Stone Frost Mounds in Shallow Bedrock Depressions at Lady Franklin Point, Victoria Island, Nunavut, Canada

Vladislav E. Roujanski
EBA Engineering Consultants Ltd.

Abstract

Unusual terrain features that resemble partially collapsed miniature pingos or stone rings have been recently observed at Lady Franklin Point, Victoria Island, Canada. These features tend to occur in clusters within shallow partially water-filled depressions underlain by frost-shattered flat-lying dolostone bedrock. The mounds are round or oval in shape, 0.5 m to 3 m in diameter, and up to 0.6 m in height. The origin of these mounds is likely associated with frost action. A distinctive central hollow portion of the mounds, partially filled with water, observed in summer at one of the two studied sites is indicative of the seasonal occurrence of an ice core that forms in winter and melts away the following summer. The seasonal formation of an ice core results in doming of the horizontally-lying flat rock fragments. The mounds observed at this site appeared active, and were characterized by loose frost-heaved flat rock fragments and a lack of vegetation. The mounds at another site resembled miniature pingo remnants with a collapsed central portion and well-defined low circular ridge composed of cobble to silt-sized material covered with vegetation. The center was marked by a small shallow depression. At first glance, these features may be viewed as a variety of a frost blister, i.e., a seasonal frost mound. However, unlike a frost blister, which usually develops in finer grained soils and collapses when its ice core melts out, the Lady Franklin Point stone frost mounds remain prominent micro terrain features for a relatively long time because the flat angular fragments of rock do not readily settle back upon melting of the ice core in summer. Therefore, morphologically speaking, the Lady Franklin Point stone frost mounds are a perennial geocryogenic phenomenon.

Keywords: dolostone bedrock; frost action; frost blister; pingo; stone frost mound; stone ring.

Introduction

Lady Franklin Point is an east-west oriented peninsula located on the southwest end of Victoria Island, in the Canadian Arctic (Fig. 1). The peninsula is about 11 km long by 4.5 km wide. The low-lying coastal landscape (the highest point is approximately 15 m above sea level) is dominated by raised beach ridges composed predominantly of gravel- and cobble-sized material with boulders disseminated throughout. Individual ridges are separated by swales or broad level areas dotted with shallow lakes and dry lake depressions. Complexes of the raised beach ridges found in the central part of the peninsula mark former strandlines (Fig. 1).

Over half the peninsula area, mainly the northern portion, is underlain by partially exposed Early Palaeozoic dolostone bedrock: flat-lying and jointed, locally frost-shattered, fractured, frost-jacked, or blanketed by recent marine sediments (mainly gravel and sand) up to 3 m thick. A veneer of glacial clay approximately 0.3 m thick covered by a blanket of marine sand and gravel was encountered at the top of shallow bedrock in one location just north of the existing airstrip. The southern portion of the peninsula consists of low-lying areas underlain by recent lacustrine deposits.

Unusual terrain features that resemble partially collapsed miniature pingos or stone rings were observed in water-filled or partially dried depressions underlain by weathered bedrock. This paper discusses the suggested origin of these landforms and other terrain features found at Lady Franklin Point.

Methods

The descriptions of the permafrost terrain features discussed in this paper are based on ground observations combined with aerial photography and satellite imagery (Google Earth and IKONOS) interpretation.

Stone Frost Mounds

Small distinct mounds were observed at two locations visited by the author of this paper in summers of 2003 and 2004 referred to as Site 1 and Site 2 (Fig. 1). These landforms tend to occur in clusters within shallow, partially water-filled depressions underlain by frost-shattered flat-lying dolostone bedrock (Figs. 2, 3).

The mounds are round or oval in shape, 0.5 m to 3 m in diameter, and up to 0.6 m in height. They resemble partially collapsed miniature pingos (Photos 1 and 2) or stone rings (Photo 3). The formation of pingos is explained in great detail by Mackay (1973, 1979, 1985), Washburn (1973) and others. The origin of stone rings and sorted circles is thoroughly discussed by Washburn (1973), Williams & Smith (1989) and others. The mounds found at Lady Franklin Point are also associated with frost action; however, the mechanism of their formation is different from either pingos or stone rings.

A distinctive central hollow portion of the mounds, partially filled with water, observed in summer of 2003 at Site 1 (Fig. 2, Photos 1 and 2), suggests the seasonal occurrence of an ice core that forms in winter and melts away the following

Figure 1. Location of study sites, Lady Franklin Point, Victoria Island.

summer. The mounds observed at this site appeared active and were characterized by loose frost-heaved flat rock fragments and a lack of vegetation.

A cluster of stone mounds observed at Site 2 in 2003 and 2004 (Fig. 3, Photo 3) is located in a shallow lake depression. The mounds at this site resemble stone rings or miniature pingo remnants with a collapsed central portion and well-defined low circular ridge composed of cobble to silt-sized material. Stones comprising the ridge are lichen-covered with vegetation present both on the ridge and in the central concave area (Photo 3). According to Washburn (1973), the presence of vegetation indicates that the mounds are inactive, which may be associated with drying out of the lake at Site 2.

The formation of the Lady Franklin Point stone mounds is likely the result of frost action. The seasonal formation of an ice core results in doming of the horizontally-lying flat rock fragments. Loose angular pieces of the underlying frost-shattered bedrock are displaced upward by frost jacking and thrusting and undergo some frost sorting. At first glance, these landforms may be viewed as a variety of a frost blister, i.e., a seasonal frost mound. However, unlike a frost blister, which usually develops in finer-grained soils and collapses when its ice core melts out, the Lady Franklin Point stone frost mounds remain prominent micro terrain features for a relatively long time because the flat angular fragments of rock do not readily settle back upon melting of the ice core the following summer. Therefore, morphologically speaking, the Lady Franklin Point stone frost mounds are a perennial geocryogenic phenomenon.

Other Frost-Modified Terrain Features

Linear fractures several hundred meters long and up to 0.5 m wide were observed in several locations within the flat surface of partially exposed dolostone bedrock. The appearance of the fractures suggests that frost action plays an important role in their formation: frost-shattered rock blocks near the ground surface, which form the edges of the fractures, appeared tilted upward by frost jacking and spread out by ice wedging and frost thrusting (Photo 4). The edges of the fractures are slightly raised above the surrounding flat-lying bedrock surface covered by mossy tundra.

Photo 3. Site 2. A cluster of stone frost mounds located in a shallow water-filled dolostone bedrock depression. A raised beach ridge in background. Lady Franklin Point, south Victoria Island. Photo taken August 27, 2003.

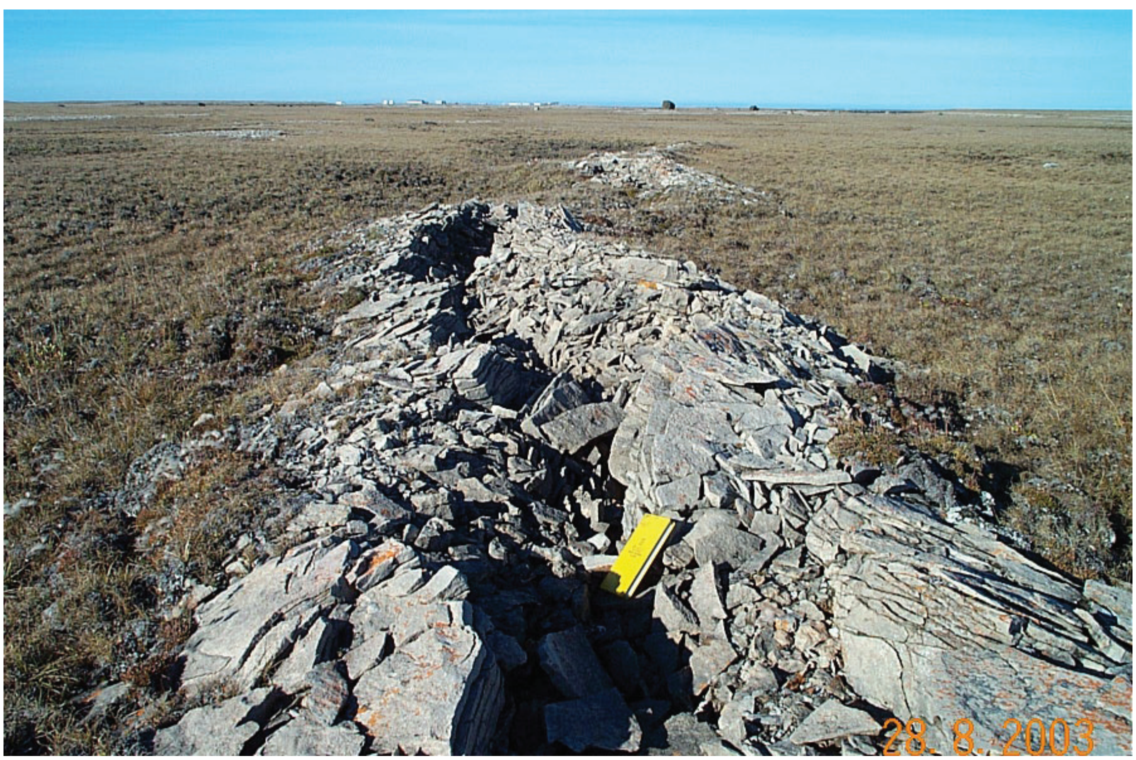

Photo 4. A frost-modified fracture in partially exposed dolostone bedrock. Lady Franklin Point, south Victoria Island. Photo taken August 28, 2003.

Conclusions

Frost action is an important geomorphic process at Lady Franklin Point resulting in unusual terrain features: stone frost mounds and frost-modified fractures in exposed bedrock.

The Lady Franklin Point stone frost mounds result from cycles of seasonal thawing and freezing in the saturated frost-shattered uppermost layer of the flat-lying dolostone bedrock. Thus, they can be considered a seasonal feature. However, morphologically speaking, they are perennial landforms that remain prominent micro terrain features for a relatively long time.

Arctic Road Research Program: Experiences and Implementation

Seppo M.I. Saarelainen
Senior Research Scientist, Technical Research Centre of Finland VTT, Espoo, Finland

Abstract

In the Arctic Road Research Program, experimental construction was carried out on the Main Road 21 in Kilpisjarvi, Northern Finland, in the years of 1986–87. The aim was to reduce or mitigate various problems caused by cold climate. The themes of test construction were as follows: control of frost-heave damage, reduction of thaw settlements of a road on permafrost, reduction of snow accumulation on the pavement, and control of icing on the pavement. According to the experience gained, frost protection at frost heave sites had functioned according to the design, and the tested materials can be used in the frost protection of road pavements, at least in the conditions of Main Road 21, Kilpisjarvi. The rate of thaw settlement of the road on permafrost had been markedly reduced. Snow accumulation on the pavement had been reduced significantly. Ice accumulation on the pavement was not observed after the experimental repair of the worst sites. The methodical experience and knowledge was seen necessary to implement and apply in the guidelines of pavement planning and design in Finland.

Keywords: design; frost heave; naled control; pavements; permafrost; snow accumulation; test construction.

Introduction

Finland is located between latitudes 60 and 70°N, and the annual mean air temperature varies between +4°C in the south and -3°C in the north. Discontinuous permafrost is found only in Northern Lapland, mainly on peatlands and fjell plateaus. Precipitation is about 350 mm/year, and the terrain is treeless tundra.

The problems are mostly manifested of the maintenance of main roads from Finland to Norway, where winters are long enough to cause problems with excessive frost heaving and naled formation, causing pavement damage and traffic safety problems (Saarelainen & Vaskelainen 1988). Permafrost, lying and thawing under the road, causes settlements, and the open terrain with high wind speeds benefits snow accumulation on the pavement. Further, indications of deficient stability of thawing fjell slopes were detected.

To find a better solution to pavement structures, a test construction program was carried out at Kilpisjarvi, Northern Lapland, at 67°N in the years of 1986–87. (Saarelainen 1993a, 1993b, 1993c, Saarelainen & Vaskelainen 1995, Saarelainen & Onninen 2000). The sites were selected according to the investigations, test pavements were designed according to the site conditions, and after construction, test pavements and structures were monitored, primarily over two years, and later in longer intervals (Fig. 1).

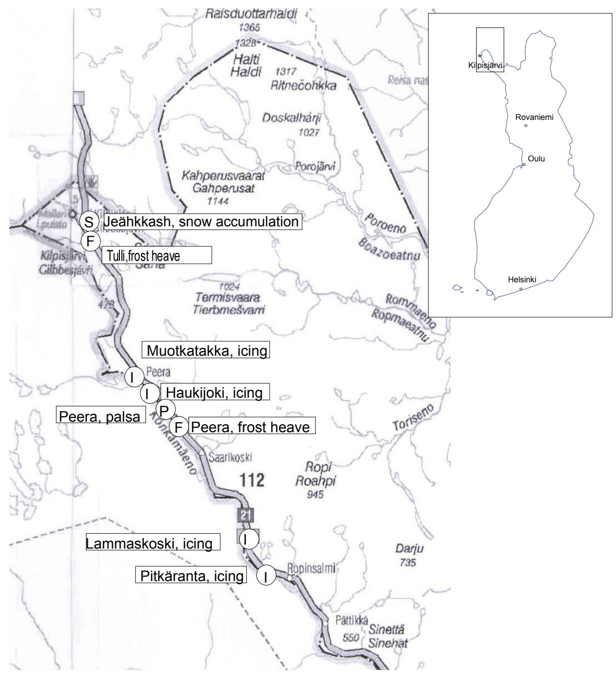

Figure 1. Arctic Road, Kilpisjarvi. Site locations.

Outline of the Problems

Frost heaving

Pavement damage and roughness, resulting from large and uneven frost heaving were found at some road stretches constructed on subgrades of silts and silty tills. The measured normal heaves varied up to 300 mm with seasonal frost penetration up to 3–4 m. At the Kilpisjärvi meteorological station in the period of 1931–1960, the annual average air freezing index was about 43,000 Kh (deg-hours), and the maximum freezing index, occurring once in 10 years, has been about 55,000 Kh (deg-hours).

Thaw settlements

Settlements due to thawing permafrost were found at some peatland sites, which also were characterised with palsa-mounds. The road line, crossing a palsa, had settled about 1.8 m since it was paved in 1982 with a settlement rate of 80 mm/y. The depth of permafrost at the site was about 7–8 m. The frozen subgrade consisted of frozen peat, that was compressed about 70% based on thaw-compression testing. The old road surface prior to paving was dark oiled gravel.

Snow accumulation

Excessive snow accumulation had been met during years in the pavement maintenance in an open mountainous terrain, where wind speed may rise considerably. The snow densities were low due to cold, continuous winters. Accumulation was most severe in road-cuts along the hill slopes. Snow plowing was normally started in December. The traffic suffered also from reduced visibility (white-out) during severe winds and storms. Along the test road, snow depths along the road profile and in transverse sections were measured. The recorded maintenance of snow accumulation started when the measured wind speed exceeded about 5 m/s or after a snowfall of 50 mm.

Naled formation

In cold winters, like in the late 1980s, ice accumulation had been observed, causing expensive maintenance work. Problematic sites were located either on a road section along a hill slope or on a road crossing a watercourse, stream, or river. Indicated problems resulted from disturbance in the winter drainage. Groundwater continued flowing during the winter in the ground below the seasonal frost. If the frost penetrated to or below groundwater level, groundwater was forced onto the ground and snow surface where it froze. In a local natural watercourse, water flow froze from bottom up and formed ice dams that forced the water onto the surface to freeze. In more southern regions, road culverts are filled with ice in wintertime. Ice-filled side ditches and bridge or culvert openings may flood over during quick snowmelt in spring and cause erosion damage and traffic risks on the road.

Solution of the Problems

Frost heaving

At selected sites, test pavements were designed so that the frost heaving in a design winter (maximum once in 10 years) was less than 50 to 70 mm. The design was done applying “Segregation potential concept” (Konrad & Morgenstern 1981)

$$\frac{\partial v_w}{\partial t} = SP\frac{\partial T}{\partial z} \tag{1}$$

where $\frac{\partial v_w}{\partial t}$ is flow of water from unfrozen soil to the freezing zone, $\frac{\partial T}{\partial z}$ is the thermal gradient in the freezing zone, SP is the coefficient of proportionality, segregation potential.

The frost heave was calculated using a layered finite-difference program SSR that solves, in time intervals, a balance equation of heat at the freezing front (Saarelainen 1992). This is based on the surface temperature and thermal properties of the layered horizon and results in calculating the frost penetration and frost heave in time. With the same procedure, the segregation potential (SP) was back-estimated and compared with the estimated frost penetration and levelled frost heaving of the old pavement during the winter of 1985–86. The back-estimated segregation potential varied between 0 and 7 mm^2/Kh.

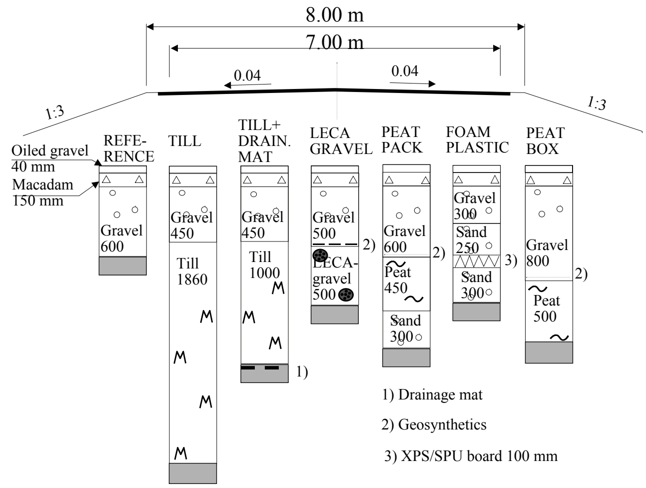

Figure 2. Tulli. The material layers of different frost-protected test pavements.

The aim of the test pavements was to study the applicability of different frost protection materials, like extruded polystyrene (XPS), LECA-gravel (lightweight expanded clay aggregate), prepacked and dried peat, local dried peat, and a slightly frost-susceptible sandy till. The layer thickness needed in frost protection was determined in the individual design. The frost heaving as well as SP varied along the line greatly, and the structures are not quite comparable with each other. The mechanical design of the pavement was carried out according to the actual road standards (minimum surface modulus during thaw more than about 170 MPa).

Structures with layer thicknesses are illustrated in Figure 2.

The test pavements were constructed in summer 1987. The frost protection materials were transported from southern-central Finland except for the local till and local peat.

Thaw settlements

Permafrost could be seen in the terrain in the form of frost mounds and palsas on peatlands. The average annual air temperature according to long-term climatic observations was about −3°C, and the elevation is about +400 m above sea level. The area is in the discontinuous alpine permafrost zone.

According to temperature profiling and electric soundings, the thickness of palsa below the test site was about 7–8 m. The top layer below the old pavement consisted of frozen peat with ice content about 50–95% by volume and thaw-compression of more than 70% under compressive stress of 25 kPa.

The test pavement contained, besides an overlay of 700 mm of gravel and asphalt, insulation of XPS, underlain with a gravel layer of 500 mm. The thickness of XPS (100 mm) was analysed using an analytic thermal FEM program, ADINA-T. The analysis with a given insulation thickness was conducted over three calendar years with the objective

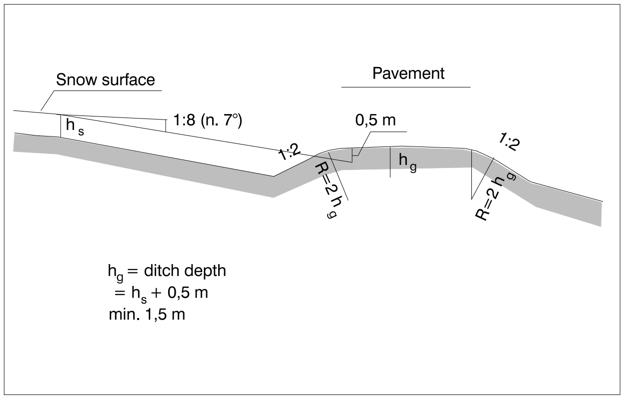

Figure 3. Type transverse profile to prevent snow accumulation on pavement in a sloping terrain.

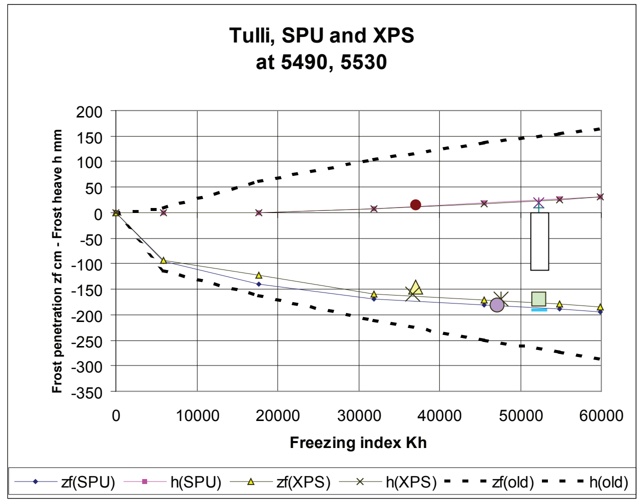

Figure 4. Tulli, the estimated and observed frost penetration (zf) and frost heaving (h) of polyurethane (SPU), and polystyrene (XPS) insulated test pavements.

that the thaw should not penetrate to the underlying frozen and thaw-sensitive subgrade.

The old pavement was removed in autumn 1986, and the new pavement with insulation was constructed in May 1987. The test section was paved in the next summer.

