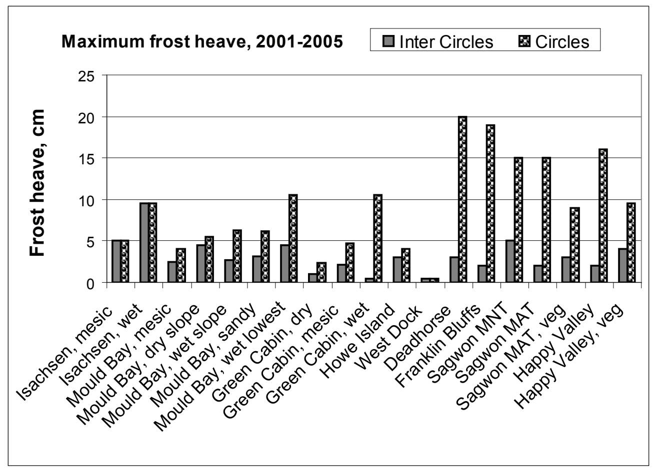

Figure 8. Maximum frost heave observed during period of measurements (2001–2005) at different sites along NAAT.

-16°C, while the mean annual soil temperatures are in the range between -2°C and -14°C.

• Snow cover differs significantly between the inland sites (Happy Valley, Franklin Bluffs), where the maximum snow depth is typically at 45–65 cm, and the coastal sites (Howe and Banks Islands, Mould Bay, and Isachsen) with 15–25 cm.

• Local differences in surface conditions (vegetation and snow cover, and soil physical properties, etc.) are associated with the nonsorted circles, which produce significant local differences in the active layer depth, soil freezing rates, soil ice formation (Nicolsky et al. 2008) and, as a result, a significant differential frost heave.

• The amount of seasonal heave is governed by the degree of these differences and by the water availability that changes along the local topographic gradients. The measured differential frost heave ranges between a few cm at mesic and dry sites to almost 20 cm at wet sites on the Alaskan Arctic Plain.

The Davidson Ditch – A Historical Review

James W. Rooney
J&F Rooney, LLC, Anchorage, Alaska, USA
Charles H. Riddle
R&M Consultants, Inc., Anchorage, Alaska, USA

Abstract

In the early 1920s, the Davidson Ditch project was initiated because of the need to develop an adequate water supply for placer mining properties on Cleary and Goldstream Creeks just north of Fairbanks, Alaska. The project, extending over a distance of 155 km along the Chatanika River drainage, was started in 1925 and completed in 1928. The water intake structure was located at the headwaters of the Chatanika River. Most of the project traversed permafrost terrain, and much of the ditch placement was located on sidehill terrain. There are still some remnants of the long-abandoned project some 80-plus years after construction. It is interesting that very little information has been provided through the years on the technical issues and facility performance, nor has any environmental assessment of the project's impact on terrain, vegetation, or regional infrastructure been addressed with regard to ground disturbance and continued climate-warming trends.

Keywords: Davidson Ditch; Fairbanks Exploration Company; global warming; permafrost; water supply.

Introduction

In the early 1920s, the Davidson Ditch project was initiated due to the need for developing an adequate water supply for the Fairbanks Exploration Company's (FE Company) placer mining properties on Cleary and Goldstream Creeks just north of Fairbanks, Alaska (Boswell 1979). James M. Davidson conceptually defined a plan and then surveyed a ditch route for collecting water along a major portion of the Chatanika drainage expected to supply water for development of the Fairbanks area dredge operations. Norman C. Stines, who believed in the application of cold water thawing of frozen gravels and who overcame considerable skepticism, with the support of the U.S. Smelting Refining and Mining Company (USSR&M), was the overall driving force that led to the Fairbanks area dredge mining activities. The Davidson Ditch was the key solution for attaining a sufficient water supply to support the planned development of the targeted placer mining areas (Stines 2006). In 1969, the senior author, while working on initial Trans Alaska Pipeline System (TAPS) route studies, had the opportunity to participate in a review of the Davidson Ditch project files at the FE Company's Fairbanks office and was impressed with the level of technical effort and some of the similarities between it and the proposed TAPS project.

Location and Concerns

The Davidson Ditch project, extending over a distance of 155 km along the Chatanika River drainage (as shown in Fig. 1), was started in 1925 and completed in 1928. The water intake structure, a small metal-faced dam, was located at the headwaters of the Chatanika River, just below the confluence of Faith and McManus Creeks. Most of the project traversed permafrost terrain. Because of the need to maintain a gradual flow gradient, much of the ditch placement was located on sidehill terrain facing south to reduce exposure to those soils having highly variable ice content. Even with the passage of more than 80 years following construction, there are still some remnants of the long-abandoned project. It is interesting that very little geotechnical and environmental information has been provided through the years on project issues and facility performance. Nor has much, if any, environmental assessment of the project's impact on terrain, vegetation, or regional infrastructure been assessed with regard to both current concerns and making future projections on manmade and climatic warming impacts. It seems apparent that both positive and negative impacts identified with this project could provide some relevant insight for our attempts to evaluate related climate-warming issues.

Project Infrastructure

This project involved construction of a 3.6 m wide main excavated ditch with a downslope fill berm. The main ditch had a gradient of 0.4 m/km and was 134 km in length. Two feeder ditches added another 9.7 km to the system. There were 15 valley-crossing siphons that had a total length of 9.8 km of steel lock-bar pipe with an inside diameter ranging from 1,168 to 1,422 mm. These siphons had a capacity to carry up to 212,340 liters of water at a maximum head pressure of 1,550 kPa. The length of the valley siphons extended from a minimum of 30 m to 1,128 m. Penstocks and flumes added an additional 0.6 km. Also, a 2.1 m square tunnel 1,128 m long was constructed between Vault and Fox Creeks.