Snow accumulation

To reduce snow accumulation, the new pavement grade was raised above the estimated maximum snow level. The snow level was measured during the previous winter along the road. (Because the observed snow thickness at the Kilpisjärvi meteorological station was maximum occurring once in 10 years, the measured snow surface level at the site corresponded also to a maximum snow level, occurring once in 10 years, see Byalobzhenskiy 1983). Applying the observation statistics of snow thickness from a neighbouring observation station, this interpretation can be done for snow depth observations at a road site. The pavement surface was set 0.2–0.5 m higher than the estimated design snow level. Because the test road was located along a mountain slope, the transverse profile of the road was smoothed with curved shoulders and the upslope ditch was widened to provide a storage area for the accumulation of snow (Fig. 3).

The snow fences installed previously were removed.

Naled formation

Improvement of winter drainage was tested at four sites, two of which were slopes with groundwater icing problems and two with watercourse icing.

The principal improvement at groundwater icing was to collect the water into subsurface drains in the upper terrain below the estimated frost penetration and to drain it into a deep insulated pipe across the road.

The principal improvement at the watercourse icing site was to lead the upstream water flow through the road into a deep insulated pipe installed below the seasonal frost depth.

The drainage installations were constructed in 1987, and no pavement icing needing maintenance measures has been observed since then. Tested approaches have been successfully applied in road maintenance operations in Finnish Lapland since then (Kaitala et al. 2007).

Experiences after Construction

Frost heaving

The calculated frost heaving and frost penetration vs. freezing index are illustrated in Figure 4 for the test pavement with frost insulation boards. Observed frost heaves and frost penetration of different winters (1987/88, 1988/89, and 1989/90) have also been marked. A reasonable match can be seen that the applied calculation model SSR reasonably estimated actual frost heave and frost penetration, and that the material characteristics applied in the analysis were of correct magnitude.

For different frost protection materials, the following estimated characteristics were summarized in Table 1.

According to the observations, the frost heaving and frost penetration corresponded well to the calculated values. This confirmed the validity of the calculation model, the back-estimated frost-heave parameters (segregation potential), and the insulation properties of the applied materials. A more comprehensive presentation of the test pavements is included in the site reports (Saarelainen 1993, 2002).

Thaw settlements

The settlements were observed along the road centerline. Observations are illustrated in Figure 5. During the first years, the pavement surface was light-coloured, and the maximum annual settlement was about 10 to 20 mm/y. After the road was paved with dark asphalt pavement, the rate of settlement increased to a maximum 30 mm/y.

It is obvious that in these marginal permafrost conditions, thaw can be decreased with thermal insulation and light-coloured surface. For further reduction, active cooling might be useful. The rate of settlement in this actual case was reduced to a level that could be maintained by normal road maintenance.

Table 1. Characteristics of applied frost insulation materials (Saarelainen 2002).

Material	Dry density kg/m³	Moisture content w_{vol}, %	Frozen thermal conductivity λ_f, W/Km Estim.	Obs.
LECA-gravel	300	7	0.2	0.2
Packed peat	300	10	0.5	0.7
SPU	40	4	0.035	0.035
XPS	38	0,4	0.035	0.035
Local peat	200	60	1.0	1.0

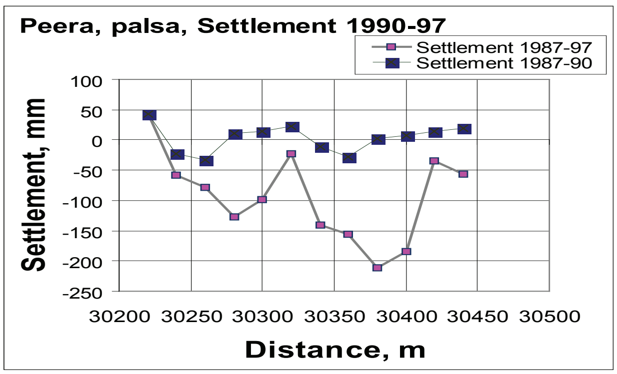

Figure 5. Peera, palsa. Pavement settlements since construction in 1987 until 1990 and 1997.

Snow accumulation

Before repair, snow and ice removal was needed by December. After the road was raised, the wind was observed to keep the pavement free from snow over the winter. In most severe winters with a very thick snow cover, heavy maintenance was still necessary as late as March.

The following recommendations to reduce snow accumulation were seen as appropriate:

- the pavement surface should be raised more than 0.5 m above the maximum design snow level,
- in a sloping terrain, a spare space for snow accumulation should be planned in the cut upslope,
- the pavement shoulders should be rounded to minimize wind turbulence on the road, and
- snow fences may still be necessary to maintain visibility during snowstorms

Naled formation

Ice accumulation in the road ditches was monitored after the repair. The ice accumulation was clearly reduced, and it did not cause any further maintenance effort, although winter temperatures were still severe.

In conclusion, the following recommendations are appropriate:

- Groundwater icing can be reduced with deep drainage in the upper terrain, and draining the water through the road in a deep thawed pipe.
- Surface water icing can be reduced or prevented by leading the water flow in the watercourse into a thermally-insulated deep culvert across the road line. During snowmelt and summer season, water then flows in the open watercourse.
- Icing can be reduced and water flow can be maintained by local heating. The electrical energy needed for heating cables can be produced with a wind generator.

It was also observed that icing problems are induced when a natural watercourse is treated and disturbed by excavation.

Conclusions

The described test construction revealed some extreme road maintenance problems in Finland. The approaches applied in the design and construction were seen as efficient, and they have been later applied elsewhere in Northern Finland. The results in the form of design models and approaches, as well as the design characteristics of insulation materials, may be useful also in other regions in cold climates.

Abstract

Ecosystem-scale measurements and investigations of the small-scale variability of methane emission were carried out in northern Siberian wet polygonal tundra using the eddy covariance technique during the entire 2006 growing season. Simultaneous closed chamber flux measurements were conducted daily at 15 plots in four differently developed polygon centers and a polygon rim from July–September 2006. Our study site was located in the southern part of the Lena River Delta, characterized by arctic continental climate and comparatively cold, continuous permafrost. Controls on methane emission were identified by applying multi-linear and multi-nonlinear regression models. We found a relatively low growing season average methane flux of 18.7 ± 10.2 mg m^{-2} d^{-1} on the ecosystem scale and identified near-surface turbulence, soil temperature, and atmospheric pressure as the main controls on the growing season variation methane emissions. On the micro-site scale, fluxes showed large spatial variability and were best described by soil surface temperature.

Keywords: closed chambers; eddy covariance; flux; methane; Siberia; tundra.

Introduction

Introduction

Arctic tundra ecosystems cover an area of about 7.34 x 10^{12} m^2 (Reeburgh et al. 1998) and are underlain by permafrost. Despite increased research, especially in connection with the much stated concern of potential increased emission of climate-relevant trace gases from warming or thawing tundra areas, these sensitive high-latitude ecosystems with their complex network of interconnected processes and controls are far from being understood. Vegetation, state of the permafrost, soil texture, hydrology, and many other relevant parameters and consequently also processes controlled by these parameters vary greatly on small spatial scales. This is especially valid for methane emission on various scales from arctic wetlands (Christensen et al. 2000, Kutzbach et al. 2004, Whalen & Reeburgh 1992).

To our knowledge, only four studies reported methane flux data from Arctic tundra on the ecosystem scale using eddy covariance techniques, namely Fan et al. (1992) from western Alaska, Harazono et al. (2006) from northern Alaska, Friborg et al. (2000) from Greenland, and Hargreaves et al. (2001) from Finland. Manuscripts by Wille et al. (2008) and Sachs et al. (2008) reporting data from the Lena River Delta, Siberia, are currently in press.

On the other hand, many studies are available reporting point data using closed chamber methods (Christensen et al. 2000, Kutzbach et al. 2004, Whalen & Reeburgh 1992). While closed chamber methods have multiple inherent problems, such as the exclusion of atmospheric parameters and induced alteration of concentration gradients underneath the chamber, resulting in disturbed fluxes, they are widely used to investigate the small scale variability of methane fluxes. The eddy covariance method does not allow for a spatial resolution high enough to investigate that kind of variability in heterogeneous areas.

We conducted intensive field studies on the ecosystem (1 ha to 1 km^2) and micro-site scales (0.1–100 m^2) using eddy covariance and closed chamber methods simultaneously in order to investigate the temporal and spatial variability of methane emissions. For the first time, methane flux measurements on the ecosystem scale in Arctic Siberian tundra were carried out during an entire growing season from the beginning of June–September 2006, and measurements on the micro-site scale were conducted within the eddy covariance footprint from July–September 2006.

Material and Methods

Study site

The study site was located on Samoylov Island, 120 km south of the Arctic Ocean in the southern central Lena River

Delta (72°22′N, 126°30′E) and is considered representative of the active delta landscape. Over the past ten years, Samoylov Island has been the focus of a wide range of studies on surface-atmosphere gas and energy exchange, soil science, hydrobiology, microbiology, cryogenesis, and geomorphology (Boike et al. 2003, Kutzbach et al. 2004, 2007, Liebner & Wagner 2007, Schwamborn et al. 2002, Wille et al. 2008, Sachs et al. 2008).

Samoylov Island covers an area of about 7.5 km². The western part of the island (3.4 km²) is a modern floodplain with elevations from 1–5 meters above sea level (a.s.l.). The study site is located in the center of the Late-Holocene eastern part (4.1 km²) with elevations from 10–16 meters a.s.l. The surface of the terrace is characterized by wet polygonal tundra with a flat but regular micro-relief caused by the development of low-center ice wedge polygons. The typical elevation difference between depressed polygon centers and elevated polygon rims is up to 0.5 m (Kutzbach 2006). The poorly drained and hence mostly inundated centers are characterized by *Typic Historthels*, while *Glacic* or *Typic Aquiturbels* dominate at the dryer but still moist polygon rims (Soil Survey Staff 1998, Kutzbach et al. 2004). As the summer progresses, these soils typically thaw to a depth of 30–50 cm.

Hydrophytic sedges, as well as mosses, dominate the vegetation in the wet polygon centers (Kutzbach et al. 2004). Polygon rims are dominated by mesophytic dwarf shrubs, forbs, and mosses. Surface classification of aerial photographs taken in 2003 shows that elevated and dryer polygon rims cover approximately 60% of the area surrounding the study site, while depressed and wet polygon centers and troughs cover 40% of the area (G. Grosse pers. comm.. 2005).

The climate in the region is arctic continental climate characterized by very low temperatures and precipitation. Mean annual air temperature at the meteorological station on Samoylov Island was -14.7°C and mean precipitation was 137 mm, ranging from 72–208 mm in a period from 1999–2005 (Boike et al. 2008). Snowmelt and river break-up typically start in the first half of June, and the growing season lasts from mid-June through mid-September. The continuous permafrost in the delta reaches depths of 500–600 m (Grigoriev 1960) and is characterized by very low temperatures between -13°C and -11°C (Kotlyakov & Khromova 2002).

Ecosystem scale flux measurements

In situ ecosystem scale methane fluxes were measured using the eddy covariance (EC) method with a tunable diode laser spectrometer (TGA 100, Campbell Scientific Ltd., USA) for CH_4 analysis. A more detailed description of the technical set-up can be found in Sachs et al. (2008).

The EC system was set up in the center of the eastern part of Samoylov Island and was surrounded by a relatively homogenous fetch of wet polygonal tundra. Larger lakes were located at the periphery of a 600 m radius around the tower. Successful measurements were conducted for 103 days from June 9–September 19, 2006, covering an entire growing season (Sachs et al. 2008).

Additional parameters measured at the eddy covariance system and an automated long-term monitoring station 700 m south of the EC tower include air temperature, relative humidity, incoming and outgoing solar and infrared radiation, photosynthetically active radiation (PAR), barometric pressure, precipitation, and soil temperature data at various depths. Additional daily manual measurements at five sites in close proximity to the tower included thaw depth using a steel probe, soil temperatures in 5 cm depth intervals, water level, and soil moisture using a Theta Probe type ML2x (Delta-T Devices Ltd., Cambridge, UK) where no standing water was present.

The area from which 80% of the cumulative methane flux originated was calculated using a footprint analysis according to Schuepp et al. (1990). The upwind distance of this flux contribution was on average 518 m, the maximum contribution originated from an average distance of 116 m.

Small scale flux measurements

For small-scale flux measurements, five different micro-sites characteristic of the prevalent surface and vegetation features within the eddy covariance fetch were established in close proximity to the flux tower (Fig. 1).

Polygon 1 was a low-center polygon with standing water in the center. The northern side of the polygon rim showed signs of beginning degradation, which might serve as a hydraulic connection to surrounding polygon troughs. Vegetation in the center is dominated by *Drepanocladus revolvens* (100% coverage) and *Carex chordorrhiza* (8% coverage).

Polygon 2 was a high-center polygon with no standing water in the center due to drainage into surrounding thermokarst cracks and troughs. The vegetation was dominated by *Hylocomium splendens* (85% coverage) and *Tomentypnum nitens* (10% coverage).

Polygon 3 was a low-center polygon with a massive rim on the western side and a completely degraded rim on the eastern side, where a large thermokarst crack of more than 2

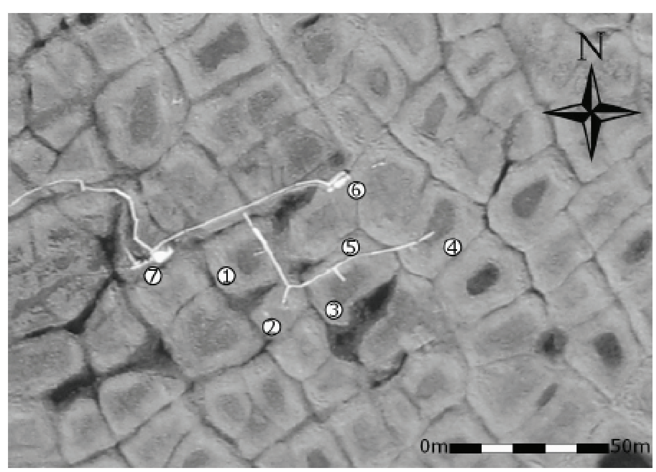

Figure 1. Aerial view of investigation site: 1 – low-center polygon, 2 – high-center polygon, 3 – low-center polygon, 4 – low-center polygon, 5 – rim, 6 – eddy covariance system, 7 – tent for equipment (Photo: J. Boike).

m depth was located. There was standing water in the polygon center and the vegetation was dominated by *Drepanocladus revolvens* (90% coverage), *Carex chordorrhiza* (10% coverage), and *Carex concolor* (10% coverage).

Polygon 4 was a low-center polygon with no apparent rim degradation and no apparent hydraulic connection to surrounding cracks or troughs. It usually maintained the highest water level and was dominated by *Scorpidium scorpidioides* (100% coverage), *Carex chordorrhiza* (8% coverage), and *Carex concolor* (3% coverage).

The polygon rim micro-site was underlain by a massive ice wedge and draining into polygon 3 to the east and the polygon crack to the west. Vegetation was dominated by *Hylocomium splendens* (60% coverage), *Rhytidium rugosum* (30% coverage), and *Carex concolor* (4% coverage).

In each of the four polygon centers and along the rim, three 50 cm x 50 cm PVC chamber collars with a water-filled channel as a seal were inserted 10–15 cm into the active layer. Chambers were made of opaque PVC and clear PVC, respectively, for light and dark measurements. Chamber volume was 12.5 l at the high-center and rim micro-sites and 37.5 l at the other sites, where higher vegetation did not allow for the use of small chambers.

Chamber measurements at all 15 plots were made daily from July 12–September 19, 2006 with both clear and opaque chambers. Sample air was drawn from a port on top of the chamber every 45 s for 8–10 minutes for simultaneous analysis of CO_2, CH_4, and water vapor using a photo-acoustic infrared gas spectrometer Innova 1412 with optical filters UA0982 for CO_2, UA0969 for CH_4, and SB0527 for water vapor (INNOVA AirTech Instruments, Denmark). A membrane pump was connected to two other ports and circulated chamber headspace air through perforated dispersive tubes for mixing.

Due to water interference with the CH_4 optical filter sample air was dried prior to entering the analyzer using 0.3 nm molecular sieve (beads, with moisture indicator; Merck KGaA, Darmstadt, Germany). Temperature and pressure inside the chamber were logged continuously by a MinidanTemp 0.1° temperature logger (Esys GmbH, Berlin, Germany) and the Innova 1412, respectively.

Flux modeling

We used multiple linear regression, as well as regression tree analysis, to identify the main controls on eddy covariance methane fluxes. All analyses were based on daily averages of measured and quality-controlled fluxes and are reported elsewhere in detail (Sachs et al. 2008). A multiplicative exponential regression model modified and extended after Friborg et al. (2000), was set up and fitted to the in situ data for small-scale flux modeling. It can be written as

$$FCH_4 = a \cdot b^{((T-\bar{T})/10)} \cdot c^{(u*-\overline{u*})} \cdot d^{(p-\bar{p})} \quad (1)$$

where a, b, c, and d are fitted parameters, T is the soil temperature at 10 cm depth in a polygon center, u_* is the friction velocity, p is the air pressure, and horizontal bars denote the mean values of the respective variables. A weighting factor of σFCH_4^{-2} was applied during the fitting process, with σFCH_4 being the daily mean of the noise estimates of the hourly flux data points.

For closed chamber measurements, we used multiple linear regression analyses to identify statistically significant controls on methane flux. Data was first tested for multi-collinearity following Schuchard-Ficher (1982) and for parameter significance using a t-test. The regressors were discarded in a stepwise procedure until only independent and significant parameters remained.

Results

Ecosystem-scale methane flux

Mean daily ecosystem methane flux was 18.7 ± 10.17 mg m^{-2} d^{-1} during the study period and showed relatively small seasonal variation (Fig. 2). However, strong variations could be observed, which coincided with pronounced decreases in air pressure and higher wind speed after calm periods.

In the first two weeks of measurements, average daily methane fluxes were already 13.8 mg m^{-2} d^{-1}, with high variability from 5.7 mg m^{-2} d^{-1} to 22.0 mg m^{-2} d^{-1}. Soil temperature was still below 0 °C when measurements started and showed very little variation in the early part of the thawing period. The lowest methane flux was observed during days with relatively high air pressure and low wind speed. Methane fluxes increased to an average of 25.0 mg m^{-2} d^{-1} in the third week. However, this increase was mainly due to an extreme peak on June 27, which coincided with the lowest observed air pressure during the summer and high wind speeds. The last ice from the bottom of ponds and smaller lakes surfaced and melted around this time.

Methane fluxes dropped to an average of 12.3 mg m^{-2} d^{-1} during the calm period at the end of June, and then steadily increased to the highest measured fluxes of on average 35.1 mg m^{-2} d^{-1} in the first week of August, roughly following variations in soil temperature and closely following variations in wind speed. Throughout July, above-average methane fluxes frequently correlated with rapid decreases in air pressure. Until the third week of August, fluxes remained between 17.0 and 20.0 mg m^{-2} d^{-1} and then decreased to less than 13.0 mg m^{-2} d^{-1} during a longer calm high-pressure period at the end of August.

During the first and second week of September, which were characterized by steadily decreasing air pressure, partly strong winds, and rain or snow events, methane fluxes increased to an average of 18.2 mg m^{-2} d^{-1} and 21.6 mg m^{-2} d^{-1}, respectively, despite a decrease in soil temperature and refreezing of the top soil layers and water bodies. By mid-September, all water bodies, except for the large thermokarst lakes, were covered with ice up to 8 cm thick. During the calm high-pressure period after September 13, methane fluxes decreased markedly to below 10.0 mg m^{-2} d^{-1} at the end of the measurement period.

All approaches showed that variation in methane fluxes could best be explained by friction velocity u_* and soil

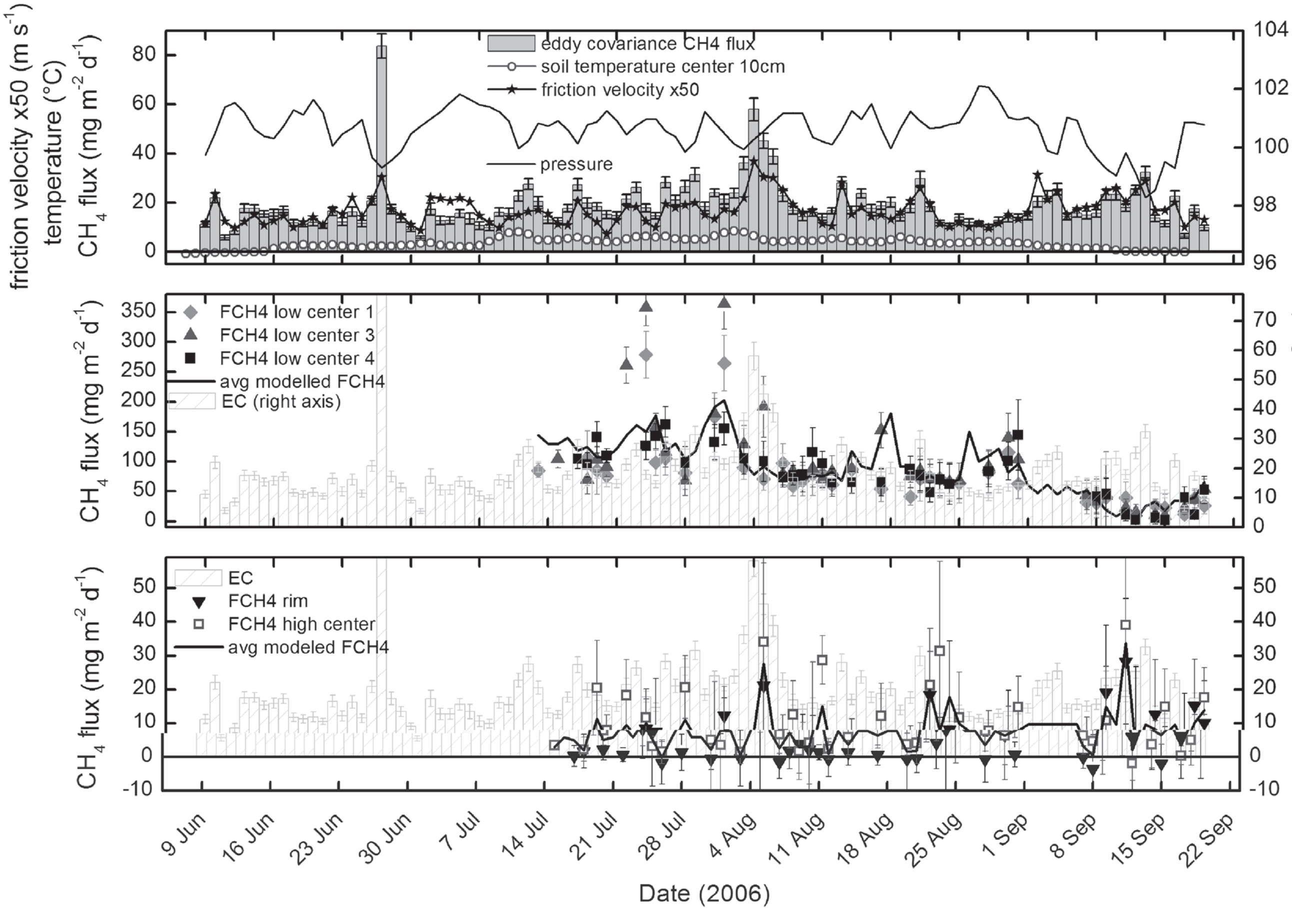

Figure 2. Top panel: Daily averages of eddy covariance methane fluxes and environmental controls during the 2006 growing season. The error bars of the eddy covariance data indicate the daily average noise level. Middle panel: Closed chamber methane fluxes from low center polygons and average modeled chamber flux. Each point represents the average of six flux measurements in the respective polygon. Bottom panel: Closed chamber methane fluxes from a polygon rim and a high center polygon and average modeled chamber flux. Each point represents the average of six flux measurements at the respective site. The error bars of the chamber data indicate the mean standard errors of the flux estimates. In the middle and bottom panel, the eddy covariance fluxes are given as light-grey columns for comparison. Note the different scale of the two y-axes in the middle panel!

temperatures at 10 cm depth in a polygon center and 20 cm depth in a polygon rim, respectively. Friction velocity alone accounted for 57% of the variance in methane emissions and another 3% could be explained by wind speed, which is closely correlated with friction velocity. Soil temperatures on the other hand only explained about 8% of the variance. The best agreement ($r^2_{adj} = 0.68$) of modeled and measured data was obtained by a model which included an exponential term that accounts for the observed influence of air pressure.

Thaw depth, which increased gradually and without variation throughout the season, did not improve the model, nor did water level, which remained above the soil surface at all times in the polygon centers.

The cumulative methane emission during the 2006 growing season was 1.93 g m^{-2}, which agrees well with the cumulative flux during the same period of a combined 2003 and 2004 dataset that amounted to 1.87 g m^{-2} (Wille et al. 2008). The model underestimated the cumulative measured flux by less than 5%.

Small-scale methane flux

Small-scale methane emission was similar among low-center polygons (Fig. 2) and differed strongly from fluxes at the high-center and rim micro-sites (Fig. 2).

At all three low-center micro-sites, mean daily fluxes in July and August were around 100 mg m^{-2} d^{-1} and decreased at the beginning of September to less than 50 mg m^{-2} d^{-1}, closely following variations in air temperature. When snow started to accumulate between September 10 and 15 during a period of below-zero temperatures, emissions fluctuated below 20 mg m^{-2} d^{-1}. At polygon 4, the seasonal course was less pronounced and variability was less extreme than at polygon 1 and 3, where peak fluxes exceeded 350 mg m^{-2} d^{-1} and were associated with spatial standard deviations of up to ±300 mg m^{-2} d^{-1}, demonstrating a large spatial variability even within micro-sites. These extreme emissions were generally associated with high temperatures.

It was not possible to construct a multidimensional regression model with independent and significant parameters. The predictor variable with the highest explanatory power within the final one-dimensional model was surface temperature.

At polygon 2 (high center) and at the polygon rim, very low methane concentrations in the closed chamber system frequently caused the analyzer to reach its detection limit, resulting in noisy data and a high exclusion rate during flux calculation. Fluxes that could be calculated were very low throughout the campaign and rarely exceeded 10 mg m^{-2} d^{-1}, which is about 10% of the average fluxes from low-center polygon micro-sites. No seasonal course is evident from the data and no statistically significant correlation with any of the observed environmental parameters was found. Gaps in the time series were filled with monthly average flux values, accounting for the small positive fluxes that were present.

Averaging closed chamber methane fluxes from wet polygon centers and drier sites, respectively, and weighing them according to the distribution of wet (40%) and drier (60%) surfaces classes results in an up-scaled closed chamber flux of 39.11 mg m^{-2} d^{-1}, which is double the eddy covariance flux during the same time period.

Discussion

Discussion

Results from eddy covariance measurements differ from closed chamber data both in terms of the seasonal variation and the identified controls on methane emissions. While ecosystems scale fluxes do not show much of a seasonal course, results from low-center polygon closed chambers show a pronounced decrease of methane emission towards the end of the season, which is more in agreement with most studies and results from deterministic process-based models used for larger scale modeling (Kirschke et al. 2008).

Emission peaks also do not match on the different scales. While ecosystem scale emission peaks usually coincide with high wind speed, low air pressure, and generally "bad weather" conditions, the largest emission from polygon centers as measured by closed chambers occurred during warm and dry days. However, the very weak peaks visible in closed chamber data from the rim and high-center micro-site tend to be more in agreement with eddy covariance emission peaks.

These differences in the seasonal dynamics may partly be explained by the very different hydrological conditions of the investigated micro-sites in combination with the importance of plant-mediated transport of methane (Kutzbach et al. 2004): in the wet polygon centers, water levels were always at or above the soil surface. Here, higher water levels could lead to decreased methane emission, as more vegetation becomes submerged and plant-mediated transport decreases. In addition, higher temperatures likely increase microbial methane production close to the surface. Hence, warm weather and falling water levels could actually increase emissions as long as the water table remains above the surface. At "drier" micro-sites, on the other hand, storm systems with strong precipitation events lead to a temporary increase in anaerobic soil volume and an increase in methane production, while lower temperatures have a negative effect on the activity of methane oxidizing microbes in the upper horizons of the active layer.

However, a large influence on the ecosystem methane flux can also be ascribed to open-water surfaces such as polygon ponds and thermokarst cracks, which were not covered by the closed chamber measurements but were present in the eddy covariance footprint. Diffusive and turbulent gas transfer between water and atmosphere is known to be proportional to the third power of the wind speed (Wanninkhof & McGillis 1999) and observation of methane ebullition (Walter et al. 2006) in the field indicates that water bodies are an important contributor to ecosystem methane efflux. These micro-sites must be included in future small-scale measurements within the eddy covariance footprint in order to more accurately scale chamber flux measurements to larger areas. A more detailed analysis of the small-scale variability and the scaling problems is in preparation.

The discrepancies in the results on the different scales also highlight the need for more non-intrusive and spatially integrating measurements from high-latitude ecosystems to verify and understand the results produced by the eddy covariance method. Larger scale methane emission models that have previously been developed on the basis of closed chamber data only, should incorporate new findings from eddy covariance or other non-intrusive techniques.

Our findings raise the question to which extent methane fluxes in permafrost ecosystems are controlled by near-surface controls including atmospheric boundary layer conditions and vegetation, or by soil characteristics and processes in the deeper active layer including microbial community structure and activity.

Acknowledgments

We would like to thank the members of the joint Russian-German expedition LENA-2006, especially Waldemar Schneider (AWI), Dmitry Yu. Bolshianov (AARI, St. Petersburg), Mikhail N. Grigoriev (Permafrost Institute, Yakutsk), Alexander Y. Derevyagin (Moscow State University), and Dmitri V. Melnitschenko (Hydro Base, Tiksi) for all logistical, travel, and administrative arrangements. We are also grateful to Günther "Molo" Stoof for technical support in the field and to Barnim Thees for valuable input regarding the statistical analysis.

Refinement of Physical Land Scheme for Cold-Region Subsurface Hydrothermal Processes and Its Impact on High-Latitude Hydroclimate

Kazuyuki Saito
International Arctic Research Center (IARC), University of Alaska Fairbanks, Fairbanks, USA
Frontier Research Center for Global Change, Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Yokohama, Japan

Abstract

Sensitivity experiments on subsurface and atmospheric hydroclimate were conducted to examine different levels of complexity in a physical terrestrial scheme in a coupled global climate model (GCM). In one-dimensional off-line experiments local impacts were examined for (1) snow cover and the organic layer, (2) soil column depth, and (3) hydrothermal parameterization in which effects of ground ice and unfrozen water under the freezing point are taken into account. The results reaffirmed the crucial role of snow and the organic layer for subsurface thermal regime. A total depth of 20 m was needed for physically-consistent simulation in the cold regions. An on-line simulation coupled with the atmospheric GCM showed the importance of the refined parameterization for better climatology and seasonality of the active layer and the high-latitude hydroclimate. The findings provide a basis for better physical representations in GCMs to investigate the hydroclimate of the Arctic, and on the larger spatial scales.

Keywords: frozen ground; global climate model; hydroclimate; physical land surface scheme.

Introduction

Global climate models (GCMs) are a useful tool to investigate large-scale permafrost and seasonally frozen ground (frozen ground, hereafter), and its impacts on the climate system, where the multiple feedbacks and interactions connect different components within the system. However, the current implementation and performance of physical terrestrial schemes in the state-of-the-art regional/global models still need substantial improvement and optimization on the resolved local physical (and biogeochemical) processes and properties, networking between different climate components, the initial and boundary conditions, and others, to be fully used.

Previous studies have pointed out the importance of a number of factors: (1) snow cover and top organic layer (e.g., Saito et al. 2007, Beringer et al. 2001), (2) total resolved depth of the soil column (Saito et al. 2007, etc.), (3) hydrothermal parameterization of the soil property, namely consideration of both solid and liquid water under the freezing point (e.g., Romanovsky & Osterkamp 2000, Flerchinger & Saxton 1989). Recently, several studies have appeared to examine the importance of those factors using the National Center for Atmospheric Research Land Surface Model (NCAR LSM) (Alexeev et al. 2007, Nicolsky et al. 2007, Yi et al. 2007). In this study, sensitivity experiments were conducted to evaluate the impact of the aforementioned factors using a land surface scheme in a Japanese-developed coupled global climate model. One-dimensional off-line experiments were intended to examine local subsurface hydrothermal impacts. On-line experiments coupled with the atmospheric component investigated the impacts on the high-latitude hydroclimate both below the surface and in the atmosphere.

Methods

Model and data

The numerical model used in the present study was CCSR/NIES/FRCGC MIROC3.2 coupled Atmosphere-Ocean global climate model (K-1 developers 2005), and the physical terrestrial scheme, MATSIRO (Takata et al. 2003). On-line experiments were performed at the horizontal resolution of Triangular 42 truncation (T42; ca. 2.5° by 2.5°).

For the off-line experiments, two different observational forcing datasets, both from the arctic tundra climate zones, were used; one taken at Barrow, AK, for 1990 through 2003 (soil temperatures were available only for the limited periods) provided by the Permafrost Laboratory, Geophysical Institute, University of Alaska Fairbanks (Mölders & Romanovsky 2006), and the other taken at Tiksi, Russia, for 1999 through 2005, provided by the Institute of Observational Research Center for Global Change, Japan Agency for Marine-Earth Science and Technology (JAMSTEC), Japan (H. Yabuki, personal communication). The period analyzed in this paper is from August 2002 to July 2003, since it is the only period during which Barrow and Tiksi observations overlapped.

Experimental conditions of the off-line experiments are summarized in Table 1. In off-line experiments (s4, g4, m4, n4, and o4) impact of snow cover and the top organic layers were examined in a 4 m soil column. Snow amount is prognostically calculated in the model, thus different amounts of precipitation were applied. Organic soil was specified by prescribing different values of thermal conductivity in the top layer. The original hydrothermal parameterization (C) does not consider the effect of either ground ice or unfrozen water on thermal properties under the freezing point. The refined parameterization (R) took both into account. Detailed explanation of the hydrothermal parameterization is found in Saito (2008). In another set of experiments (C4, C10, C50;

Table 1. Summary of the settings and conditions for the off-line experiments.

a) Specified only in the top layer (5 cm thick). Default value is that of mineral soil. b) Parameterization methods for soil thermal conductivity and heat capacity. C: Conventional, R: Ground ice and unfrozen water. See text for details.

R4, R10, R50), difference in total soil column depth was examined at three different depths (Table 1.).

Four integrations were performed online for combinations of presence/absence of the top organic soil layers in taiga and tundra zones (TOS/NoTOS), and the hydrothermal parameterization in the conventional (C) or refined (R) form. The top organic layer was prescribed only in tundra and taiga regions. The soil column depth was set to 4 m in all cases to focus on the above effects. The model was forced by monthly climatological sea surface temperatures and sea ice concentrations for the period between 1980 and 2000. Ten year outputs after 20-year spin-up were used for analysis.

Results

Near-surface conditions

Annual soil temperature range is shown with depth in Figure 1. Similarly, the seasonal evolution in the near-surface hydrothermal regime is shown in Figure 2. For both sites, Barrow and Tiksi, excessive snow cover led to a smaller annual amplitude and warmer soil temperatures for all layers; in Tiksi, the zero curtain was found below 2.5 m (s4; Figs. 1, 2).

When the snow amount and, therefore, the snow-covered period were more realistically simulated (g4), the thermal regime was closer to the observed. When snow cover was removed, cooling in winter was expectedly enhanced, whereas summer temperatures showed little impact (m4). On the contrary, inclusion of the top organic layer exerted a larger impact in summer than in winter for both areas (n4 and o4). The wetness of the upper soil layers was different with and without the top organic layer; it was kept close to saturation when the organic layer was present (Fig. 2c). With a stronger organic layer effect (o4), freezing and thawing at 20 cm depth occurred at a later time and proceeded more slowly.

Total depth and thermal parameterization

Examination of different total soil column depths showed that 15 m or below that annual amplitude is almost zero so that the zero heat flux condition at the lower boundary should be justified (Fig. 3). The refined parameterization (solid lines) simulated larger annual amplitude (warmer maximum) of soil temperature between 2 and 10 m. The equilibrated temperature below 15 m was warmer for the R runs by about one degree.

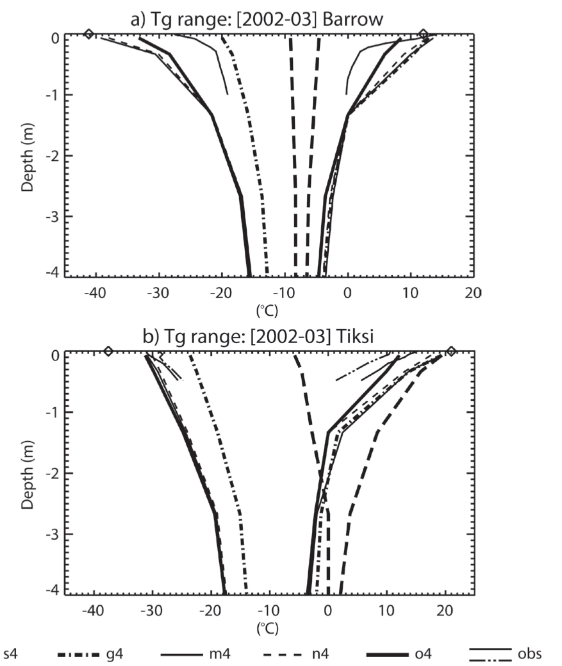

Figure 1. Annual range of soil temperature with depth, simulated for a one-year period from August, 2002 to July, 2003 for a) Barrow and b) Tiksi. Thin lines down to 1 m at Barrow and .48 m (two locations) at Tiksi are the observed values. Thick dashed lines are for experiment s4, and similarly, the thick dot-dashed for g4, the thin solid for m4, the thin dashed for n4, and the thick solid for o4.

On-line experiments

Figure 4 shows the latitudinal profile of atmospheric and hydrological variables in January and July, averaged over

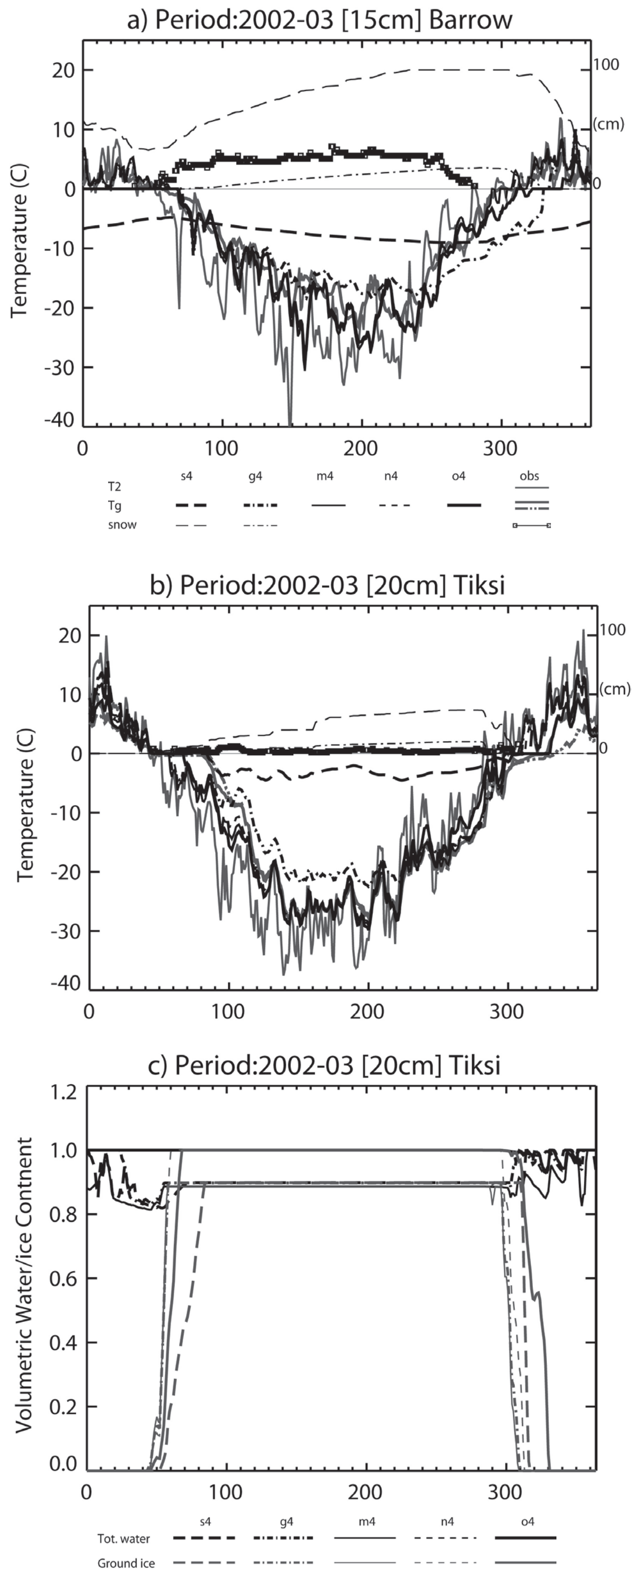

Figure 2. Seasonal evolution of soil temperature at (a) Barrow at the depth of 15 cm, (b) Tiksi at 20 cm depth. Line styles are the same as in Figure 1, except the thin solid gray line for surface air temperature at 2 m [forcing data]. Thinner lines above the 0 level are snow depth, and observed snow depth is shown with box symbols. (c) Seasonal evolution of soil moisture (thick lines) and ground ice content (thin gray lines), both relative to the saturation, at Tiksi; no observations were available for the period.

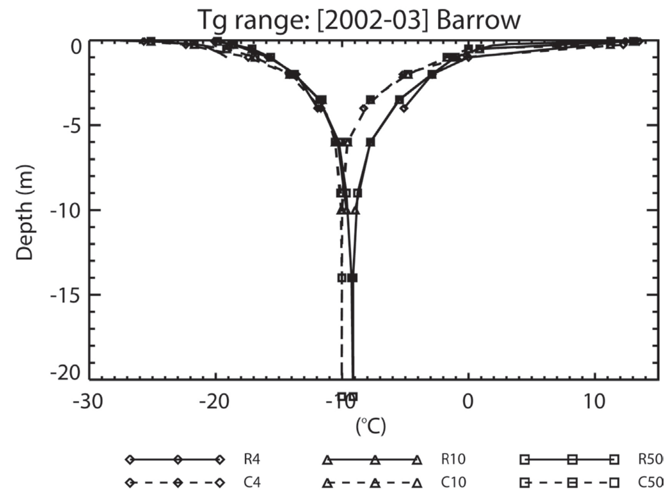

Figure 3. Annual range of soil temperatures, against depth, for different soil column depths (4 m, 10 m, and 50 m), and for the different thermal parameterizations. Dashed lines show the result of the conventional parameterization (C), while solid lines show that of the refined one (R).

land grids (excluding ice-covered areas) in each zonal band. Near-surface hydrologic conditions (i.e., soil moisture content) showed little difference between the four runs in all months (not shown), but subsurface thermal regimes (and ground ice content) differed to a substantial degree by the thermal parameterization (Figs. 4e, 4g). In the R4 runs it was cooler and a substantial amount of ice was retained in the summertime.