Design Features

The project was designed by J.B. Lippincott, a consulting engineer from Los Angeles, California, who had prior experience on projects in areas with permafrost. His reports describe excavation of frozen muck containing pure ice

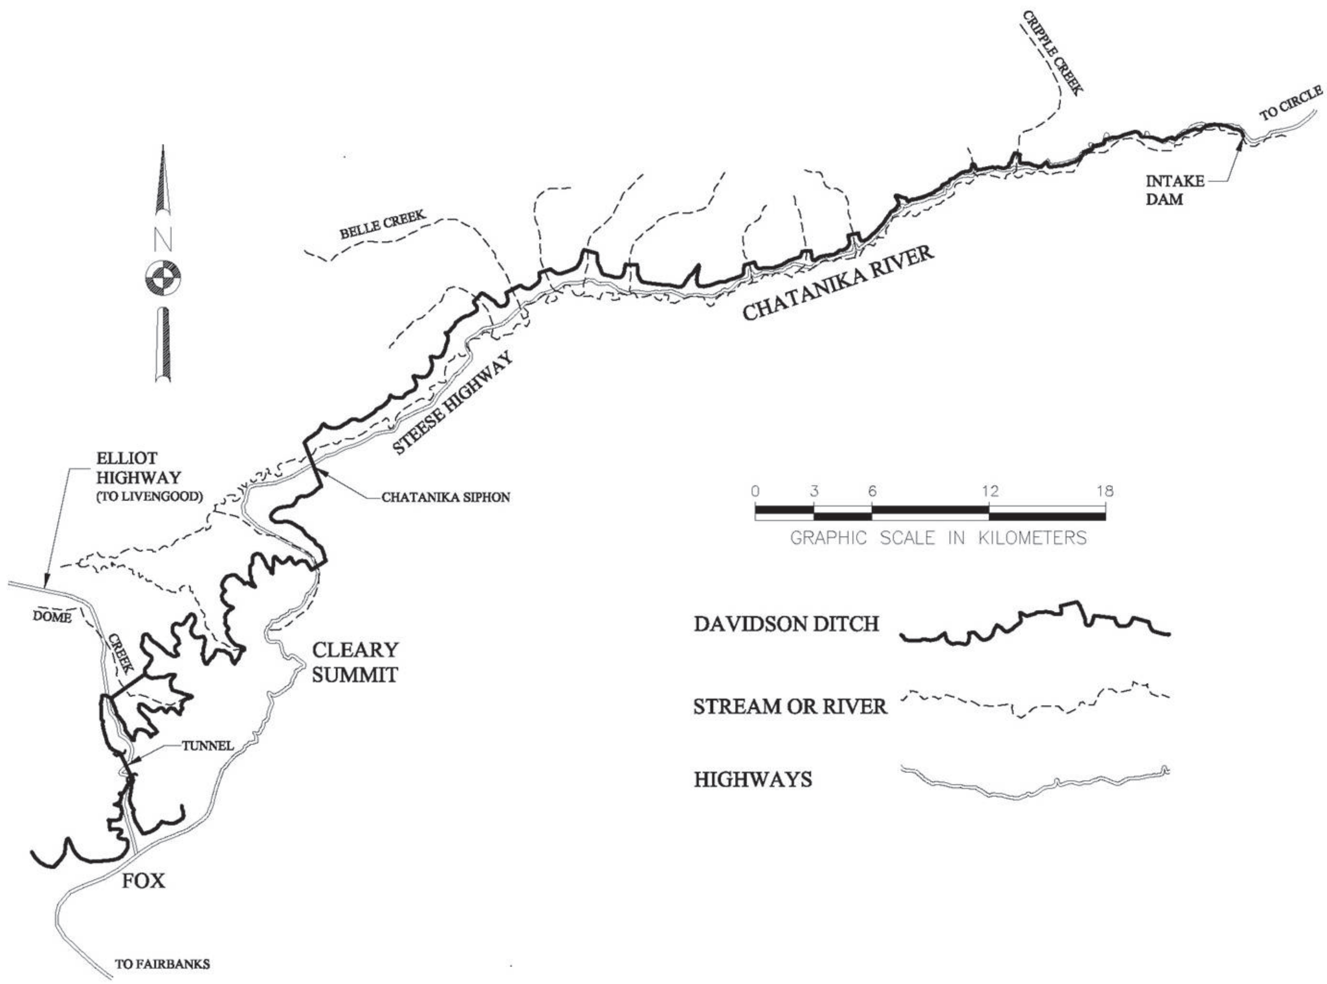

Figure 1. Davidson Ditch route map.

and silt soils having from 150 mm to 600 mm of organic mat overburden. The valley bottoms were described as containing soils with much higher ice content. Preference was given to the south-facing slopes to minimize exposure to the valley slopes that have higher ice content and face north. Concerns were also expressed with accomplishing the valley crossings on timber pile supported trestles with pile bents being spaced at 6 m. The timber piles were installed using steam jets and allowing pile freezeback, or were driven into competent soils to obtain pile support. Valley icing was a significant concern because of the possibility of pile flotation with spring breakup and flooding. The extreme effects of large temperature variation on the siphons were also considered. Temperature extremes of plus 37ºC to minus 57ºC and a full range of 94ºC were utilized to address expansion and contraction concerns along the siphons. Insulation of the pipe anchors to reduce ground warming was also addressed. Anchor systems were employed at the siphons to resist both anticipated vertical and horizontal forces associated with the potential for flotation, water flow, and temperature extremes. The anchors were installed midway between expansion joints.

A typical cross-section of the Davidson Ditch is shown in Figure 2. The construction zone width including the edge of clearing limits extended to over 15 m. Lippincott's evaluation of soil and permafrost conditions along the route, as quoted by Boswell (1979), in one of his reports follows:

> The material through which the ditch was excavated consisted of frozen muck, ranging from almost pure ice to almost solid silt, and covered with from six inches to two feet of moss; heavy slide rock, also covered with heavy moss; decomposed schist slide, usually covered with light moss; rock in place, but shattered so as not to require blasting; solid schist… The northern slopes of the hills are much more frozen than the southern ones… In this report, frozen ground is considered as distinct from the ancient glacial ice which contains but 20 to 30 percent of earth. Such ice is found usually in the valley flats.

The extent of earthwork involved in ditch construction, as summarized by Boswell, was:

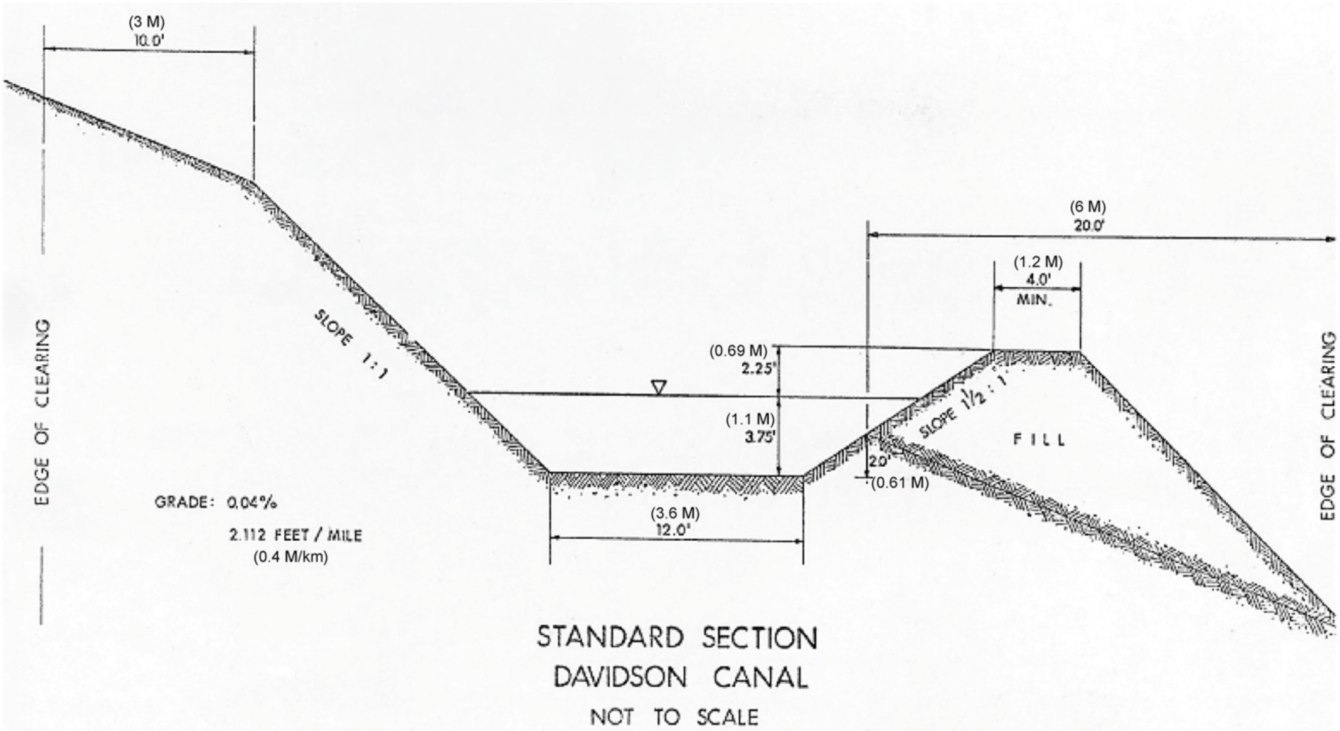

Figure 2. Davidson Canal standard section.

Soil and loose rock	1,455,324 y^3 (1,112,675 m^3)
Solid rock	118,401 y^3 (90,524 m^3)
Total:	1,573,725 y^3 (1,203,199 m^3)

The valley siphon crossings were accomplished through the frozen soils, noted in the above quote, using the pile bents to support the siphon pipe above flood flow levels and anticipated surface icing conditions. Other than comments on evident frost-jacking of the timber piles, little information has been provided on the overall performance of these pile supports. Each siphon crossing was restrained at the center point by a weighted and braced anchor system for restraining excessive siphon pipe movement. This restraint system was placed in an excavation of the frozen soil and supported as shown on Figure 3. While long-term performance of the anchor system appears to have been acceptable, it would be interesting to learn what ground conditions now exist after over 80 years.

Operation Issues

Operation of the ditch required considerable maintenance efforts as a result of ground deformation, soil and ice thaw instability, and berm washouts. Ditch tending personnel were utilized along the grade to maintain and repair the ditches throughout the summer. The ditches and siphons were drained each fall under controlled conditions in order to minimize potential sudden drawdown or freeze damage to the siphon pipe. The extent of ground thawing below and around the ditch construction zone over the period does not appear to have been documented and the current thermal state after over thirty years of abandonment is unknown. It would seem worthwhile to review current ground conditions, past climate as well as site-specific history in order to develop a better understanding of our modeling capabilities and improve our ability to define potential future project impacts.

The Davidson Ditch operated until it was closed in 1942, due to the closing of major placer mining during World War II. It was reopened in 1945. The Davidson Ditch was again in operation until 1952. At that time, the system was acquired by the Chatanika Power Company which utilized the water supply head, at approximately 1,068 N of pressure, to generate an average 9,000 MJ of electricity. The Davidson Ditch continued to function until August, 1967 when major flooding took out the arch bridge supporting the siphon and also collapsed over 213 m of uphill pipe.

Some project photographs taken during early operations, and shown in Figures 4 through 8, identify: the intake and diversion dam, siphon pipe, a typical siphon pipe support, anchor and outlet penstock, and the Chatanika River bridge that supported the siphon pipe.