As for the atmospheric impact, surface air warmed faster and greater from spring to summer in R4 (Fig. 4a), and, similarly, cooled faster and greater in winter (Fig. 4b). The difference was most apparent in high latitudes. This led to an earlier and larger snow accumulation in winter (not shown), although precipitation did not vary much between the four simulations (Figs. 4c, 4d) in the high-latitudes. It was in the lower latitudes during summer monsoonal period that large precipitation differences were found; wetting of the Tibetan Plateau and drying of coastal China (not shown). The differences were canceled when taking the zonal average in Figure 4d. Land-average total annual runoff did not vary greatly between integrations; however, its seasonal distribution did change between the R4 and C4 runs. During the high-latitude melting season, runoff was greater for the R4 runs due to shallower active layer depth (Fig. 4g). On the contrary, it was smaller in summer because a larger amount of soil moisture was removed to the atmosphere by evapotranspiration (Fig. 4h, cf. Fig. 4b).

Distributions of frozen ground depended on both the organic soil and the hydrothermal parameterization (Fig. 5). The classification of the frozen ground followed the same methodology used in Saito et al. (2007). *Near-surface permafrost* is defined as an area with the maximum active layer thickness shallower than the model soil depth, in this case 4 m, for two consecutive years. Similarly, *seasonally-frozen ground* is defined as an area with its soil experiencing

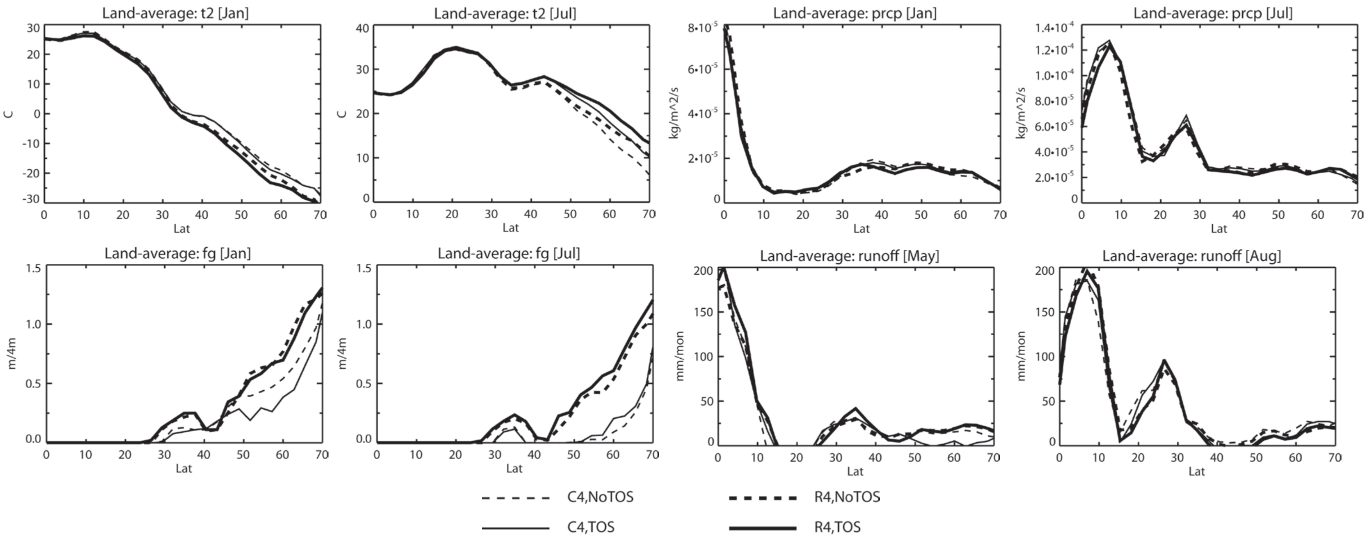

Figure 4. Latitudinal profiles of the a) surface air temperatures (T2), c) precipitation (total of liquid and solid), e) total ground ice amount in the 4 m column, averaged over land grids (except for permanently ice-covered areas) in January. Thick lines show the results by the refined thermal parameterization, whereas the thin lines show the conventional one. Solid lines denote the top-organic-soil (TOS) runs, and dashed lines the no-top-organic-layer (NoTOS) runs. Except for July b), d), and f) are same as a), c), and e). Except for runoff in May and August g) and h) are same as a) and b), respectively.

subfreezing at any time of a year. Distribution of near-surface permafrost (dark shades) is surprisingly different between R4 and C4; in the C4 runs it is very scarce largely due to excessive warming and thawing in summer (Fig. 4f). In contrast the R4 runs overestimated, when compared to the present-day observational estimate (e.g., Fig. 5c in Saito et al. 2007). Seasonally-frozen ground distribution did not differ much between runs and the observations (again, cf. Fig. 5c in Saito et al. 2007) for it is largely determined by surface air temperatures, which did not vary south of 30°N between runs (Figs. 4a, 4b).

Discussion

Weather-regime difference

The impact of snow cover appeared differently in Barrow and Tiksi, although both sites are located in arctic tundra, (Figs. 1, 2). The exaggerated warming in the s4 case for Tiksi likely resulted from warmer summer surface air temperatures (T2), which led to complete thawing down to 4 m in summer and to shallower snow cover climatology in winter. Tiksi's annual T2 range was -37.6°C to 21.0°C, while it was -41.2°C to 12.0°C for Barrow, for the examined period. Average snow depth was 6.7 cm for Tiksi and 23.0 cm for Barrow, although snow covered both sites for about 63% of the period (63.5% for Tiksi, and 62.4% for Barrow). Therefore, snow cover greater than observed had a larger insulation impact in Tiksi than in Barrow. There we also found seasonal differences affected the quality of the simulations: for the early snow accumulation period in Tiksi (days 50–85 in Fig. 2b) soil temperature was simulated best by the g4 run, whereas it was the no snow cover cases (m4, n4 and o4) that simulated the thermal regime best. In Barrow, discrepancies between the simulated and observed thermal regime are large during the snow melt season. Delayed snow melt led to slower subsurface warming (days 260–320 in Fig. 2a). These discrepancies, however, may be due in part to improper snow calculation in the model; it is prone to slower accumulation in the early cold season, greater insulation effects in midwinter, and slower melting in the warming season (Figs. 2a, 2b).

Another source of discrepancy from the observed thermal regime was the depth of the top organic layer. It is about 30 cm in Barrow and more than 50 cm in Tiksi, as inferred by the observed soil temperature profiles (cf. Figs. 1a, 1b). Hence, the prescribed organic layer of 5 cm may have been insufficient.

The experiments showed similar outcomes in Barrow and Tiksi, but also gave different responses in some variables or in different seasons, although both sites are located in the same arctic tundra climate zone. Similar evaluations with observations taken at places with varying weather and bio-climate regimes (not only arctic tundra, but also arctic taiga, high-altitude areas, etc.) will be instrumental to verify the findings in the present study, confirm the generality, and understand the heterogeneity between the regions more quantitatively. Similarly, knowledge of the geographical distribution of depth and physical/ biogeochemical properties of the organic layers, for example, will also be beneficial for more plausible future climate predictions.

Interactions with the atmosphere

Implementation of the physically-based parameterization of the soil hydrothermal properties impacted not only the subsurface but also the near-surface atmosphere. Surface air temperature in high latitudes decreased by about 5°C in winter (zonal average, only over land), and increased about 2°C in summer (Figs. 4a, 4b). Takata (2002) and

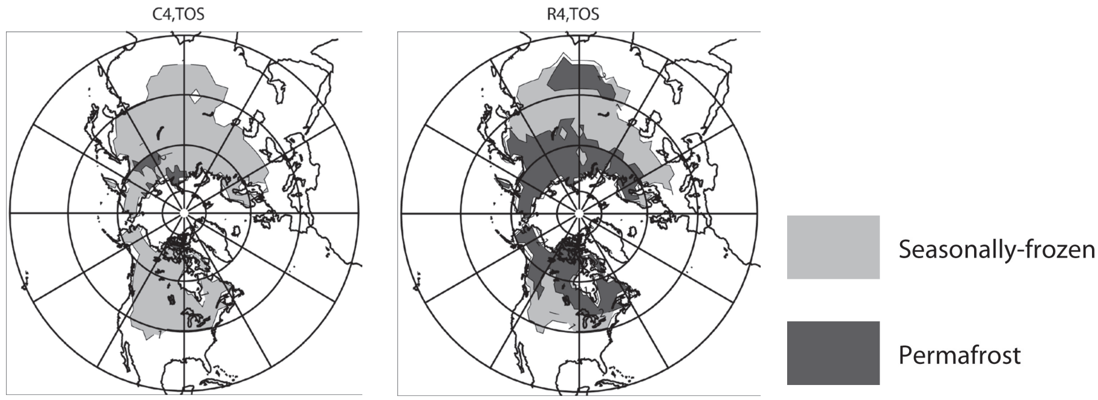

Figure 5. Distribution of near-surface permafrost (dark shades) and seasonally-frozen ground (light shades) simulated with a) the conventional thermal parameterization and b) the refined thermal parameterization. Near-surface permafrost is defined as the areas in which some layers are frozen for more than two consecutive years. Seasonally-frozen ground is defined as the areas in which soil temperatures in any layer is below 0°C at least once a month.

Takata and Kimoto (2000) have previously examined the impact of land processes (including freezing/thawing, but with "conventional" parameterizations) on the atmospheric hydroclimate. They showed changes in the regional-scale atmospheric circulations, and argue that the warming of high-latitude land in summer and the cooling in winter enhance the thermal contrast between the continents and oceans, leading to a stronger monsoonal circulation.

In high latitudes, surface heat fluxes were different between C4 and R4 runs. In the R4 runs, both sensible and latent heat fluxes to the atmosphere were stronger from spring to early summer due to a higher conductivity of heat with ground ice present, and to the near-surface moisture abundance resulting in a warmer near-surface air. From autumn to winter, again because of a higher heat conductivity, downward sensible heat flux (i.e., from the atmosphere to the ground) was stronger in the R4 runs, leading to a cooler air.

Inclusion of the top organic soil (50 cm for taiga and 20 cm for tundra, shown as difference between solid and dashed lines in Fig. 4) further added to the annual amplitude of surface air temperature, but stabilized the annual change in the subsurface ground ice content. This is a reasonable response because the organic layers tend to thermodynamically decouple the atmosphere and the subsurface more efficiently.

Overestimation of the near-surface permafrost in the R4 runs likely resulted from prescribed organic layers being too thick in Central to Western Eurasia, Central to Southern Canada, and the Tibetan Plateau (Fig. 5). On the contrary, the near absence of near-surface permafrost in the C4 runs was primarily due to the warmer T2 in winter with the prescribed sea surface temperature experiments as compared to the coupled ocean runs (Saito et al., 2007). The cause of these differences needs to be investigated further.

Summary and Implications

A series of sensitivity experiments performed off- and on-line in the present study showed the importance of representing complexity for frozen ground simulations. Of crucial importance in the physical terrestrial schemes is physically-based hydrothermal parameterization; that is, consideration of ground ice and unfrozen water under the freezing point. It affects not only subsurface hydrothermal regimes, but also the exchange of energy and water between the soil and the atmosphere. For a physically consistent thermal simulation, a soil column of 20 m or deeper was found necessary. Implementation of these components should be seriously considered when impact of atmospheric warming on frozen ground and its feedback to the atmosphere are to be investigated.

Snow conditions and soil properties (such as top-layer organic soil) need more localized attention. Snow calculations still require a considerable amount of elaboration, on both the atmospheric (cloud formation, advection, radiation, atmospheric thermal and hydrological conditions, etc.), and terrestrial (snow microphysics, radiative properties, thermodynamics, and their regional differences) sides of the GCM. In the current version of the model, the organic soils are only prescribed and do not vary in the course of integrations. This may suffice for short-term simulations, for example, for 30 years. However, one of the anticipated targets in the next Assessment Report of the Intergovernmental Panel for Climate Change (IPCC), is to consider a timescale where the residence timescale of subsurface organic contents in the cold regions matter. For such longer-term simulations, in which 100 or 300 years are targeted, adaptation strategy will be needed to reflect biogeochemical changes in time.

Portable Shallow Drilling for Frozen Coarse-Grained Material

Tohru Saito
International Arctic Research Center, University of Alaska Fairbanks
Kenji Yoshikawa
Water and Environmental Research Center, University of Alaska Fairbanks

Abstract

We are drilling boreholes for a permafrost outreach program that involves schools in arctic regions. The purpose of the project is to establish permafrost-monitoring stations at schools and have students and teachers participate in gathering data. We drill a 6 m deep borehole for the monitoring stations to measure ground temperatures. There are more than 50 sites established, and many of the schools are located in remote villages in Alaska and Canada. This created a great opportunity and necessity to develop a portable, lightweight, small-diameter drill system. However, permafrost conditions and local geology vary greatly. A portable drill system is strongly affected by the grain size of the frozen materials. The design for the auger and coring bits (mechanical properties) for fine-grained, frozen soils are already well developed. However, frozen gravel, boulders, and glacial sediments are extremely difficult to drill, even when using heavier track-mounted hydraulic drill systems. In our outreach project, we tried to develop a method of drilling through frozen gravel using a portable drill system. This study presents our experiments and an introduction to different techniques for a portable drill system.

Keywords: auger; frozen gravel; percussion drill; portable drill; rotary percussion system.

Introduction

Portable drilling systems were probably developed as percussion systems to find shallow groundwater. Sample percussion systems were established and widely used in Japan as 'Kazusa-hori' in the early 18th century. After the industrial revolution, rotary-type drilling systems became more popular than the traditional percussion systems. Today, there are many more different types of drill systems widely available. Table 1 lists the classification of various drilling systems.

Drilling systems should meet the following conditions to be useful for the permafrost outreach program:

1. Lightweight: All systems should be compact and light enough to carry on a small airplane, helicopter, snowmobile, and small boat to reach remote villages.
2. Portable: The operation should only require one or two persons to start and complete all work to establish the monitoring station.
3. Small diameter hole: The hole should be as small as possible to minimize site disturbance, and the borehole only needs to be large enough to install a 1-inch (25 mm) PVC casing.
4. Versatile: The drill should be able to penetrate different types of frozen ground (materials). Most sites consist of widely different types of sacrificial geology. It is important to be able to adapt to any kind of ground condition to successfully drill at each school.

Drilling techniques for fine-grained soils, such as frozen silt and sand, are well researched and developed, especially by the US Army Corps of Engineers Cold Regions Research and Engineering Laboratory (CRREL) (e.g., Mellor 1976, Lawson & Brockett 1980, Sellmann & Brockett 1986, 1988, Calmels et al. 2005). Sellmann & Mellor (1986) summarized extraordinary work on drill-bit design for frozen fine-grained soils. They concluded that for best performance, the drill bits should (1) stay sharp as long as possible, (2) resist damage from impact with any coarse-grained material, and (3) be large enough to allow penetration at the maximum feasible design rates. Lack of adequate clearance angle between bits and flute is a common problem.

This study focuses on attributes of a portable drilling system for frozen, coarse-grained materials, such as frozen gravel, because this material is one of the most difficult materials to drill and is very common around the study sites. We also need to be able to drill boreholes through these materials in many remote villages.

Table 1. Popular drilling systems used today. Experiments on prototype portable drilling systems are indicated.

type	system	in this study
percussion	rope drill	no
	rod drill	yes
	hammer drill	yes
	down-hole drill (in line drill)	yes
rotary	spindle drill	yes
	rotary table drill	no
	drive head drill	yes
	power swivel drill	yes
	bit rotation (turbo drill, dyne drill, electro drill)	no
other	earth auger	yes
	push casing	yes

Figure 1. Hot water jet system employed for old borehole (left) and prototype lightweight compact disassembled rotary drill with air swivel (right).

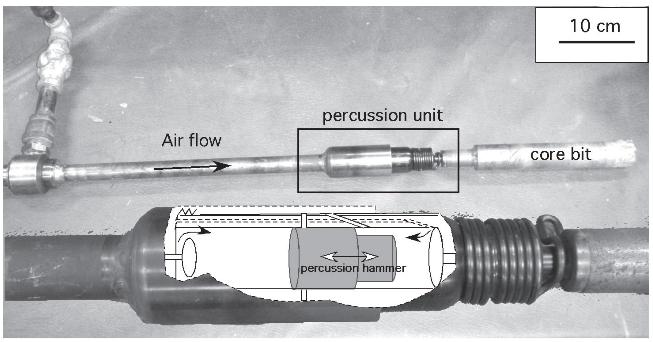

Figure 2. Prototype down-hole drill unit (in-line percussion drill)

Methods

Drilling system
Water jet drill

Water jet (hot water jet) systems (Fig. 1) are widely used for glaciological investigations. This method is definitely effective for boreholes on glaciers, sea ice, and ice rich permafrost. We used a Honda 5HP pressure jet pump with a custom-made nozzle and also tested a hot water jet unit from Kovacs Enterprise Ltd.

Jackhammer

A jackhammer is a powerful tool to break hard, solid material such as rock or ice, but limited drill depth is a weak point of this tool. Usually jackhammers can only dig 1–3 m or less. However, we used a gas-powered Swedish rotation jackhammer (Pionjar 120) that could drill a hole 6 m deep to bedrock, even through granite. The jackhammer was capable of producing two actions: percussion and rotation. By design, percussion is the primary action and rotation is the secondary action. Problems occur when the ground material melts from the drilling. The borehole becomes wet from the thawing silt, and the rotating driving shaft starts to stick to the mud and eventually stops rotating. The wet silty material and melt water generated by the action also absorb the percussion power of the jackhammer. As a result, jackhammers work wonderfully in dry bedrock but not in frozen silty gravel.

Figure 3. Portable hydraulic spindle (rotary) drill with air swivel. This is lightweight unit compared with track rig machine, but it is still heavy (more than 100 kg) to carry around.

Down-hole drill (in-line percussion drill)

It is generally known that shock and vibration action is very efficient for gravel or bedrock drilling to separate each grain (Borisovich 1990). We tried to employ this action in an adaptation with our portable drilling system. We modified the in-line shock actions using an air hammer tool (Aircoworld air hammer: bore diameter 19.05 mm, 4500 blow per minute (RPM), average air consumption 143 cubic meter per minute) (Fig. 2). This unit has about 100 g of weight moving up and down in the cylinder 4500 times per minute controlled by pressurized air. Air is supplied by the air compressor through the ¾-inch steel rod.

Rotary drill and earth auger

Both rotary drills and earth augers use rotation action for drilling. We used three different types of rotary drills: (1) Electric drills are easiest to use and work well in cold temperatures. (2) Mechanical (gasoline powered?) drills (Fig. 1) are probably the most commonly used portable drills, because they are relatively lightweight and strong, but they can be hard to start in colder temperatures. (3) Hydraulic drills are best for deeper boreholes. They are easy to handle and strong, which is why most commercial drillers use this method. Hydraulic systems, however, require many different heavy components that prevent them from converting into a portable system (Fig. 3). Also the hydraulic fluid needs to be kept warm during operation.

Percussion drill

The electric percussion/rotation drill is one of the best portable drill systems. We tried the heavy-duty, electric percussion drill to see if we could drill in permafrost (Fig. 4).

Figure 4. Electric percussion drill with water swivel. This hammer drill has 14A/120V power with 120–250 RPM rotation with impact (energy: 13.3 ft/lb)

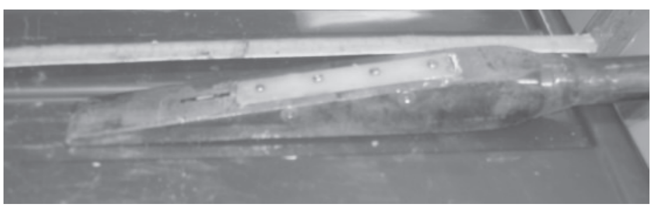

Figure 5. Prototype percussion drill bit with thermistor and electric resistivity contact points (Wenner configuration).

Drill bits

Drill bits are one of the most important components of drilling. We tested many different bits for this experiment. Auger bits with a rotating system are faster and easier to drill. However, this is difficult in a gravel layer. In general, core bits are used for core sampling but can also be used for drilling in gravel layers. We used several different shapes of core bits with carbide or diamond chips.

Drill bit experiment

The drill bit comparison experiment was carried out in an outdoor laboratory using a controlled frozen soil medium, comparing the drill speed in fine-grained soil and coarse-grained material. Auger bits and drills were tested on artificially frozen blocks of frozen ground about 50 cm x 50 cm and 30 cm deep. Time was recorded every 10 cm to compare the speed of the drill with different drill bits.

Figure 6. 30 mm diameter core bit for gravel (negative rake angle) (on left) and for silt (positive rake angle) (on right).

Figure 7. Fifty mm-wide auger bit for multi-grained (no rake angle [left]) and for silt (positive rake angle [right]).

Results

In general, the in-line percussion method worked better than just using the rotational drill. Figure 8 shows results from the experiment with the rotational drill using the in-line percussion and without it, in fine and coarse-grained materials. This figure shows that the inline system works well for both (fine- and coarse-grained) materials. However, the benefit of the percussion action is clearer in coarse gravel. The in-line percussion drill system performs 2.2 times more efficiently than using a rotation drill alone (Fig. 8, open dots).

Using water/air is a great way to remove materials (chips) from the borehole and also keep the bit tip clean. The water/air swivel allows pressurized water or air to flow through the tips of the drill bit while the drill is rotating. The chips are then blown out of the borehole. The system requires a large air compressor (>100 CFM) or high-pressure water pump (2 GPM), and it worked great with our portable drill system. This drilling system, therefore, includes three major components when digging the ground: (1) rotation action, (2) high pressure forced water/air - pushing action to remove chips, (3) impact (percussion) action. The swivel effectively blows chips out of the borehole, but working with permafrost

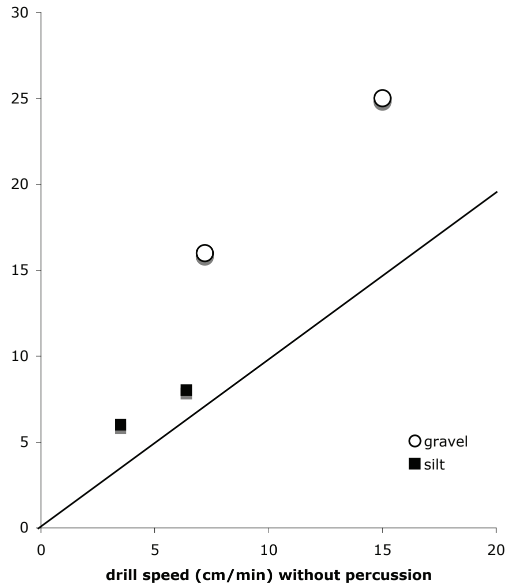

Figure 8. Drill speed performance with/without percussion action (inline) for frozen silt and gravel.

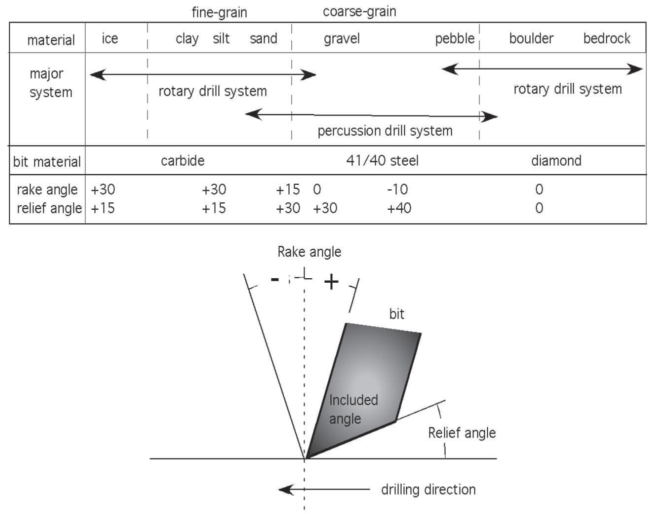

Figure 9. Ideal main drill system and bit properties of portable drill system for different frozen materials. Rake and relief angles for ice and fine-grained soil is after Sellmann & Mellor (1986). The rake and relief angle is the angle between the surface of the permafrost to the carbide bit. The relief angle is to prevent the land from rubbing on the surface of the work being cut.

we would like to keep the study site frozen while we drill. Therefore, a cooling system is needed for the water or air sent through the swivel. If supercooled water or chilled air is used, the system will cause minimal disturbance.

In general, physical theory for effective drilling depends on three major functions: rotation of the bit, down loading, and chip removal. When one of these functions does not work properly, drill speed slows down significantly or even stops. Using the portable drill system in a graveled area, the depth of the cutting blade is significantly smaller than the grain size of the gravel restricting rotation. Also, removing the chips requires water, air, or auger flights to establish a large enough flow pathway. The velocity of the flow pathway is related to the grain size of the chips. Maximum grain size (G:mm) is calculated by the following equation (Mori 1981).

$$G = 0.0055v^2\, G_w/(G_s - G_w)$$

where v = velocity(cm/sec), G_s = density of grain, and G_w = density of water. Using this equation, 6–10 mm diameter grains require 40–60 cm/sec of velocity using water. Although this is not an impossible pressure to create, it makes it unlikely to easily convert a portable drill system. Drilling through coarse-grained material clearly exceeds the limit of the physical theory for drilling, and our experience suggests the following conclusions for drilling frozen, coarse materials:

1. Rotation systems do not work properly.
2. Percussion systems aid in removing grain particles
3. Pyramid shaped bits (zero apparent rake) (Fig. 9) work well for removing pebbles, especially when very fine grain material content is present in the matrix.
4. Bentnite works well to keep the wall stable.
5. Diamond core bits work great to drill through any kind of gravel, rock, and boulder, but take longer and generate heat.

Figure 10. Human-powered traditional percussion system using steel rod.

Table 2 shows a summary of our experiments. Percussion action helps to separate each grain and remove the gravel

Table 2. Summary of the portable drilling operation for fine- and coarse-grained frozen materials.

type	system	for fine-grained materials	for coarse-grained materials	benefit	weakness	remarks

from the frozen matrix allowing it to move. However, the chips (grain) could not be removed from the borehole because of the grain size. A smaller diameter driving-rod is an essential parameter to successfully drill through coarse-grained material.

Percussion power simply depends on the weight of the hammer (Borisovich 1990). Heavier weights on the driving rod generate greater percussion energy. However, the reality of drilling in remote villages limits the size of a human-powered percussion system to about 30 kg (Fig. 10). Using a smaller diameter rod (12 mm) instead of using heavy weights for percussion can reduce weight and still allow effective drilling. Because of the smaller diameter, the speed of drilling was increased, and the borehole is small enough that the grainy materials can be pushed to the inside wall of the borehole.

Conclusion

The rotating drill is highly effective for fine-grained materials and even in coarse-grained material if the pore space is filled with silt or clay. The percussion system creates an effective action for drilling in coarse grain materials. This is illustrated in Figure 9. Heavier weights on the driving rod generate better percussion energy. However, the reality of drilling in remote villages limits the transport of heavier weights. Using a smaller diameter rod for percussion reduces weight, yet allows effective drilling.

The inline percussion (down-the-hole) drill improved drilling performance with the combination of percussion action and bit rotation. The combined actions are important systems for drilling through the coarse grain permafrost. We still need to design and build an inlinein-line percussion system for heavy-duty use and stronger impact energy in the future.

Acknowledgments

This project was funded by the National Science Foundation EPSCoR program (#0346770, #0701898) and the State of Alaska. We would like to thank the UAF Mechanical Engineering machine shop (Ned Manning and Eric Johansen) for building the prototype in-line percussion system, and Jon Holmgren and Sam Skidmore for developing many prototype bits, and VECO Polar Resources for logistical support.

Abstract

Permafrost soils cover about a quarter of the Earth's land surface. The soils are continuously frozen throughout the year, and only the active layer thaws near the surface during the short vegetation period. Microbial life of the polygonal Siberian tundra is influenced by extreme gradients of temperature and moisture. During nitrification, ammonia is oxidized by chemolithoautotrophic nitrifiers, the ammonia (AOB) and nitrite oxidizers (NOB), in two steps via nitrite to nitrate. Cell numbers of nitrifiers and potential activities of AOB were determined in geochemical characterized soil samples of the active layers. Results obtained by MPN-counts showed clearly that higher cell numbers of AOB and activities were found in the upper part of the dryer polygon rims compared to the waterlogged polygon centres. Our results reveal the existence of AOB in permafrost soil, which are well-adapted to the extreme environment.

Keywords: ammonia-oxidizing bacteria; Lena Delta; nitrifiers; nitrification; permafrost; Siberia.

Introduction

Since artic wetland soils are the most important natural source of the climate-relevant trace gas methane, many investigations focused on the microbial C-cycle of permafrost soils. But despite a close connection between C-cycle and N-cycle, the N-cycle is mostly unexplored.

Nitrogen as well as carbon cycling in arctic ecosystems is dominated by physical and biogeochemical controls which are unique to the generally cold-dominated environment. Drastic seasonal fluctuations in temperature, a short growing season, cold soil temperature, and the occurrence of permafrost are some of the obvious physical controls on nitrogen cycling and biological activity. Most of the nitrogen accumulates in the organic substance in response to low soil temperatures, excessive soil moisture, and low soil oxygen concentration (Gersper et al. 1980, Marion & Black 1987, Nadelhoffer et al. 1991, Schimel et al. 1996). Standing crops in tundra vegetation store about two times more nitrogen than temperate grasslands (Van Cleve & Alexander 1981). But through the low N-mineralization rates and lack of N-input by N-fixation and N-pollution, the soils are nitrogen deficient and rely to a large extent on internal recycling (McCown 1978).

N-cycling in the soil is crucial for growth of plants and microorganisms. Imbalances in N-cycling are due to nitrate leaching, nitrogen oxide release, and increase the methane emission (Adamsen & King 1993, Carini et al. 2003). Most of the N-transformations were catalyzed by microorganisms (Fig. 1, Fiencke et al. 2005). Nitrification, the microbiological oxidation of ammonia to nitrate via nitrite, occupies a central position within the terrestrial nitrogen cycle. Aerobic chemolithoautotrophic ammonia (AOB) and nitrite oxidizing (NOB) bacteria represent the most important group of nitrifying bacteria (Fiencke et al. 2005). As a result of nitrate and acid formation, the nitrification process has various direct and indirect implications of soil systems. It increases the loss of soil nitrogen due to leaching of nitrate and volatilization of nitrogen gases directly or by denitrification and therefore, influences the nitrogen supply to plants.

Beside ammonia oxidizing Proteobacteria, it has been mentioned that Archaea (AOA) participate in ammonia oxidation and have been found in different soils and habitats. (Nicol & Schleper 2006, Leininger et al 2006). Some representative of the AOA were enriched and described (Könneke et al. 2005, Hatzenpichler et al. 2008). In some habitats, more archaeal than bacterial genes were detected. (Leininger et al. 2006), but at this moment it is not clear which group of microorganisms dominate in the N-cycle.

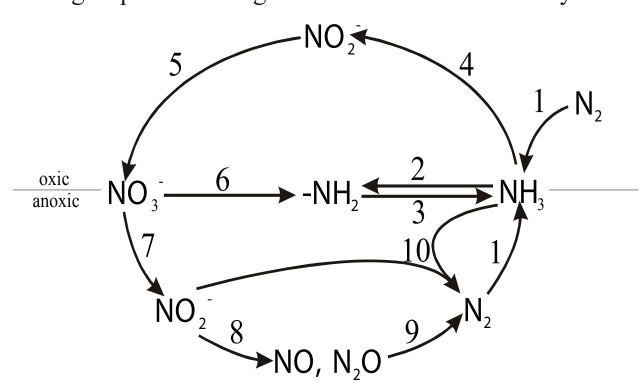

Figure 1. Nitrogen cycle. (1) dinitrogen (N_2) fixation, (2) assimilation of ammonia (NH_3) to amino group ($-NH_2$) of protein, (3) ammonification, (4) ammonia oxidation, (5) nitrite (NO_2^-) oxidation, (6) assimilation of nitrate (NO_3^-), (7, 8, 9) denitrification via nitrite, nitric oxide (NO) and nitrous oxide (N_2O), (10) anaerobic ammonia oxidation.

Nitrifying bacteria are found in the upper layer of soils, like the rhizosphere, where organic matter is mineralized, and ammonia and oxygen are present. The slow growth rates and difficulties in recovering pure cultures have hampered cultivation-dependent approaches to investigating the number, community composition, and dynamics of nitrifiers in soil. The number and turnover rate is, therefore, determined by traditional methods like most-probable-number (MPN) technique and activity tests.

During the *Expedition to the Lena Delta* in Summer 2005 and 2007, microbial nitrification was investigated by field experiments. Furthermore, soil and gas samples were taken for further ecological, molecular, and soil analyses.

Investigation Area

The study site is located on Samoylov Island (72°22′N, 126°28′È) in the southern part of the Lena Delta on the north coast of Siberia (Fig. 2).

The climate is true-arctic, continental, and characterized by low annual temperatures (-13,6°C) and low annual precipitation (319 mm) (ROSHYDROMET 2007). The main soil unit of Island Samoylov is covered mainly by the soil-plant-complex consisting of Glacic Aquiturbels and Typic Historthels (Fig. 3b).

The Typic Historthels are Gelisols that have in 30% or more of the pedon more than 40% by volume, organic materials from the surface to depth of 50 cm (Soil Survey Staff 2006). They formed in the depressed centers of low-centered ice wedge polygons characterized by water saturation to the soil surface and organic matter accumulation due to anaerobic condition. The Glacic Aquiturbels formed at the elevated borders of the polygons, are characterized by prolonged inundation, but with less organic matter accumulation and pronounced cryoturbation.

Materials and Methods

The investigations of nitrification were carried out on Samoylov in August 2005 and July 2007. Soil samples were taken from the active layer of two low-centered polygons, at the polygon rim and polygon center, at 3 depths (0–5, 5–15, 15–25 cm) (Fig. 3). Samples were analyzed freshly on-site and after transportation (frozen or unfrozen at about 6°C) lasting for two months to our institute in Hamburg, Germany.

On-site and after transportation, nitrification was determined by enrichment and ammonia oxidizing activity tests. Therefore, ammonia (AOB) and nitrite oxidizing bacteria (NOB) were enriched for further quantification by MPN-technique in media with 1 mM ammonium and 0.3 mM nitrite for three months at about 6°C. The ammonia oxidizing activities were measured at different temperatures (6°C, 12°C, 17°C, 20°C, 28°C, 37°C) and 0.75 mM ammonium sulfate using ISO/DIN 15685:2001 standard tests. The activities were measured by ammonia consumption and nitrite formation up to a period of 6 weeks in the field and eight weeks in the laboratory. Samples for the test were taken twice a week.

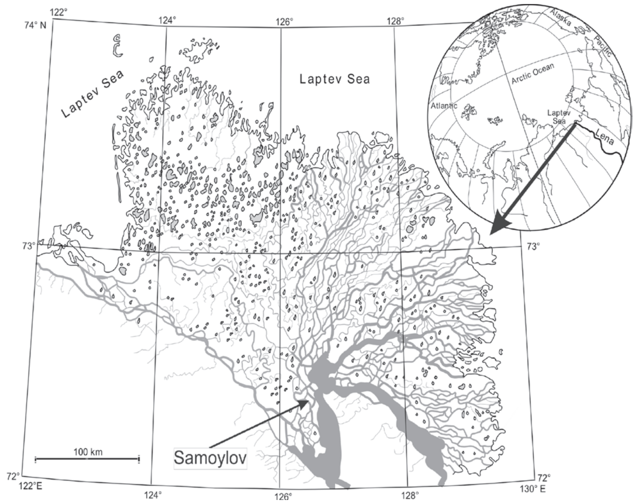

Figure 2. Map of the Lena Delta with location of Samoylov Island.

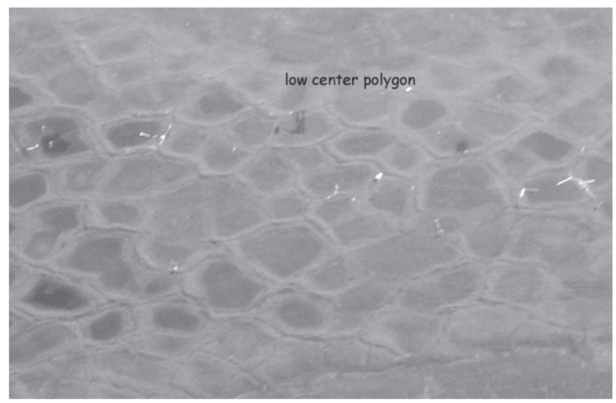

Figure 3a. Low-center polygon landscape on the island Samoylov.

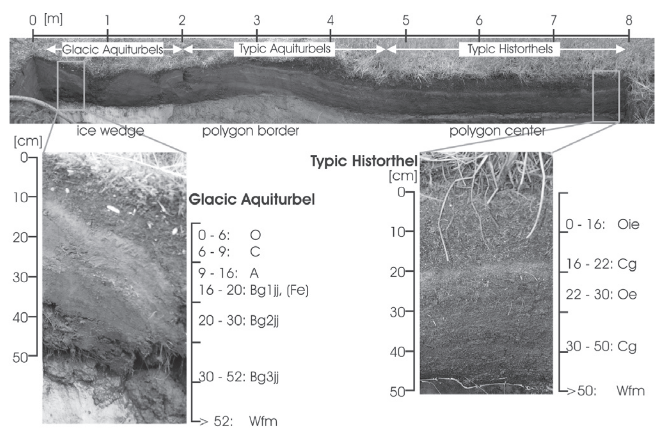

Figure 3b. Soil cross-section of a low-centered polygon and investigated soil-profiles (Classification U.S. Soil Taxonomy).

Chemical characterization of soils was done after transportation. For pH determination, soil suspensions with dest. water were measured after an equilibration of one hour. C/N was analyzed after oven drying (105°C) and grinding by Vario MAX element analysator. For ammonium, nitrite, and nitrate detection, soil samples were extracted with 0.0125 M $CaCl_2$ and were analyzed by spectral photometer tests. Methane was measured in situ by gas chromatography.

Results and Discussion

Chemical parameters

The chemical characterization of the soil samples shows that ammonium accumulates in the moist, anaerobic, and methane-containing Typic Historthel of the polygon center, and only low concentrations of nitrite and nitrate were found (Fig. 4a). In contrast to the moist polygon center, in the Glacic Aquiturbel of the dryer polygon rim, high nitrate concentrations were found in the oxic top soil (Fig. 4b).

Ammonia oxidation

Ammonia oxidation was measured by MPN-counts and ammonia oxidizing activity tests. Highest cell numbers of nitrifiers (AOB and NOB) were found at depths of 5–15 cm in the Glacic Aquiturbel of the polygon rim ($2 \cdot 10^5$ cells/g dw, data not shown).

During the field survey in August 2005 and July 2007, all soil samples were tested for ammonia oxidation activity. Additionally, all soil samples were tested again after two months of transportation.

In the field experiments of 2005 and 2007, ammonia-oxidizing activity was only detected in soil samples in depths 5–15 cm of the Glacic Aquiturbel of the polygon rim. In July 2007, activities of 22,56 ng N-Nitrit per g dry weight and hours were found.

After two months of unfrozen transportation, the same samples were analyzed again. After that time, the activities in the 5–15cm polygon rim sample increased, and few activities were found in the surface sample (0–5 cm) of the polygon center (Fig 5a). In soil samples which were taken one and a half months later (August 2007), ammonia oxidizing activity was also detected in upper layers of the polygon rim and center (Fig. 5b). Higher activities in the upper parts of the center in August might be due to lower water content (July 412 %, August 173%) due to decrease of water level in the polygon center.

The results indicate that small-scale differences in soil hydrology have significant impact on the N-cycle. Better drained, reduced acidity and methane concentration of oxic soil samples of the polygon rim favor nitrification, and therefore, lead to the accumulation of nitrate. Nitrate was possibly not degraded in dry sites, owing to lack of denitrification in these more aerated micro-environments. Instead, in the moist polygon center, nitrification was inhibited by oxygen deficiency, and therefore the ammonium formed by mineralization accumulated. In the moist anoxic environment, nitrate was possibly quickly reduced by denitrification.

Furthermore, the activity of the most active soil sample was analyzed at different temperatures. As shown in Table 1, activities depend on transportation of soil samples and temperature used for activity tests. Generally, higher activities were found in the soil samples after an unfrozen

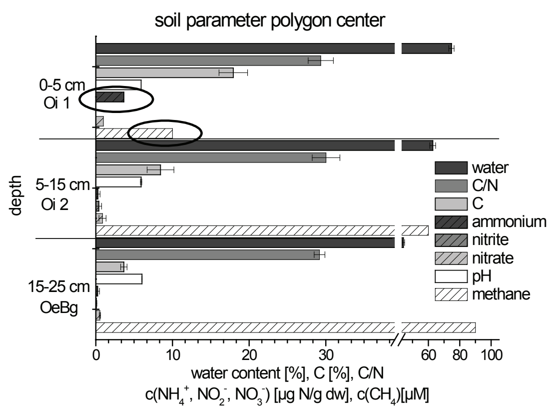

Figure 4a. Chemical soil parameters of the Typic Historthel of the polygon center. Soil samples were taken in August 2005. Error bars represents 4 parallels.

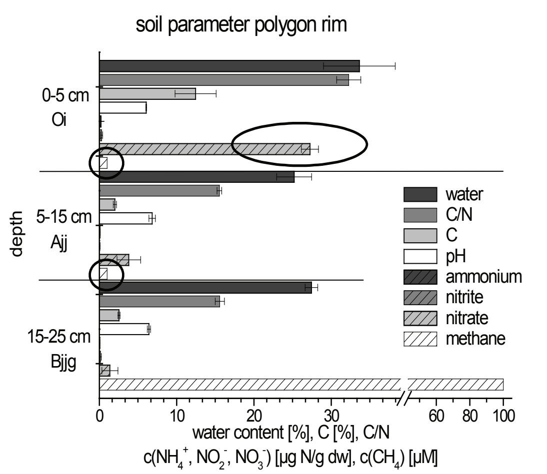

Figure 4b. Chemical soil parameters of the Glacic Aquiturbel of the polygon rim. Soil samples were taken in August 2005. Error bars represents 4 parallels.