Closure

Evidence of the ditch and some pile bents may still be observed along segments of the route. Photos of the abandoned project, taken by the senior author in the fall of 1970, are included as Figures 9 through 13. These identify some selected features that remained at that time. These include: the ditch itself, siphon pipe penstock inlet and outlet structures, and a siphon pipe valley crossing. The siphon pipe was salvaged in 1974 and many features of the project were obliterated (Fradley 1974). Consideration was given to making the Davidson Ditch a national historical site that would have

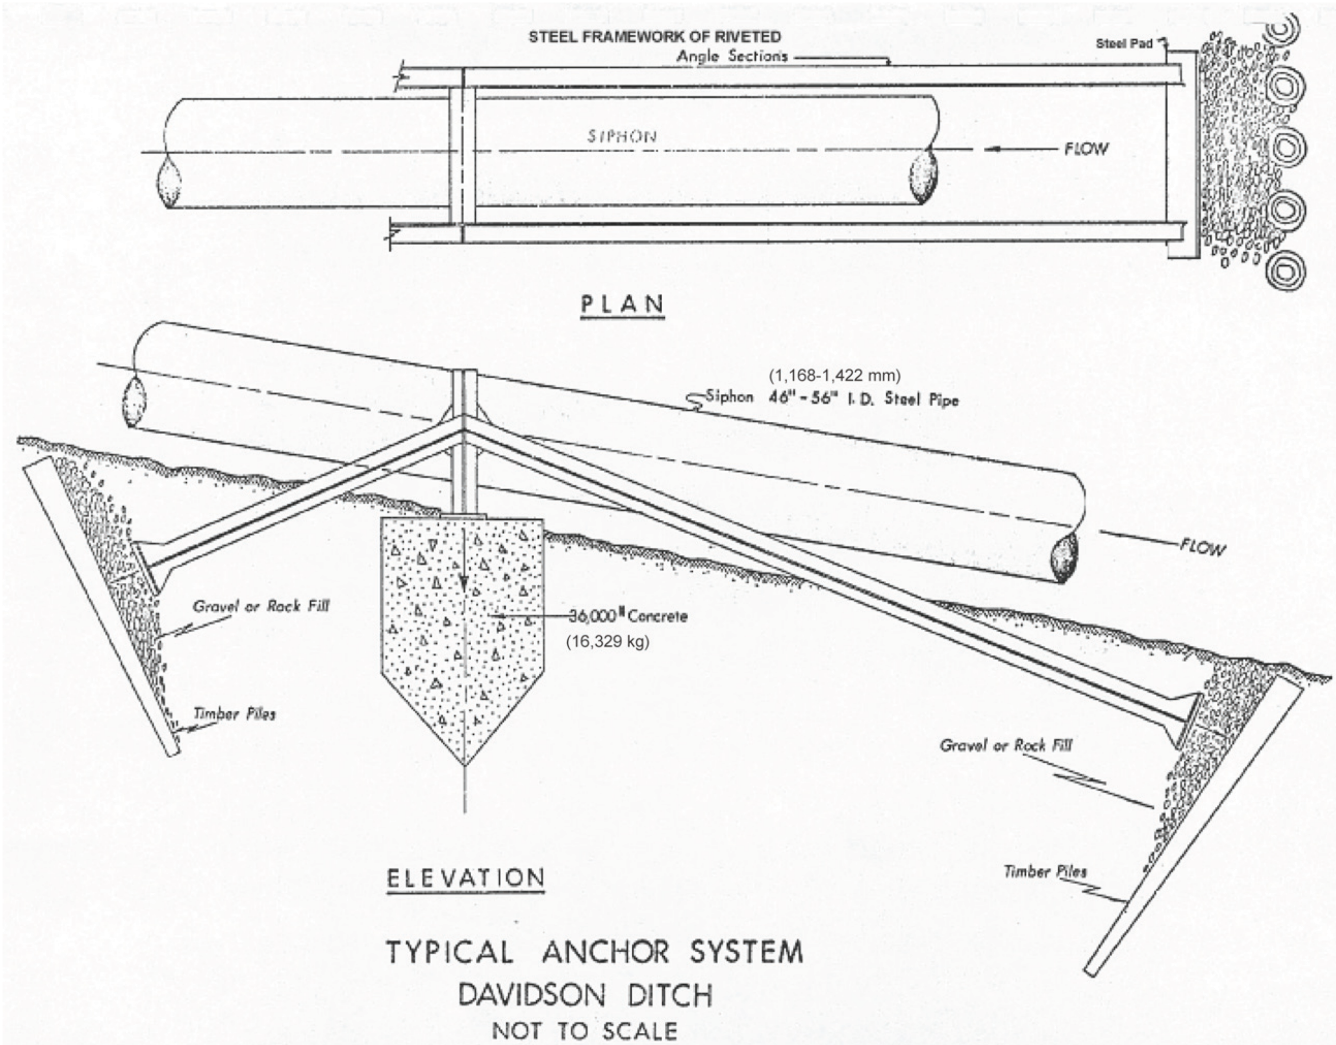

Figure 3. Davidson Ditch typical anchor system.

Figure 4. Intake and diversion dam at headwaters of Chatanika River.

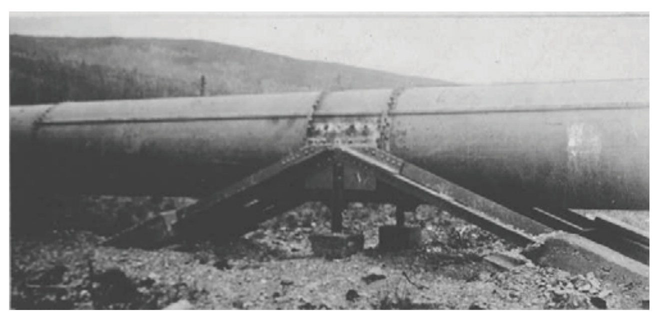

Figure 5. Typical siphon pipe anchor.

included a trail system along the route. Unfortunately, property ownership issues did not allow this to happen.

Details associated with the FE Company's earthwork effort and the economic impact of the Davidson Ditch because of its capability to deliver water to the Fairbanks mining region was documented by Boswell (1979) and Deyos (1925) as follows:

Est. stripping of overburden	7,000,000 y^3 (5,351,884 m^3)
Est. dredging of gravel	5,500,000 y^3 (4,205,052 m^3)
Est. initial investment	$10,000,000
(included cost of Davidson Ditch at $1,773,800)	
Est. total payroll 1926 to 1969	$50,552,175
Est. total gold value recovery (at $35/oz.) from all dredges in the Fairbanks area	$125,000,000

Most of the areas dredged by the FE Company were generally covered by frozen, relatively unstable soils that were totally modified by the mining operations. Much of the

Figure 6. Typical siphon pipe support on timber pile trestle bent.

impacted areas have since been developed and are now the site of both residential and business activities.

In closing, it seems the total socio-economic and environmental impact of the FE Company's Davidson Ditch operations should be reviewed and assessed for both historical value, its possible modeling value, and with regard to estimating any potential future impacts associated with climate-warming trends.

Abstract

We report on the detection of periglacial landforms at high mid-latitudes in the Thaumasia Highland (Mars) that are characterized by lobate to tongue-shaped flow and creep morphologies and which have a close resemblance to terrestrial landforms found in mountainous permafrost regions. It appears that pristine ice-related landforms are best described by small-scale protalus lobes, with few to no distinct impact craters at both HRSC and MOC NA scale. Exposure to solar insulation seems to control the distribution of rock glacier-like landforms, with a preferred occurrence on south-facing slopes. Older, less pristine lineated crater fills, which are commonly considered to represent landforms related to the viscous deformation of ice and debris, show, however, a less systematic distribution of flow directions. Both relatively young landforms are likely related to climatic variations on Mars orbital variations in its recent past and form the youngest witnesses of high obliquity.

Keywords: climate change; Mars; mid-latitudes; periglacial landforms; protalus lobes.

Introduction

Several landforms on Mars have been suggested to be related to the presence of ground ice (Mangold 2003, Squyres 1978, Squyres & Carr 1986), including lobate debris aprons, concentric and lineated crater fill and fretted terrain (Colaprete & Jakosky 1998, Lucchitta 1984, Squyres 1978). These landforms are commonly related to the creep of ice and debris as documented from various latitudes and in a varying geologic context (Crown et al. 2003, Head et al. 2005, 2006, Mangold 2001, Mangold & Allemand 2001, Squyres 1979, van Gasselt et al. 2007).

Large-scale features at the Martian fretted terrain and so-called lobate debris aprons have been primary candidates for periglacial landforms, but the availability of high resolution image and topography data over increasingly large portion of the Martian surface has allowed discovery and exploration of smaller features, comparable in size to terrestrial rock glacier systems. Recent landforms interpreted as glacial or periglacial have been described extensively also at tropical to equatorial latitudes on Mars (Head et al. 2006, Rossi et al. 2000, van Gasselt et al. 2007, 2008) during the last decade.

Also, the presence of ground ice has been indirectly assessed on Mars with non-image data by instruments such as the Neutron Spectrometer onboard 2001 Mars Odyssey spacecraft (Feldman et al. 2004): the large-scale inventory of potential ice-rich deposits in Martian soil indicates regional high abundances of thick bodies of ground ice, especially at mid to high northern latitudes.

Data and Methods

In the present work we used image and topographic data from different sources: MGS (Mars Global Surveyor) MOLA (Mars Orbiter Laser Altimeter) topographic data, MEX (Mars Express) HRSC (High Resolution Stereo Camera), and 2001 Mars Odyssey THEMIS (Thermal Emission Imaging System). In selected areas, we also used THEMIS visible (VIS) and MGS MOC (Mars Orbiter Camera) narrow angle (NA) images. HRSC-derived digital elevation models have been used as well (Gwinner et al. 2005). HRSC data, with their high spatial resolution and large swath, are well complemented by very high resolution MOC NA data. MOLA topography has been used mostly in the form of single profiles (Precision Experiment Data Records, PEDR), in order to avoid any resampling effect introduced during data gridding, because of the small scale (few km) of several of the studied landforms; gridded MOLA Mission Experiment Gridded Data Records (MEGDR) data were used in areas where profiles could not be extracted.

The nomenclature used here is descriptive, trying to avoid genetic terms or implications whenever possible. The

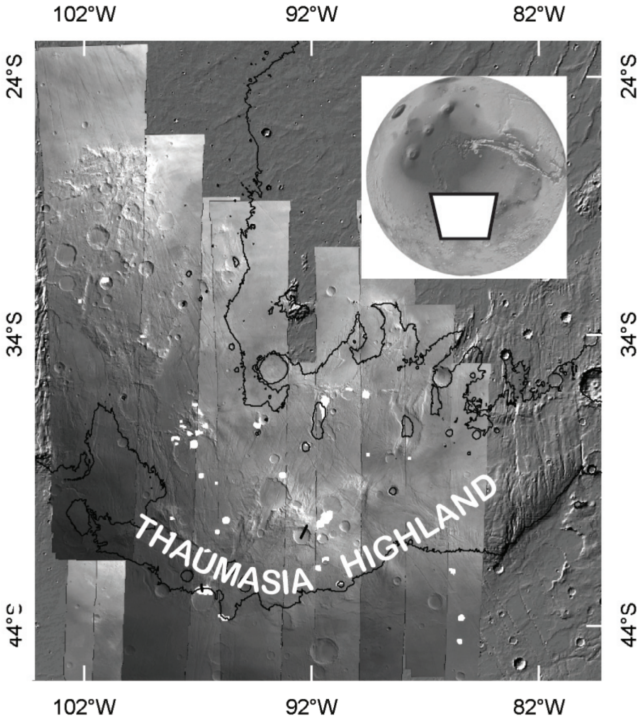

Figure 1. Location of possible periglacial landforms outlined in white, on top of HRSC Nadir Mosaic (Nadir channels from orbits 266, 279, 292, 344, 357, 380, 420, 431, 442, 453, 486, 497, 508, 530, 563) of Thaumasia Highland. The 4000 m altitude contour line is indicated in black; the background is a MOLA topography-based shaded relief.

terminology is similar to the one used by Whalley & Azizi (2003).

Thaumasia Geology and Geomorphology

The Thaumasia region on Mars located in the eastern hemisphere near 35° latitude is well known for its primarily volcanic and complex tectonic history (Fig. 1).

The Thaumasia region on Mars has a rich and complex geological history (Dohm et al. 2001, Dohm & Tanaka 1999). It comprises a tectonic plateau, characterized by high plains and dissected by various graben systems (Grott et al. 2007). In addition several smaller-scaled compressional tectonic features, such as wrinkle ridges (Dohm & Tanaka 1999) indicative of the volcano-tectonic history are observed frequently.