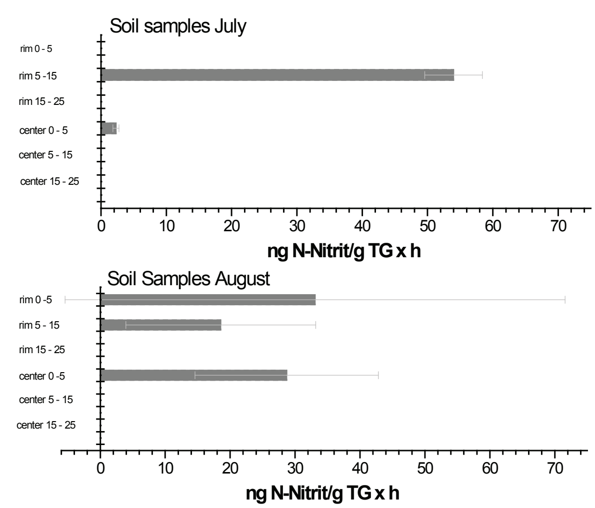

Figure 5. Ammonia-oxidizing activities measured by formation of nitrite in Typic Historthel of the polygon center and Glacic Aquiturbel of the polygon rim. Samples were taken in July (5a) and August (5b) 2007 and activities were measured over a period of 8 weeks at 6 °C. Error bars represent 4 parallels.

Table 1. Activity of the ammonia-oxidizing bacteria at the polygon rim of the depth of 5 to 15 cm at temperatures between 6°C and 37°C. Frozen and unfrozen transported samples were analyzed after two months of transportation.

Temperature [°C]	Ammonia-oxidizing activity [ng N-nitrite/g dw·h]	
	unfrozen	frozen
6	23.4	0.6
12	6.6	1.3
20	60.5	12.0
28	9.1	2.5
37	0.2	0.2

transport of the samples from the field to the laboratory. In frozen transported soil samples, ammonia oxidizing activity is obviously lower. Highest activity was found at tests conducted at 20°C, second highest at 6°C. Therefore, two peaks of activity were found independently of frozen or unfrozen transportation. An explanation for the two peaks could be that two different ammonia-oxidizing communities got different temperature optima.

Summary

The results indicate that small-scale differences in soil hydrology of the polygonal tundra have significant impact on the N-cycle. In the dryer, aerobic Glacic Aquiturbel of the polygon rim, high nitrate and low inhibitory methane concentrations correlated with high cell numbers and activities of ammonia oxidizing bacteria. In contrast, in the moist, anaerobic, methane-containing Typic Historthel polygon center, lower cell numbers and activities of ammonia-oxidizing bacteria were detected. The ammonia-oxidizing activities depended on the temperature. Highest activities were found at 6 and 20°C.

Conclusions

This paper show preliminary results on one special part of the nitrogen cycle. Further investigation will consider unstudied processes and fluxes of the N-cycle like mineralization and denitrification. It should also be clarified which group of ammonia-oxidizing organisms, Proteobacteria or Archaea, take part in the activities in that environment. First results may help to understand how predicted climate changes influence the N-cycle in soils of the polygonal tundra.

Acknowledgments

We thank the Russian–German parties of Expedition Lena 2007 for the pleasant teamwork in the field. Special thanks go to the staff of the Alfred Wegener Institute, Research Unit Potsdam for making the expedition to the Lena Delta possible. Thanks, also, to the University of Hamburg and the Institute of Soil Science for advice in the planning of the work.

Abstract

Structural pipe-in-pipe cross sections have significant potential for application in oil and gas production systems because of their property that combines insulation performance with structural strength in an integrated way. By making use of such excellent structural properties, however, we consider that this pipe-in-pipe system can be also applicable to pipelines in cold or permafrost regions. In this case, bending characteristics become one of the most important factors for the structural design of the pipelines. The purpose of this research is to investigate the bending characteristics of such pipe-in-pipe systems analytically by considering the Brazier effect. Results are presented to show the variation of the degree of ovalization and the Brazier moment with the relative elastic modulus of the filler and pipe materials, the filler thickness, and the thicknesses of the inner and outer pipes.

Keywords: Brazier effect; pipe-in-pipe; pipeline; pure bending.

Introduction

Structural pipe-in-pipe cross sections have significant potential for application in oil and gas production systems because of their property that combines insulation performance with structural strength in an integrated way. Such cross sections comprise inner and outer thin walled pipes with the annulus between them fully filled by a selectable thick filler material to impart an appropriate combination of properties. The technology of the pipe-in-pipe system has developed in the field of offshore engineering. One of the authors investigated the elastic buckling behaviour of pipe-in-pipe cross sections under external hydrostatic pressure (Sato & Patel 2007). By making use of such excellent structural properties, however, we consider that this pipe-in-pipe system can be also applicable to pipelines in cold or permafrost regions, such as chilled gas pipeline systems installed under ground. In this case, bending rigidity or flexibility near the boundary between permafrost and non-permafrost areas become one of the most important factors for the structural design of the pipelines.

In pure bending, the cross sections of a hollow cylindrical pipe ovalize, and this reduce the flexural stiffness of the pipe as the curvature increases. This is known as *the Brazier effect* (Brazier 1927), and it is quite important to evaluate this effect accurately in order to understand the bending behaviour of the pipe-in-pipe system.

From this point of view, the purpose of this research is to investigate the bending characteristics of such pipe-in-pipe systems analytically by considering the Brazier effect. The *Brazier moment*, which is the maximum moment carrying capacity of the ovalized cross section, can be calculated by introducing the strain energy per unit length of the pipe in terms of the degree of ovalization for outer and inner pipe curvature. The total strain energy of the pipe-in-pipe system is the sum of the strain energy of the outer and inner pipes and the compliant core. It is also clear that the moment of inertia of the cross section is increased by the presence of the core compared with single wall pipes.

Results are presented to show the variation in degree of ovalization and the Brazier moment with the relative elastic modulus of the core and outer/inner pipes materials, the core thickness, and the thicknesses of the inner and outer pipes.

Analytical Model

Figure 1 shows the configuration of a perfectly cylindrical pipe-in-pipe cross section that is analyzed here. The pipe-in-pipe cross sections under consideration have an annulus fully filled with a material that provides continuous structural support to both the thin-walled outer and inner pipes with Young's modulus E_P and Poisson's ratio ν_P. The geometric variables are the thickness of the outer pipe, t_1, that of the inner pipe, t_2, the middle surface of the outer pipe, a_1, and that of the inner pipe, a_2. In the following formulation, the subscripts 1 and 2 correspond to the outer and inner pipes, respectively.

As shown in Figure 2(b), in pure bending the cross sections of a hollow circular cylindrical pipe-in-pipe ovalize and this reduces the flexural stiffness of the pipe as the curvature increases.

Formulation

Strain energy associated with ovalization of the core

The strain energy U_1 per unit length in the ovalized core is expressed as

$$U_1 = \frac{1}{2}\int_0^{2\pi}\int_{a_2}^{a_1}(\sigma_r\varepsilon_r + \sigma_\theta\varepsilon_\theta + \tau_{r\theta}\gamma_{r\theta})rdrd\theta \tag{1}$$

where σ_r, σ_θ, $\tau_{r\theta}$ and ε_r, ε_θ, $\varepsilon_{r\theta}$ are the core stresses and strains in the radial, circumferential, and shear directions, respectively. As shown in Figure 2(b), the radial and tangential displacement, u_i and v_i, respectively, of outer and inner pipes ovalized by ζ_i are (Calladine 1983)

$$u_i = a_i\varsigma_i\cos 2\theta = \delta_i\cos 2\theta \tag{2a}$$

$$v_i = -\frac{1}{2}a_i\varsigma_i\sin 2\theta = -\frac{1}{2}\delta_i\sin 2\theta \tag{2b}$$

The basic equation for the core is expressed by the stress function $\phi(r,\theta)$ in polar coordinates as (see Timoshenko & Goodier 1970)

$$\left(\frac{\partial^2}{\partial r^2} + \frac{1}{r}\frac{\partial}{\partial r} + \frac{1}{r^2}\frac{\partial^2}{\partial\theta^2}\right)^2\phi(r,\theta) = 0 \tag{3}$$

The normal stresses in the radial and circumferential directions σ_r, σ_θ and the shear stress $\tau_{r\theta}$ are determined from

$$\sigma_r = \frac{1}{r}\frac{\partial\phi(r,\theta)}{\partial r} + \frac{1}{r^2}\frac{\partial^2\phi(r,\theta)}{\partial\theta^2} \tag{4a}$$

$$\sigma_\theta = \frac{\partial^2\phi(r,\theta)}{\partial r^2} \tag{4b}$$

$$\tau_{r\theta} = -\frac{\partial}{\partial r}\left(\frac{1}{r}\frac{\partial\phi(r,\theta)}{\partial\theta}\right) \tag{4c}$$

In the problem considered here, the two displacement components for the core, the radial displacement $u(r,\theta)$ and the circumferential displacement $v(r,\theta)$, are assumed to have circumferentially periodic forms written as:

$$u(r,\theta) = u_C(r)\cos 2\theta \tag{5a}$$

$$v(r,\theta) = v_C(r)\sin 2\theta \tag{5b}$$

Therefore, $\phi(r,\theta)$ should be expressed as follows:

$$\phi(r,\theta) = f(r)\cos 2\theta \tag{6}$$

The general solutions of Equation 3 are as follows:

$$f(r) = Ar^{-2} + B + Cr^4 + Dr^2 \tag{7}$$

where *A*, *B*, *C*, *D* are arbitrary constants. In this case, the corresponding stress components are

$$\sigma_r = -(6Ar^{-4} + 4Br^{-2} + 2D)\cos 2\theta \tag{8a}$$

$$\sigma_\theta = (6Ar^{-4} + 12Cr^2 + 2D)\cos 2\theta \tag{8b}$$

$$\tau_{r\theta} = (-6Ar^{-4} - 2Br^{-2} + 6Cr^2 + 2D)\sin 2\theta \tag{8c}$$

The strain components for the plane strain problem are derived by

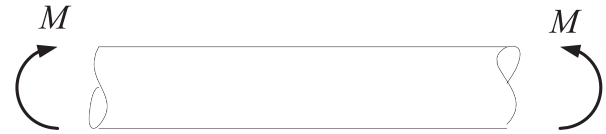

Figure 1. Pipe-in-pipe system in pure bending.

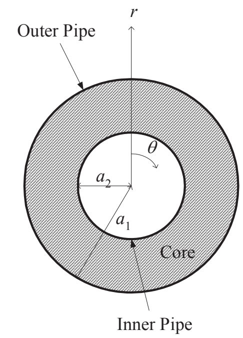

Figure 2. Pipe-in-pipe cross section.

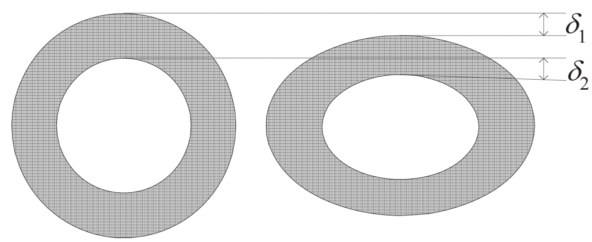

(a)Before bending (b) After bending

Figure 3. Ovalization for pipe-in-pipe cross sections. (The degree of ovalization is $\zeta_i = \delta_i / a_i$ (i = 1, 2).)

$$\begin{Bmatrix}\varepsilon_r\\ \varepsilon_\theta\\ \gamma_{r\theta}\end{Bmatrix} = \frac{1}{E_C}\begin{bmatrix}1-\nu_C^2 & -\nu_C(1+\nu_C) & 0\\ -\nu_C(1+\nu_C) & 1-\nu_C^2 & 0\\ 0 & 0 & 2(1+\nu_C)\end{bmatrix}\begin{Bmatrix}\sigma_r\\ \sigma_\theta\\ \tau_{r\theta}\end{Bmatrix} \tag{9}$$

The corresponding displacements in the radial and circumferential directions $u(r,\theta)$ and $v(r,\theta)$ can be obtained from Equations 8 and 9, and the following displacement-strain relationship is derived:

$$u(r,\theta) = \int\varepsilon_r dr = \frac{1+\nu_C}{E_C}\left\{\frac{2A}{r^3} + \frac{4B(1-\nu_C)}{r} - 4\nu_C Cr^3 - 2Dr\right\}\cos 2\theta + P \tag{10a}$$

$$v(r,\theta) = \int(r\varepsilon_\theta - u)d\theta = \frac{1+\nu_C}{E_C}\left\{\frac{2A}{r^3} + \frac{2B(2\nu_C-1)}{r} + 2C(3-2\nu_C)r^3 + 2Dr\right\}\sin 2\theta + Q \tag{10b}$$

where *P* and *Q* are constants of integrations. For the problem considered here, the outer and inner pipes are assumed to be perfectly bonded to the core. The middle surface outer pipe displacements (u_1, v_1) and inner pipe displacements (u_2, v_2) are taken to have circumferentially periodic forms written as:

$$u(a_i, \theta) = u_i \tag{11a}$$

$$v(a_i, \theta) = v_i \tag{11b}$$

From Equations 2, 10, and 11, we can obtain the constants A, B, C, D as functions of δ_1 and δ_2. This fact indicates that the strain energy associated with ovalization of the core (Eq. 1) can be expressed by the displacements of the outer and inner pipes. Substituting the constants in the stresses and strains, we obtain the strain energy which is the function of δ_1 and δ_2.

In addition to this, we find the strain energy of the outer and inner ovalized pipes is (Calladine 1983)

$$U_2 = \sum_{i=1}^{2} \frac{3}{8} \pi E_P \frac{t_i^3}{a_i \sqrt{1-\nu_P^2}} \zeta_i \tag{12}$$

Strain energy associated with bending of the pipe-in-pipe system

The strain energy per unit length to bend a pipe of flexural rigidity $(EI)_{PIP}$ to a curvature C is

$$U_3 = \frac{1}{2} (EI)_{PIP} C^2 \tag{13}$$

where

$$(EI)_{PIP} = E_P (I_1 + I_2) + E_C I_C \tag{14}$$

For a hollow pipe with ovalizaton, the moments of inertia are (Calladine 1983)

$$I_i = \pi a_i^3 t_i (1 - \frac{3}{2} \varsigma_i + \frac{5}{8} \varsigma_i^2) \tag{15a}$$

$$I_C = \frac{\pi a_1^4}{4} (1 - \frac{3}{2} \varsigma_1 + \frac{5}{8} \varsigma_1^2) - \frac{\pi a_2^4}{4} (1 - \frac{3}{2} \varsigma_2 + \frac{5}{8} \varsigma_2^2) \tag{15b}$$

Substituting Equations 14 and 15 into Equation 13 gives

$$\begin{aligned} U_3 &= \frac{1}{2} C^2 E_P \pi a_1^3 t_1 (1 + \frac{E_C a_1}{4 E_P t_1})(1 - \frac{3}{2} \varsigma_1 + \frac{5}{8} \varsigma_1^2) \\ &+ \frac{1}{2} C^2 E_P \pi a_2^3 t_2 (1 - \frac{E_C a_2}{4 E_P t_2})(1 - \frac{3}{2} \varsigma_2 + \frac{5}{8} \varsigma_2^2) \end{aligned} \tag{16}$$

Moreover, the strain energy per unit length associated with Poisson's ratio to maintain the circular cross section due to bending is then (Karam & Gibson 1995)

$$\begin{aligned} U_4 &= \frac{1}{2} \int_{a_2}^{a_1} \int_0^{2\pi} (2\sigma_r \varepsilon_r + \tau_{r\theta} \gamma_{r\theta}) r d\theta dr \\ &= \frac{\pi}{16} \frac{\nu_C^2 (5 - 2\nu_C)}{(1+\nu_C)(1-2\nu_C)} E_C C^2 (a_1^4 - a_2^4) \end{aligned} \tag{17}$$

Brazier moment

The final result for the strain energy of the pipe-in-pipe system is expressed by the summation as

$$U = U_1 + U_2 + U_3 + U_4 \tag{18}$$

We can find the optimum value of ζ_1 and ζ_2 for a given value of C from the condition $\partial U / \partial \zeta_i = 0$ and then obtain an expression for M from $M = \partial U / \partial C$. Moreover, the Brazier moment and the ovalization at the Brazier moment can be obtained from $\partial U / \partial C = 0$.

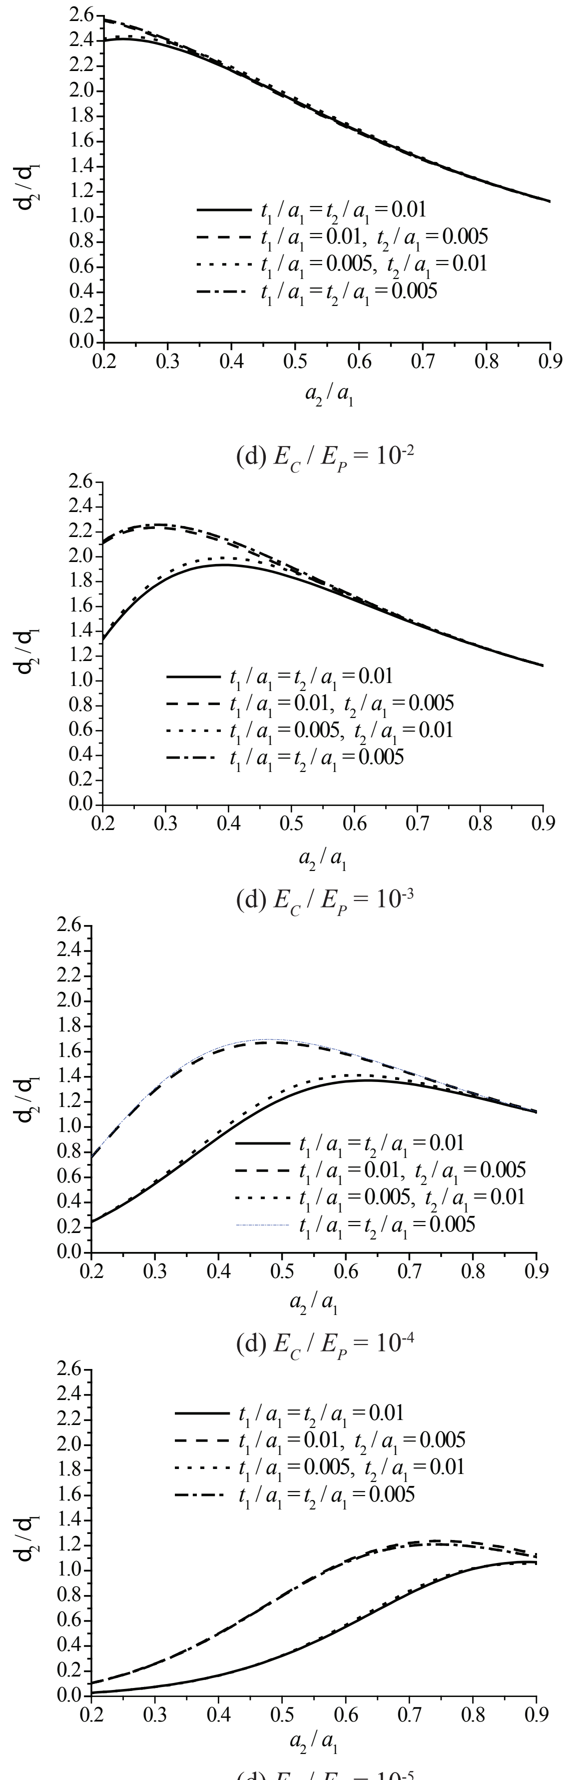

Figure 4. Displacement ratio (Inner to outer pipe, $\nu_P = 0.4$).

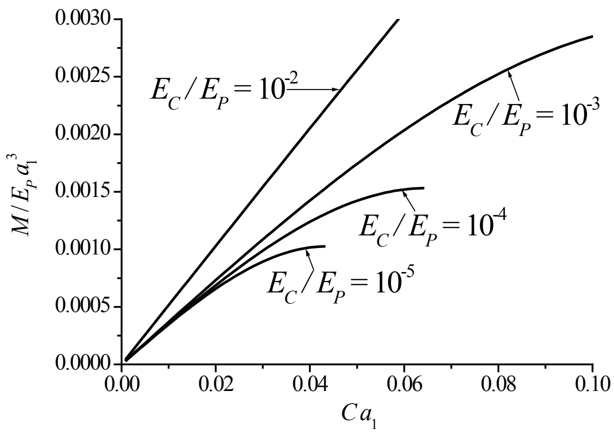
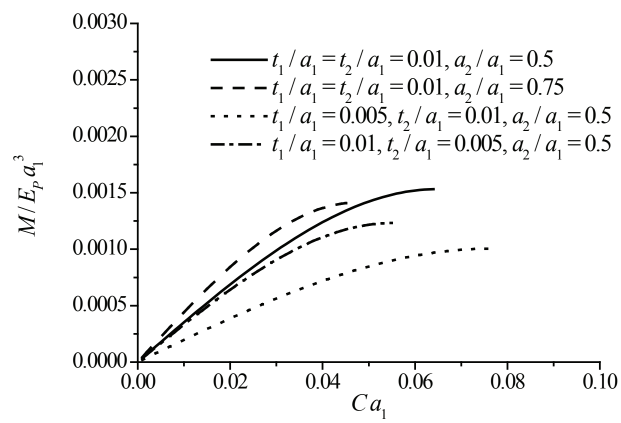
Results and Discussion

Ovalization at the Brazier moment

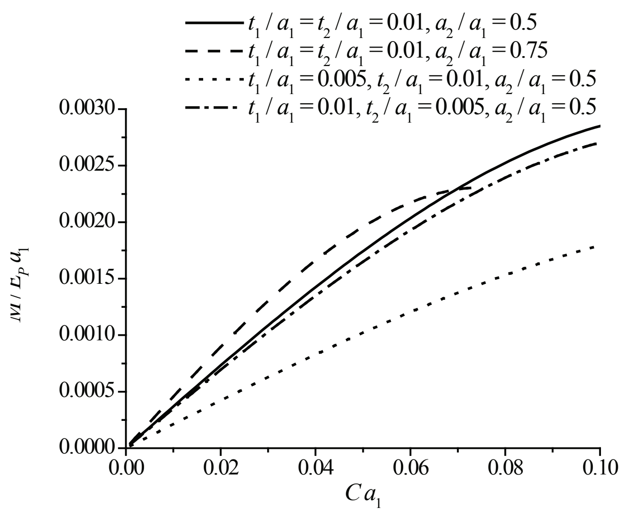
Figures 4a–4d show the plot of the displacement ratio δ_2/δ_1 due to bending against core thickness ratio a_2/a_1 for the various values of outer and inner pipe thicknesses to outer pipe radius ratio and core to pipe stiffness ratio. It is clear from the comparison of these figures that, as the core stiffness increases, the displacement for the inner pipe increases. Moreover, the effect of the change of the outer pipe thickness on the displacement ratio is quite little and this value can be determined by the core thickness and inner pipe thickness ratio.