Among younger water-related surface features (Ansan & Mangold 2006), there is also an abundance of geomorphic evidence for cold-climate resurfacing processes such as a variety of periglacial landforms or glacial-like flows. Low latitude glacial or glacial-like morphologies have been described mostly from the northern hemisphere (Head et al. 2006), and recently also from the southern one (Dickson et al. 2006, Rossi et al. 2006),

The Thaumasia region was one of the areas on Mars where work on periglacial and glacial landforms is relatively sparse (Dickson et al. 2006, Rossi et al. 2006) which is predominantly caused by a substantial lack of high resolution data coverage (e.g., MOC) at the time when large-scale mapping efforts were started (Dohm et al. 2001).

Description of Study Area and Landforms

The study area spans in latitude from 25°S to 45°S. The altitude of identified ice-related landforms is more constrained, being in general higher than 4000 m above Mars MOLA datum with elevations as high as 5000 m. (Fig. 1).

Three main kinds of possible ice-assisted creep-related landforms have been found in Thaumasia Highland: lineated crater (and valley) fills, debris aprons, and protalus lobes.

Lineated crater fills

This group of features appears to be very widespread in the study area and was described initially from the northern dichotomy boundary and the southern-hemispheric impact basins (Squyres 1978, 1979).

There is a high abundance of impact craters larger than a few kilometers in diameter that show this peculiar surface texture in Thaumasia Highland.

Lineated crater and valley fills are usually associated to each other and form curvilinear ridges and saddles, usually arranged with slightly concentric to transversal geometries (Figs. 2A, 2C). Longitudinal ridges, similar to the ones present in fretted terrains (Squyres 1978) are usually not observed. Lineations appear as ridges and furrows arranged transversally with respect to the inferred flow direction. The surface texture of lineated fills is relatively rough. Circular to sub-circular features, possibly being degraded small impact craters (Fig. 2C) are visible within the infill. The lack of high-resolution data (e.g., in Fig. 2C) does not allow generalizations over the complete population of lineated craters. Circular to irregular depressions with unclear impact origin are also abundant in crater fills: they show a certain resemblance with thermokarst features (Costard & Kargel 1995).

Lineated and/or curvilinear crater fills on Mars have been interpreted as related to ice flow (Squyres & Carr 1986), or were alternatively attributed to eolian erosion (Zimbelman et al. 1989).

Most lineated fills are showing general slopes consistently with flow directions derived from morphology (Figs. 2A, 2B). The direction of flows in these crater fills shows a correlation to regional slope orientation but little to no connection to local exposure, unlike protalus lobes features as described below.

The actual thickness of these fills in not well constrained, since they appear completely contained within crater rims and no cross-section cuts are visible in the study area.

Debris aprons

Certain craters in the Thaumasia Highland are showing features with a strong resemblance with debris aprons (Colaprete & Jakosky 1998, Squyres 1978, Squyres & Carr 1986) (Fig. 3B). They are isolated or appear superimposed on lineated crater fills. These landforms often show concave upward profiles

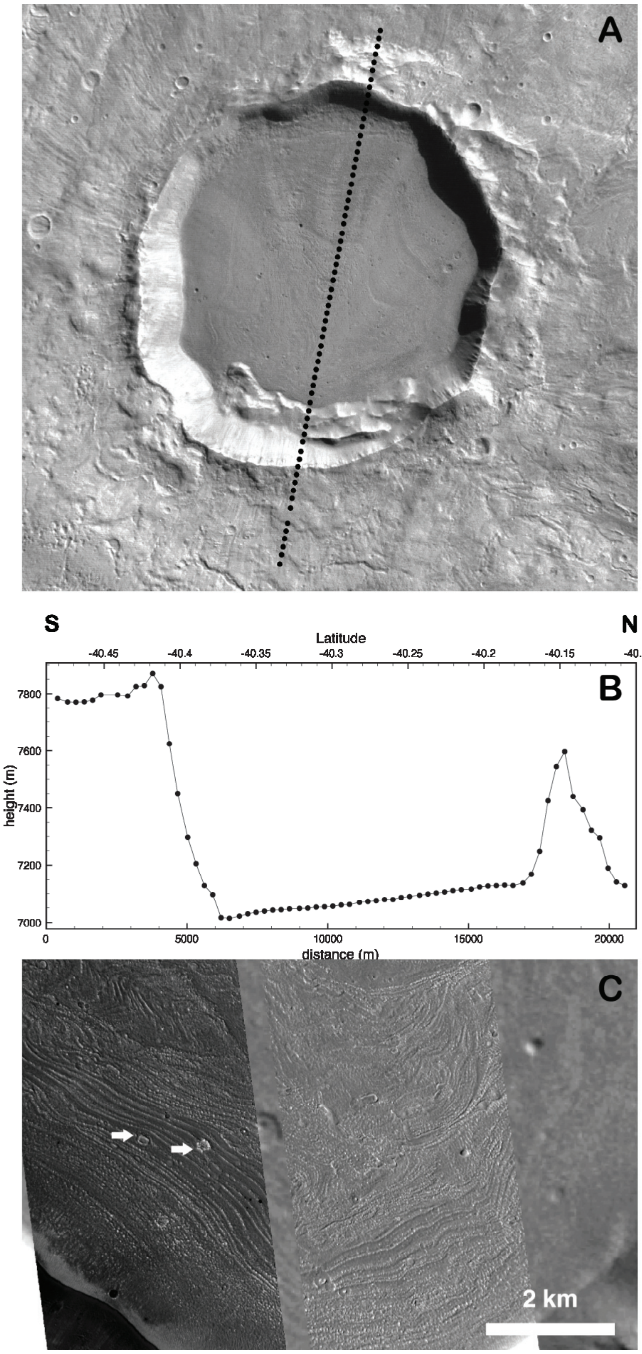

Figure 2. A) HRSC nadir from orbit 442 (north is up), the footprints of MOLA PEDR shots are indicated by black dots; the scene is about 20 km wide. The flow-like lineated crater fill is mainly emanating from the northern part of the crater. B) Portion of MOLA profile from orbit 19873: the lineated crater fill has an almost constant slope of about 0.5° southwards. C) Detail of the morphology of a lineated crater fills at MOC scale (HRSC orbit 508, MOC NA E1200147 and E0501814). Arrows indicate sample deformed (compressed) crater-like features embedded in the crater fill.

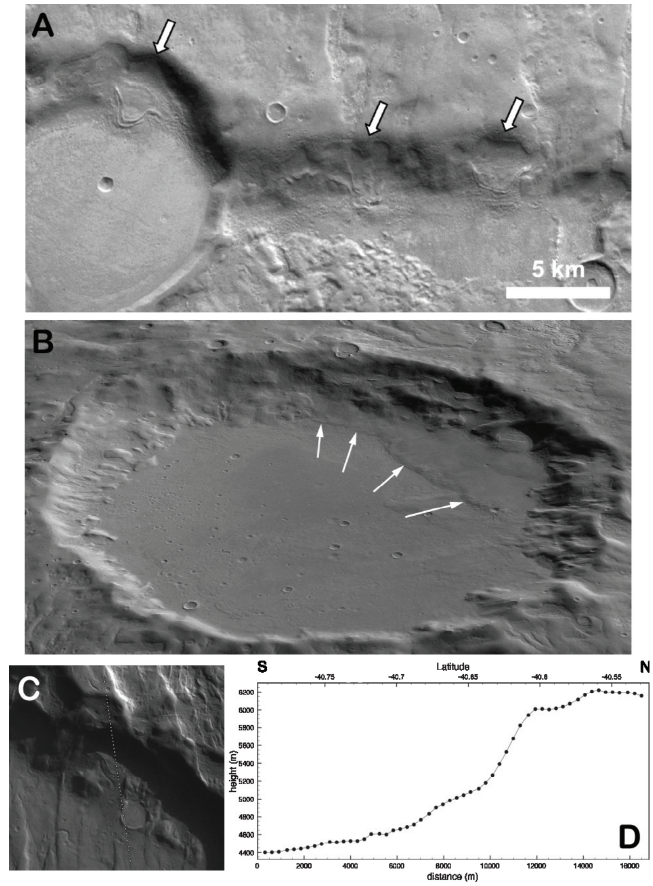

Figure 3. A) Example of well-developed protalus lobes, indicated by arrows (HRSC nadir band from orbit 292, north is up). These lobate forms are developed on crater floors or fills and linear slopes. B) perspective view of HRSC nadir from orbit 453 draped on HRSC stereo-derived DTM (Gwinner et al. 2005). Arrows indicate the edge of a concave debris apron. Small, apparently younger protalus lobes are located on the highest part of the rim, well above the debris apron. C) HRSC nadir from orbit 508, the footprints of MOLA profile shown in 3-D are indicated; the protalus lobe is facing southward and it's largely in shadow; the image is about 25 km wide; the lobate feature is about 5 km long; north is up D) Portion of MOLA PEDR profile from orbit 13002: The protalus lobe in 3C shows a convex upward profile, unlike some debris aprons such as the one in 3B. The inferred thickness for this particular lobe is about 200 m.

on MOLA and HRSC DTM (Gwinner et al. 2005) contrasting to large-scale features observed at the dichotomy boundary which usually are convex upward (Chuang & Crown 2005, Mangold & Allemand 2001, Squyres 1978, van Gasselt et al. 2008). They are characterized by smooth to moderately rough surface texture. Both in term of scale, apparent chronology, and degradation level, they appear to be transitional between larger, older lineated crater fills and smaller protalus lobes. They tend to emanate from south-facing slopes, but with a less clear correlation to the general direction of exposure when compared to protalus lobes.

Protalus lobes

Protalus lobes (Whalley & Azizi 2003) are the most common possible periglacial landform which could be found in the study area. They are characterized by multiple lobate concentric ridges. Their width usually exceeds their length (Figs. 3A, 3C), thus forming broad features along footslopes. Their total length is in most cases limited to few kilometers and few of them are just 2 to 3 km long (Fig. 3A).

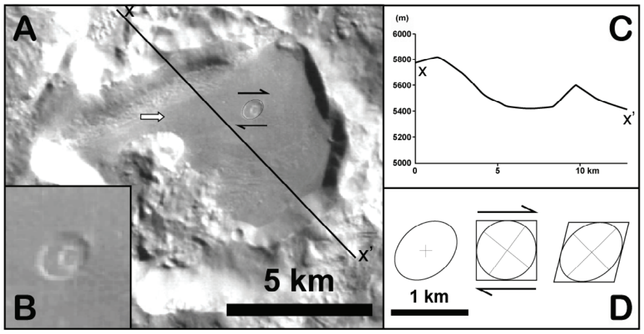

Figure 4. A) Example of possible finite strain of an originally circular impact crater. The black arrows symbolize the simple shear direction, and the white one indicates the directions of linear features in the crater fill with an azimuth consistent with the simple shear inferred by the elliptical crater-like feature; HRSC orbit 497. B) Enlargement of the apparently deformed circular feature (impact crater?) C) Topographic profile across the valley fill imaged in 4A from MOLA gridded topography: the local slope is consistent with the inferred direction of movement and the observed finite strain. D) Strain of a supposed originally circular impact crater under simple shear, hypothesized in this case.

Their texture is moderately rough as observed at scales of HRSC (~15–20 m/pixel resolution) and MOC (~3–5 m/pixel resolution): where high-resolution MOC image data are available, their surface even appears blocky.

Protalus lobes develop preferentially on south-facing slopes, both in case of linear south-facing scarps and northern impact crater rims. The apparent flow direction is from north to south. The correlation between exposure and development for protalus lobes is much stronger than for any other landforms discussed herein.

The impact crater density on these lobate landforms is very scarce: it is the lowest among all morphologies described here. This is also consistent with the observed geometrical relationship between all the different possible periglacial landforms in Thaumasia.

The thickness of protalus lobes can be evaluated using MOLA PEDR profiles: thicknesses range from a few tens of meters up to approximately 200 m (Fig. 3D).