(a) $t_1 / a_1 = t_2 / a_1 = 0.01$, $a_2 / a_1 = 0.5$



(b) $E_C / E_P = 10^{-4}$



(c) $E_C / E_P = 10^{-3}$

Figure 5. Non-dimensional moment-curvature relationship ($\nu_P = 0.4$).

Moment-curvature relationship and Brazier moment

Figures 5a–5c show the nondimensional bending moment-curvature relationship. In all cases, for small values of Ca_1 we can find that the relationship between bending moment and curvature is almost linear. However, as the curvatures increase, the relation becomes nonlinear and finally the values of M reach maximum, in other words "the Brazier moment." As expected, the Brazier moment increases, with increasing the core thickness. Figures 5b and 5c are the comparison with regard to the different outer/inner pipe thickness and core thickness ratio. The contribution of the outer pipe thickness rather than that for the inner pipe toward bending moment-curvature relationship is significant. In addition, we can find from these figures, that as the core thickness increases, Brazier moment also increases.

Conclusions

This paper presents the bending characteristics of pipe-in-pipe systems analytically by considering the Brazier effect. It should be noted that the outer pipe thickness and the core stiffness, rather than the inner pipe thickness, play an important role in the bending moment-curvature relationship for pipe-in-pipe systems. At the moment, this research is the simplified analytical investigation. However, further studies will address the experimental investigations planned by the authors' research group, and comparisons between analytical and experimental results will be carried out.

Origin and Age of Perennial Ice Within a Block Slope in the Shikaribestu Mountains, Hokkaido, Japan

Yuki Sawada
Institute of Low Temperature Science, Hokkaido University, Sapporo, Japan

Abstract

Borehole drilling and core sampling were conducted at the base of a block slope, where extra-zonal permafrost is preserved by winter air circulation and subsequent formation of the ground ice. A 3.8 m deep borehole displayed a vertical structure of the block slope. The sediment is composed of Sphagnum moss and peat (0–0.1 m depth), boulders (0.1–1.2 m), ice and boulder mixture (1.2–3.2 m), gravelly sand (3.2–3.35 m), and gravelly silt with ice lenses (3.35–3.8 m). Ratios of stable isotopes (δ18O and δD) of the perennial ice show similar linear correlations (gradient 7.5 and intercept 10.5) to the Global Meteoric Water Line, indicating that the ground ice is fed by meteoric water. AMS Radiocarbon datings of the trapped organic materials in the perennial ice indicate that the ground ice started to form between 8411–3728 Cal BP and has accumulated discontinuously throughout the late Holocene. Accumulation of the Sphagnum moss and peat layer on the blocky sediment may contribute to insulation and the gradual growth of the perennial ice.

Keywords: block slope; extra-zonal permafrost; paleoclimate; perennial ice; radiocarbon dating; stable isotope.

Introduction

Permafrost ice has the potential to archive paleo-climatic information within the stable-isotope composition, because most permafrost ice originates from meteoric water. For example, ice-wedge ice in continuous permafrost regions is generally formed by refreezing of snowmelt water. For this reason, stable oxygen isotope signals in the ice wedge have been used as an indicator of paleo-winter temperature (e.g. Mackay 1983, Meyer et al. 2002).

Ground ice in mountain permafrost environments also has a potential for paleoclimate reconstruction (e.g., Steig et al. 1998, Humlum 1999). Humlum (1999) reported that the relict glacier ice within a rock glacier in Greenland exhibits relatively lighter oxygen isotopes, which are indicative of the cooler climate in the little ice age.

Perennial ice bodies are also preserved in block slopes and talus slopes where extra-zonal permafrost is formed by air circulation where mean annual air temperature (MAAT) is positive (Kneisel et al. 2000, Sawada et al. 2003, Sawada 2003, Gude et al. 2003, Delaloye et al. 2003, Gorbunov et al. 2004, Zacharda et al. 2007). Previous studies by the author (Sawada et al. 2003, Sawada 2003) reported that ground ice formed in snowmelt periods and concluded that the ground ice probably originated from refreezing of snowmelt water. If the ground ice is considerably old, ice in the block slope may contain stable isotope signals of past climate changes.

This study presents stratigraphic and stable isotope data from a 3 m long core of ice and boulder mixtures obtained from a block slope in the Shikaribetsu Mountains, Hokkaido Island, Japan. AMS 14C ages of the organic materials in the sediments and ice are measured to determine the age of preserved ice. The oxygen and hydrogen isotope data are used to discuss the origin and formation processes of the perennial ground ice.

Study Area

The study area is located on the summit slope of Mt. Nishi-Nupukaushinupuri (1251 m a.s.l.) in central Hokkaido Island, Japan (Fig.1). This mountain is one of the lava domes which erupted in the last glacial period. MAAT ranged from 0.7°C–1.7°C in 1998–2003. Annual precipitation at the nearest meteorological station (Nukabira, 10 km NW) is 1175.8 mm, an average based on 12 years of data (1979–1990). The drill site is situated on the valley bottom which lies at the base of the block slope (Fig. 1). The lower portion of the block slope is dominated by spruce (Picea glehnii) and dwarf pine (pinus pumila), with ground surface cover of Sphagnum sp. and alpine shrubs (mainly Ledum palustre). Cold air blows during summer and autumn from the hollows opened in the moss mat.

Between 2000 and 2001 the depth of ground ice surface and ground temperatures at the drilling site showed the annual variations of the ground ice and related thermal regime (see for details Sawada et al. 2003, Sawada 2003). In winter the lower block slope was strongly cooled by air circulation driven by the temperature difference between atmosphere and inside of the block slope, while warmer air in the voids of the block slope moved upward and escaped from the top slope. The drained air was compensated by the penetration of colder outside air into the lower and middle part of the block slope (Sawada et al. 2003). Ground ice did not grow in winter, due to the lack of source water. In April, ground ice started to accumulate co-incidentaly with the initiation of the snowmelt (Sawada et al. 2003).

Ice ablation was triggered by heavy rainfall, and it continued until the subsurface was cooled to the freezing point in November 2001 (Sawada 2003). The annual maximum depth of the ground ice (i.e., active layer depth) ranged from -157.8 cm to -143.6 cm between 2001 and 2005 (Sawada unpublished data).

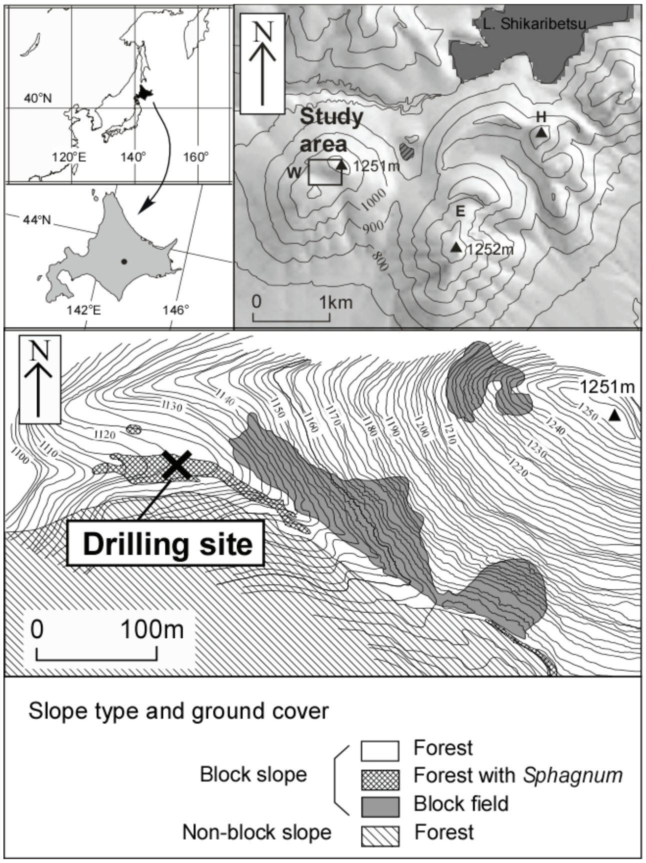

Figure 1. Study area and drilling site.

Methods

Drilling operation

Drilling was conducted on 11 July 2005, when the seasonal ice accumulation reached the annual maximum. The surficial soil and blocks were excavated down to the depth of 1.2 m. Drilling started on the surface of the seasonal ice. A drilling bit with tungsten carbide cutting teeth was used for the ice-predominant part, while a diamond bit with water injection was used for passing through andesite blocks. As a consequence, core samples of the ice and rock mixtures were obtained to the depth of 3.8 m during the 2-day drilling operations.

Sample analysis

The samples were sketched in the cold room at -20°C. Thereafter, these were cut into smaller pieces 2–11 cm in length. The length varied with the material of the samples: shorter length for pure ice, longer samples for ice-boulder mixture. The sample pieces were melted at room temperature. Water and organic materials were separated in the glass vials. AMS 14C datings of organic materials were conducted in Beta Analytic Inc., USA and Paleo Labo Co. Ltd., Japan. The 14C dates were converted into the calendar years with the calibration curve INTCAL04 (Reimer et al. 2004).

Oxygen and hydrogen isotope ratios were measured with the Delta-Plus mass spectrometer and Isoprime-PyrOH mass spectrometer, respectively. Both mass spectrometers are managed at the Institute of Low Temperature Science, Hokkaido University. Stable isotope ratios were given as permil difference to V-SMOW, with errors less than 0.02‰ and 0.5‰ for δ18O and δD, respectively. The results were presented in δ18O-δD diagrams with respect to the Global Meteoric Water Line (GMWL), in which fresh surface water was correlated on a global scale (Craig 1961).

Results

Structure of the core samples

Figure 2 shows sketch and pictures of the sample core. The core is classified into four segments: (A) ice and boulder mixture, (B) boulders, (C) gravelly sand with charcoal fragments, and (D) gravelly silt with ice lenses. Because the maximum thaw depth in the previous year (2004) was -141 cm, the upper 20 cm of ice is interpreted as seasonal ice formed in the spring of 2005.

Segment A contains clear ice and numerous organic materials. The ice displayed a layered structure (Fig. 2) similar to that of the glacier ice. The ice includes organic materials (leaves, branches, and fecal pellets). The fecal pellets piled up on the boundary of the ice layer have rounded shape with a diameter of 2–3 mm. These fecal pellets and plant materials indicate that the voids in the block layer are inhabited by Japanese Pikas (Ochotona hyperborea yesoensis) which commonly live in blocky landforms such as block slopes or moraines. They use the voids as nests or tunnels through which they carry plants (Kawamichi 1969). In addition, Japanese Pikas stock dried plants in the voids to survive in winter (Kawamichi 1969). The presence of the branches, leaves, and fecal pellets within the ice suggests the diets of Japanese Pika in the past.

Segment B does not contain clear ice, and this is probably due to thermal disturbances from drilling with a diamond bit. Because the tungsten bit became unstable at depth, a diamond bit with water injection was used to penetrate this segment. The ice may have melted from the heat of the pouring water.

Segment C consists of gravelly sand. Small particles of charcoal 2–5 mm in diameter are scattered in this layer. Visible ice is absent in this segment.

Segment D is composed of gravelly silt. A number of ice lenses are formed within this layer.

Chronology of the sediments and ground ice

The radiocarbon ages are listed in Table 1. The sediment structure is composed of the upper boulder layer and lower finer materials (sand and silt layers). The charcoal particles within the sand layer (Segment C, Fig. 2) exhibits ages of 8411–8211 Cal BP. There are two possible routes in which the charcoals fall onto the sand layer. One route is direct input to the sand layer. In this case, the accumulation of the boulder layer is considered to occur after the mixing of charcoals with the sand layer. The other is through the voids in the boulder layer. In this case charcoals penetrate into the existing block layer. In both cases the ground ice within the

Table 1. AMS radiocarbon ages of organic remains.

Depth	Host material	Type of organic material	Lab. Number	14C yr BP	Cal. yr BP 2-σ range
−159cm	ground ice	stem	PLD-7814	-65±15	N.A. (1950AD–Present)
−182cm	ground ice	stem	PLD-7815	570±15	633–537
−194cm	ground ice	fecal pellet	PLD-7816	720±15	683–661
−249cm	ground ice	leaf	Beta-213965	3590±40	4065–3728
−324cm	gravelly sand	charcoal	Beta-213966	7530±40	8411–8211

boulder layer is formed after the charcoals are mixed with the sand layer.

Accordingly, the organic materials in the infilling ice (Segment A, Fig. 2) exhibit much younger radiocarbon ages than the charcoals in the sand layer. The oldest age of 4065–3728 Cal BP was obtained from a leaf enclosed within the ice at depth of -249 cm. This leaf was extracted along with fecal pellets from the ice, indicating Japanese Pika stocked leaves in this depth. The age of the leaf also indicates that the ground ice was formed at this depth after the leaf had been transported. Thus, the age of the leaf gives the oldest estimation of the ice that included the leaf.

The ages of the organic materials become younger toward the ground surface. The ages of fecal pellets at -194 cm and stem at -182 cm are 683–661 Cal BP and 633–537 Cal BP, respectively (Fig. 2, Table 1). These two ages indicate that the perennial ice between -194 cm and -182 cm accumulated in 13–15 centuries. The age of stem at -159 cm exhibits a future age, which is apparently affected by recent nuclear testing. Thus, this age of ice shallower than -159 cm is interpreted to be modern (i.e., after 1950 AD).

Stable isotopes

Table 2 shows the isotopic composition of rain, snow, seasonal ground ice, and perennial ground ice samples. These isotope values are also plotted on the δ18O–δD diagram (Fig. 3).

Rain water (N=8) was collected during precipitation events between May and September 2004 at the shore of Lake Shikaribetsu (810 m a.s.l.). The mean isotopic composition of the rainwater was -11.0‰ for δ18O and -78.0‰ for δD. The samples are characterized by the d-excess of 9.7‰ and the slope of 7.4 on the δ18O–δD diagram, which are similar to the GMWL (d-excess of 10 and slope of 8: Craig 1961).

On 17 April 2005, snow cover was sampled at the drilling site (N=5). The snow cover was 2.2 m thick, and the upper 0.2 m started to melt. The isotopic composition of snow differs significantly from that of the rainwater. The mean isotopic composition of snow was -14.7‰ for δ18O and -90.5‰ for δD. The mean d-excess was 27.2‰, and the slope was 7.11. The larger d-excess value of snow indicates non-equilibrium evaporation from the Sea of Japan. In winter, northern Japan suffers westerly prevailing wind which originally blows from Siberia. The cold air causes fast non equilibrium evaporation from the Sea of Japan, where the Tsushima warm current flows from south to north (Waseda & Nakai 1983). Consequently, the winter precipitation has a large

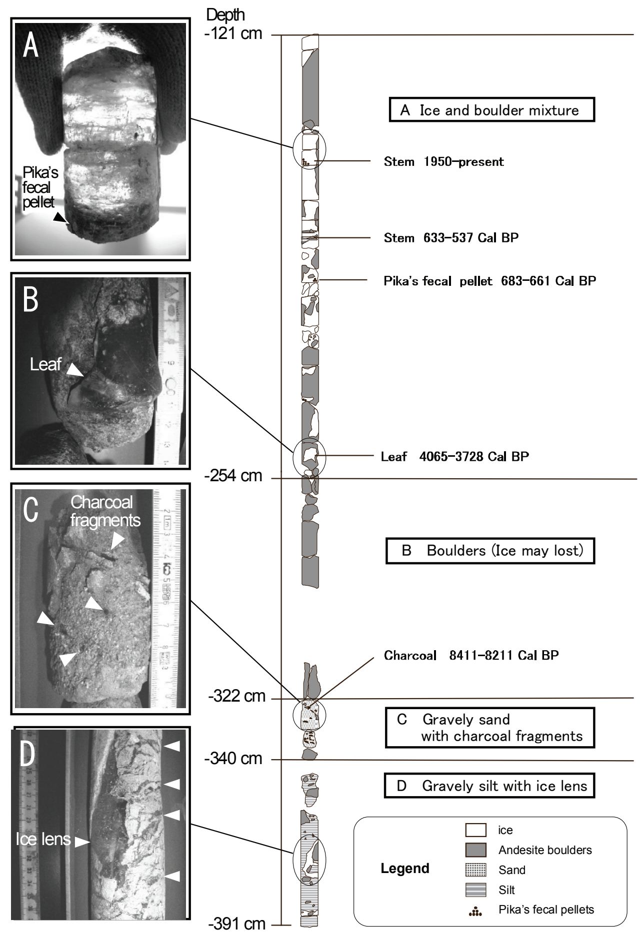

Figure. 2. Stratigraphy of the core samples obtained on the valley bottom.

Figure 2. Stratigraphy of the core samples obtained on the valley bottom.

d-excess value (>20), while the summer precipitation has a small value (<10), because vapor comes from the Pacific Ocean in summer (Waseda & Nakai 1983). Thus, the large d-excess value of snow is thought to originate from vapor from the Sea of Japan in winter.

The mean isotopic composition of seasonal ice formed between April and July 2005 was -12.3‰ for δ18O and -80.5‰ for δD, and mean d-excess was 17.8‰ (Table 2). These values were intermediate between rain and snow water, indicating two possibilities for isotope fluctuations: (1) the recent ground ice was fed by a mixture of rainwater and snowmelt water; (2) the ground ice was fed by snowmelt water, which was isotopically enriched before entering the block slope. Unnikrishna et al. (2002) reported that the initial

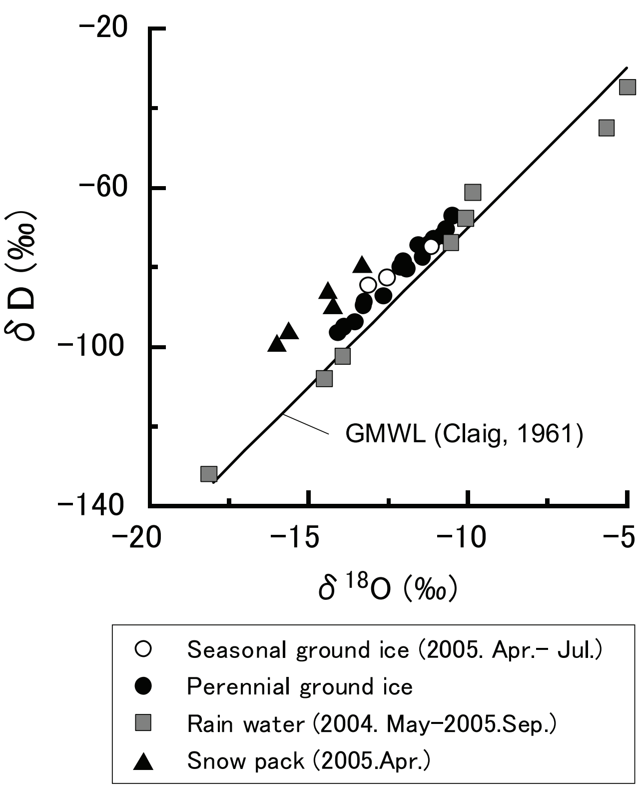

Figure 3. δ18O–δD diagram for rain, snow, seasonal ice, and perennial ice samples. GMWL is the Global Meteoric Water Line.

snowmelt water had higher δ18O than the original snowpack, because it originate from the lower snowpack layers which were isotopically enriched by snowmelt infiltration. This indicates that the rainwater may not be necessary for ground ice, which has a higher (heavier) δ18O than the snowpack.

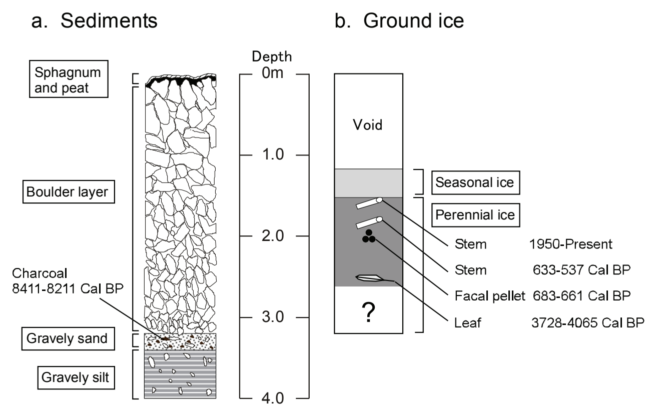

Figure 4. Vertical profiles of (a) sediments and (b) ground ice.