In addition, features similar to protalus ramparts (Whalley & Azizi 2003) have been observed in various parts of Thaumasia Highland (Fig. 3). They appear less widespread than lobes. They tend to develop on top of other larger flow features, such as lineated valley fills.

Morphometric aspects—finite deformation of fills

Both MOLA altrimetric data (single profiles) and HRSC-derived DTM data have been used to characterize the morphology and morphometry of landforms in the Thaumasia Highland.

Crater fills are characterized by very gentle slopes, consistent with the flow direction that could be derived from morphological observations (Fig. 2). The slopes are usually less than one degree. The slopes of crater fills imaged in Fig. 2 are averaging at 0.6 degrees dipping southward. The more convex portion of protalus lobes shows a slope inclination of up to about 7 degrees (Fig. 3D).

Apart from the local disruption and deformation (Fig. 2C), some lineated crater fills show evidence of horizontal deformation/movement. In one case (Fig. 4), it was possible to measure finite deformation of a presently elliptical feature, interpreted as a deformed impact crater (Fig. 4B). Linear features in the crater fill units (Fig. 4A) show a direction consistent with horizontal simple shear, as deduced from the deformation of an original circular impact crater (Fig 4B). The simple shear deformation assumes area conservation on the surface of the fill, which appears to be a reasonable assumption. The assumption of an original circularity of the structure in Fig. 4B is also consistent with the observed crater features (at available resolution), which are ruling out an oblique impact event (an alternative explanation for such an oblique structure), because a hypothetical projectile with a 5–10 degrees incidence angle, needed to produce such an elliptical crater (Gault & Wedekind 1978), would impact on the outer rim before reaching its interior (Fig. 4C).

The finite maximum linear deformation (and linear movement within the fill) of the crater is of about 200 meters. The timescale is not well constrained. Also, the thickness of the deformed fill (and the vertical component of the deformation) is not well constrained.

Relative chronology

Lineated valley/crater fills appear to be the oldest feature among the ones described in the present study. Debris aprons and, later, protalus lobes are characterizing the most recent landscape evolution in the Thaumasia Highland area.

The relative chronology of the landforms in the study area indicates progressive shrinking of landforms confirming the ideas of ice-assisted creep and flow. This view is consistent with considerations of the preservation of morphologies and the local stratigraphic relationships (protalus lobes are clearly postdating lineated crater fills.).

Lineated crater fill units appear often from poorly to slightly altered by crater impacts. At several places, these units have a slightly deflated appearance, which suggests that the present fretted appearance is related partially to erosive effects, also suggesting again an older age of lineated crater/valley fills when compared to protalus ramparts and lobes.

Discussion and Conclusions

Our analysis shows distinct landform development through time in Thaumasia Highland. A generic sequence of periglacial landform development in the study area includes, in chronological order:

a) Large lineated crater fills (areas of ~150–170 km^2), containing possible thermokarst features.
b) Moderate debris aprons (areas of several tens of km^2), with a general “deflated” appearance.
c) Small protalus lobes with little to no impact craters visible at available image resolutions (lengths of ~2–5 km).

d) Locally very small protalus ramparts (several hundred meters to few kilometers in size).

Crater-size frequency analyses to deduce absolute ages will produce unreliable absolute ages due to high degradational effects as well as due to flow deformation of surfaces. The very small size of discovered protalus lobes makes absolute dating even more difficult. Geometrical and stratigraphic relationships are in any case showing a sensibly more recent age of small protalus lobes with respect to lineated crater/valley fills.

Also, the size of these two main groups of landforms is very different: lineated (and sloping) crater fills are large, up to more than 100 km^2, while protalus lobes are usually covering areas of not more than 5–10 km^2.

The flow direction inferred from lineated crater fills show little to no correlation with slope orientation, being more correlated with local and regional topography. On the other hand, mostly concave-upward debris aprons and mostly convex-upward protalus lobes are developed preferentially on south-facing slopes, suggesting a stronger and temporarily closer role of morpho-climatic conditions during their development. This is consistent with previous observations on glacial/periglacial features at mid to low-latitudes (Head et al. 2005).

In the Thaumasia highlands, the dominant concave-upward profile of debris aprons (Mangold & Allemand 2001, Squyres 1978), where present, is indicative of a past scenario involving the melting of ice-cored rock glaciers or debris-covered glaciers (Clark et al. 1994). Contrasting to this, protalus lobes mostly show clear convex-upward profiles (Fig. 3D), which together with their apparent relatively young age is indicating that they might have been active recently or might even be active today.

Although the nature and evolution of such landforms are often controversially discussed, there is observational evidence that the existence and evolution of such landforms is related to climatic variations controlled by the orbital configuration of Mars (Forget et al. 2006, Laskar et al. 2004, Murray et al. 1973, Ward 1974), which was responsible for the deposition of equatorial ice during high-obliquity phases and depletion of an ice reservoir during periods of low obliquities.

The Thaumasia highlands provide the geomorphologic settings necessary for formation of creep-related landforms due to an abundance of high-relief slopes and tectonically dissected terrain allowing accumulation and supply of wall-rock debris at footslopes.

We identified flow and creep morphologies exhibiting a lobate to tongue-like shape and which are characterized by linear to curvilinear ridges and furrows closely resembling large-scale gelifluction lobes or terrestrial rock glaciers and protalus landforms indicative of periglacial environments.

The general lack of impact craters suggests young surface ages. Although water ice is not considered to be stable at equatorial latitudes on Mars today, there are morphologic indicators suggesting re-activation and/or even initial formation of such landforms in the transitional belt between equatorial latitudes and mid-latitudes on Mars during geologically recent times.

Acknowledgments

We thank the HRSC Experiment Teams at DLR Berlin and Freie Universitaet Berlin, as well as the Mars Express Project Teams at ESTEC and ESOC, for their successful planning and acquisition of data as well as for making the processed data available to the HRSC Team. We acknowledge the effort of the HRSC Co-Investigator Team members and their associates who have contributed to this investigation in the preparatory phase and in scientific discussions within the Team.