The perennial ground ice also has a smaller range of isotopic composition than rain and snow. The mean isotopic composition of the perennial ice was -11.2‰ for δ18O and -79.9‰ for δD, and mean d-excess was 16.0‰. The ranges were 2.1‰ for δ18O and 23.6 ‰ for δD. These small ranges indicate that the source water of the ground ice is basically unchanged for long periods.

Age and Accumulation Process of the Perennial Ice

The chronology of the sediment and ice of the core samples is shown separately in Figure 4, because the formation ages of these two materials are apparently different. Figure 4a shows the stratigraphy of the sediments. The perennial ice did not formed in the age of the charcoal particle within the sand layer (8411–8211 Cal BP), because the charcoal particles could not enter the sand layer if the above boulder layer was filled with ice. Thus, initiation of the perennial ice is younger than the charcoal age.

The calibrated age of the leaf trapped in the perennial ice at -249 cm depth (4065–3728 Cal BP: Table 1, Fig. 4b) gives the youngest estimation of the ground ice formation. The leaf had been preserved in good condition in the ice, indicating the leaf did not experience any decomposition. Thus, the real age of the ice formation at -249 cm approaches the age of the leaf. From these assumptions, the onset of the ground ice within the block layer can be assumed to be between 8.4–3.7 ka.

The age of organic materials within the perennial ice decreases toward the top (Fig. 4b), indicating the upward accumulation of the ice. Because the top of the perennial ice is determined by the seasonal thaw depth (active layer thickness), this sequence also suggests upward migration of the permafrost table. In the study site, Sphagnum mat, peat, and tephra layers cover the blocky sediments. These organic and volcanic soils may act as an effective insulator to reduce the heat input and to preserve the perennial ground ice even in the positive MAAT environment.

Conclusions

The drilling operation and subsequent geochemical analysis allowed paleoclimate reconstruction from the perennial ground ice preserved in a block slope. The AMS 14C dating of organic materials revealed that the perennial ground ice is preserved at least 3700 years. The 14C age became younger towards the top of the ice, indicating that the law of superposition is applicable to the ground ice sequence in the block slope.

Comparison of the stable isotope compositions between perennial ice, seasonal ice, rain, and snow suggests that the ground ice originates from purely meteoric water, while the isotope composition is changed from the original source water. The perennial ice has the potential to preserve long-term fluctuation in the isotope composition of the meteoric water.

Abstract

Measurements of streaming potentials were carried out on rock glaciers and talus slopes in a test site of the southern Swiss Alps. After some theoretical considerations and a brief description of the measurement technique, a method of data treatment in high declivity topography is presented. The results of self-potential prospecting measurements are generally in accordance with the geomorphological observations. In particular, the groundwater runoff is influenced by the occurrence of permafrost, which creates surfaces of water migration partially independent from ground porosity.

Keywords: geophysics; rock glacier; self-potential; streaming potentials; Swiss Alps; talus slope.

Introduction

Self-potential (SP) (or spontaneous potential measurements) in the study of periglacial environments is a recent and not well-developed geophysical method in geomorphology, geocryology, and glaciology. Natural electrical potentials measurements have been carried out to monitor the thawing front movement and to study the active layer and permafrost parameters in arctic periglacial environments (e.g., Gahé et al. 1988, Fortier et al. 1993), for the study of subglacial drainage (e.g., Blake & Clarke 1999, Kulessa et al. 2003) or for the investigation of landslides (e.g., Bogoslowsky & Ogilvy 1977, Gex 1993).

In alpine periglacial environments, no studies on streaming potentials associated with groundwater runoff in rock glaciers and talus slopes have been carried out. Rock glacier hydrology has been studied with water tracing (e.g., Tenthorey 1992, Krainer & Mostler 2002) or thanks to borehole logging (e.g., Haeberli 1985, Vonder Mühll 1992), whereas talus slope hydrology is not well known (e.g., Rist & Phillips 2005).

The present paper presents and discusses results of streaming potentials mapping in the Sceru Valley (Fig. 1), in the Eastern part of the Blenio Valley (Lepontine Alps of the Tessin, southern Switzerland). The objectives are to present the measurement technique and a method of data treatment in high declivity topography.

Theory and Methods

Macroscopic streaming potential mapping was realized from field measurements carried out in 2006 and 2007. The method is completed by geomorphological observations and mapping, frequency-domain electromagnetic lateral mapping and 2D resistivity profiling (Geonics EM-16R and EM-31), direct current (DC) resistivity soundings, and

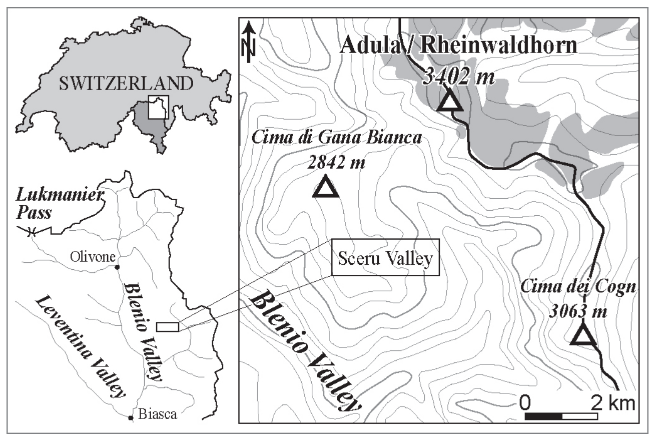

Figure 1. Geographical location of the study area.

thermal prospecting (miniature ground temperature data loggers and spring temperatures). In this paper, only the field measurement technique and the interpretation of large geomorphological structures (> 1000 m^2) are presented.

The streaming potentials

Streaming potentials, or electrofiltration potentials, are natural electrical potentials produced by water flow through a porous and permeable soil (Reynolds 1997). The streaming potentials are directly proportional to the selective filtration of ions (electrofiltration) at the microscopic scale. Water, acting as an electrolyte, creates at the interface mineral-water a positive load flow between the immobile part of the electrical double layer (composed by the Stern layer—in contact with the mineral and with fixed cations, and the Gouy-Chapman diffuse layer—with a lower cations concentration) and the free neutral electrolyte (Revil et al. 2004). The Helmholtz-Smoluchowski law links up the electrofiltration potential (EF) amplitude with the electrolyte characteristics:

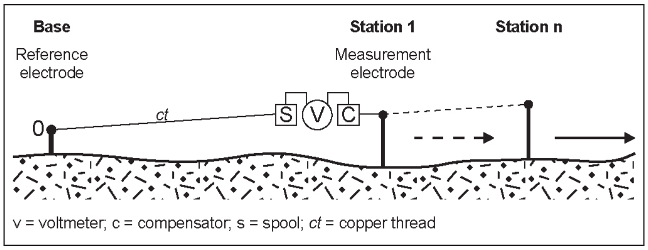

Figure 2. Field acquisition of self-potential data.

$$EF = \frac{\rho \varepsilon \zeta}{4 \pi \eta} \Delta P \tag{1}$$

where ρ is the resistivity, ε the dielectric constant and η the dynamic viscosity of the electrolyte. ζ is the electrical potential of the double layer (zeta potential) and ΔP is the pressure difference between the measurement points of EF.

Ultra-fresh and fresh groundwaters induce the maximum electrofiltration fields (Bogoslowsky & Ogilvy 1973). Indeed, in presence of much conductive water (with a mineral concentration exceeding 5 g/l), the electrolyte short-circuits the spontaneous electrical current.

Self-potential variations are also due to the granulometry and permeability of the soil. In a homogenous and isotropic terrain and where granulometry and permeability are known, the streaming potentials reflect the contours of the water table. In this case, self-potential mapping and inversion can supply information about some characteristics (configuration, direction, and intensity) of seepage flow both in horizontal and vertical planes (Revil et al. 2004).

Measurement of streaming potentials

SP is a passive method. The technique applied in this study is based on the fact that each value of self-potential measured at the ground surface is linked up with one electrode fixed at a base station situated outside of the geomorphological landforms studied. The potential difference (in mV) is measured between the reference electrode and a measurement electrode, which is moved along a traverse (Gex 1993, Reynolds 1997).

The range of the measured potentials is generally comprised between several millivolts (mV) and one volt. Because the sign of the zeta potentials could be positive or negative according to the earth materials, the sign of the difference of voltage measured is an important factor for the interpretation of SP anomalies (Reynolds 1997). For convention, the self-potential value at the reference electrode is zero. SP cartography has been carried out with a distance between every measurement of 3 to 5 m.

The measurement material used in this study was developed at the Institute of Geophysics of the University of Lausanne. The reference electrode of the model non-polarisable with Cu-$CuSO_4$ was realized in PVC and wood. The measurement electrode is fixed on a stick one meter long; its thin section allows us to drive it into the ground comfortably. It is linked up with the reference electrode by an isolated copper wire. A spool, fixed on the back of the operator, permits us to unwind the copper wire. The measurements are carried out with a high impedance (100 MΩ) digital voltmeter. The scale range of the voltmeter is comprised between -2000 and 2000 mV. A compensator is associated with the voltmeter to settle the SP value to the zero at the reference electrode. Finally, the voltmeter is provided with a filter that permits us to stabilize the measurements when the ground presents perturbations to the natural electrical fields. The field data acquisition is schematized in Figure 2.

Very Low Frequency-Resistivity (VLF-R)

The VLF-R technique (see Hoekstra et al. 1975, Hoekstra 1978, McGrath & Henderson 1985) uses electromagnetic energy radiated by a very low frequency (VLF) transmitter. In this study the Hauderfehn transmitter (23.4 kHz) located in Germany was used. The measurement of the horizontal component of the electric field and of the horizontal magnetic component perpendicular to the azimuth of the transmitting station allows the apparent resistivity of the near surface to be determined using the Cagniard (1953) equation:

$$\rho_a = (0.2/f)(E/H)^2 \tag{2}$$

where ρ_a is the apparent resistivity (Ωm), *f* the frequency (Hz), *E* the electric field (mV/km) and *H* the magnetic field (nT). The ratio between *H* and *E* gives a phase angle that changes according to variations of resistivity with the depth.

The field data acquisition was carried out using a Geonics EM-16R instrument.

Field Site Characteristics and Data Acquisition

The Sceru Valley (46°27'N, 9°01'E) is an east-facing glacial cirque situated between 2000–2787 m a.s.l. The morphology and hydrology of the Sceru Valley were studied by Scapozza (2008). The morphology is characterized by the presence of several rock glaciers with different degree of activity, talus slopes, and Lateglacial moraines (Fig. 3).

Permafrost is present in the Piancabella rock glacier and in the lower part of the Gana Rossa talus slope (Scapozza 2008). The hydrology of the southern part of the Sceru Valley is influenced by the presence of rock glaciers. Because of the high porosity of the blocky surface, no subaerial water runoff can be observed (the spring in the lower part of the Gana Rossa talus slope is situated one meter below the ground surface).

In 2006 and 2007, 17 SP profiles were carried out on the Sceru I rock glacier, 2 on the Piancabella rock glacier, 1 on the Gana Rossa talus slope, and 2 on the Sasso di Luzzone talus slope/rock glacier complex. In total, about 1300 SP measurement points were listed.

In the talus slopes and the active rock glacier, several SP profiles were combined with Geonics EM-16R and/or EM-31 mapping along the same traverse.

Results and Discussion

Data treatment

In high declivity topography like the alpine periglacial

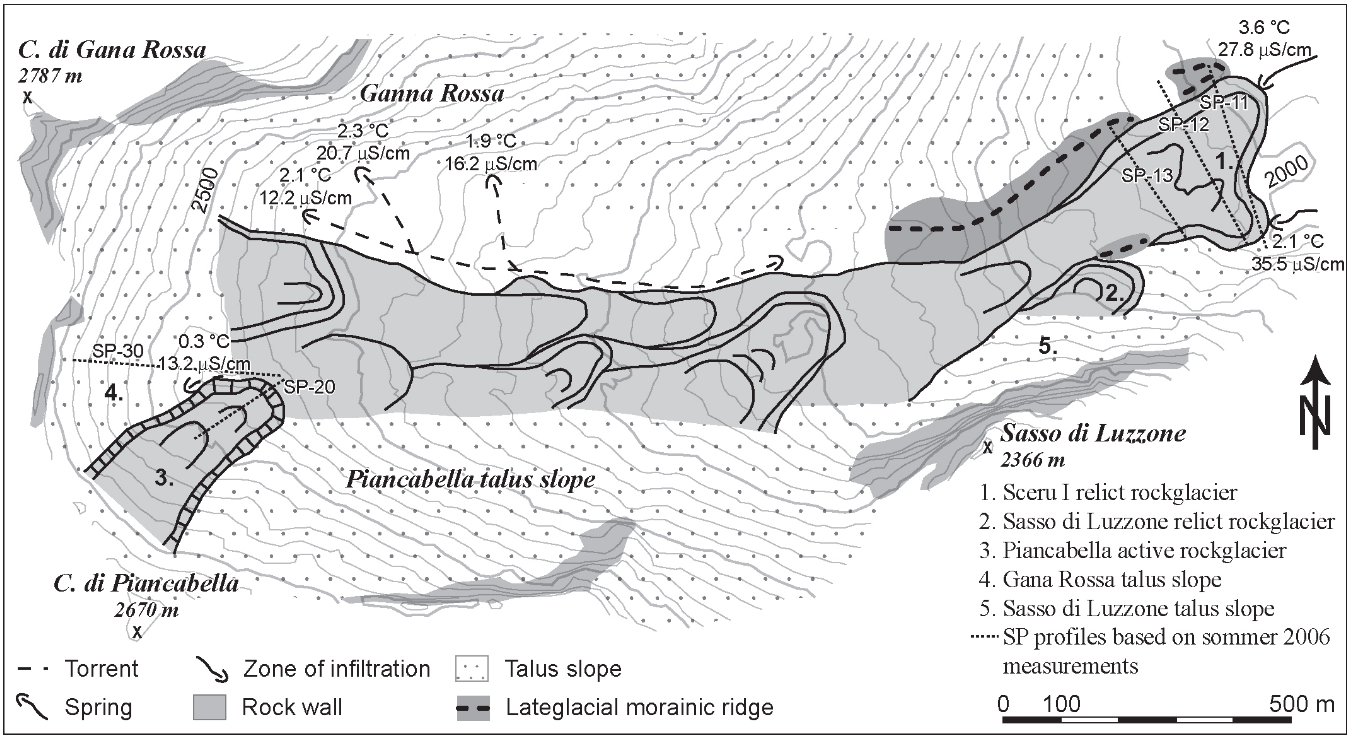

Figure 3. Geomorphological map of the Sceru Valley. For further information, see Scapozza (2008).

environment, the natural streaming potential linked to the slope is important, and its effect on the difference of voltage (in mV) measured by self-potential prospecting is very high. This perturbation, named "Topographic Effect" (TE), has been known to geophysicists for more than 90 years (Ernstson & Scherer 1986). The TE presents, for a constant electric field, an increasing negative potential linked with the elevation in altitude. For these reasons the regional anomaly (due to the TE) has to be subtracted from the measured values, which gives a final residual anomaly. The TE is calculated with a statistical analysis of linear regression between self-potential data and altitude. In practice, the average of the first four values of 11 traverses, measured between 2000–2450 m outside of the body of the Sceru I rock glacier, were used to calculate the TE, with a correlation between SP and altitude of -0.86. The calculated gradient of the TE is -68 mV per 100 m difference in elevation.

SP data were exposed in the form of potential profiles and equipotential maps. For the equipotential maps, a geostatistical interpolation of SP data was made with ordinary kriging. All the SP data (except for profiles SP-20 and SP-30) refer to the reference electrode placed outside the Sceru Valley (Fig. 4). For profiles SP-20 and SP-30, the reference electrode was placed at the Swiss Grid coordinates 720'215/145'660, at 2460 m a.s.l.

Sceru I relict rock glacier

The SP prospecting of this rock glacier shows an almost continuous negative residual anomaly in the northern lobe and another negative residual anomaly in the southern lobe. A zero millivolt residual anomaly is located between the Sceru I rock glacier and the Sasso di Luzzone talus slope/rock glacier complex situated south of it (Fig. 4).

According to the geoelectrical prospecting (2 DC resistivity soundings and one 2D resistivity profile), the bulk resistivity structure of the rock glacier seems to be relatively homogeneous. Indeed, the ground apparent resistivity is comprised between 3–5 kΩm (Scapozza 2008).

The groundwater runoff of two springs with different temperatures and electrical conductivities situated at two different lobes of the rock glacier could be followed by the self-potential prospecting (Figs. 4, 5). The link between the negative anomaly and the groundwater runoff is clearly evidenced in three SP profiles executed in summer 2006 (Fig. 5).

The two continuous anomalies may indicate the presence of two locations of preferential saturated groundwater flow. The two systems are probably independent, as evidenced from the constant difference throughout the year of temperature and conductivity of the two springs situated at the front of the rock glacier. Following this hypothesis, SP measurements would confirm that the two springs are alimented with groundwater of different origin (Fig. 4).

The torrents situated in the northern part of the Sceru Valley possibly feed the northern lobe spring (as pointed out by a warming of water temperatures), whereas the southern lobe spring would be alimented by an important aquifer situated into the Sceru I rock glacier. This water may be stored in the rock glacier for several months. The relatively high water conductivity (compared to the other springs in the valley, see Figure 3) and the constant water temperature (between 2.0°C and 2.2°C) all year long would confirm that the water transfer in this rock glacier is very slow, as it was pointed out by Tenthorey (1992) in a similar environment.

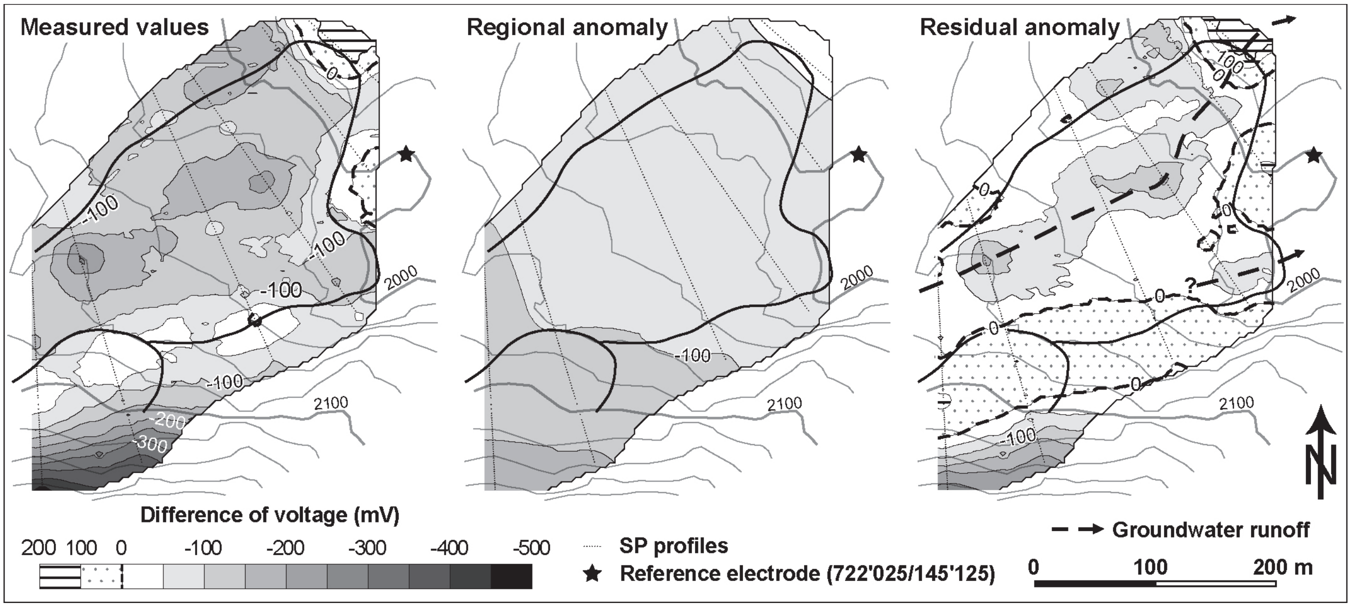

Figure 4. SP equipotential map of the Sceru I rock glacier and the Sasso di Luzzone talus slope/rock glacier complex based on summer 2007 measurements. For topographic names, see Figure 3.

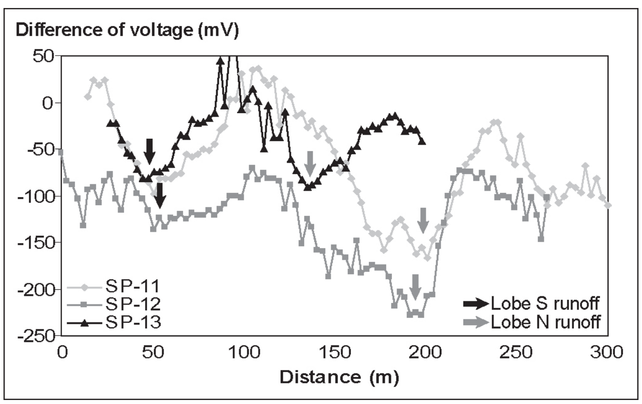

Figure 5. SP profiles executed across the Sceru I rock glacier. The arrows show negative anomalies linked with groundwater runoff. For the location of SP profiles, see the Figure 3.

The cold water temperature of the southern spring may be linked to a process of winter-ascending air circulation (the so-called chimney effect), which facilitates the cooling of the ground in the lower part of a porous sediment deposit (Delaloye & Lambiel 2005).

Piancabella active rock glacier

Prospecting of this landform shows a rise of the SP at the foot of the rock glacier front and a low increase of SP values all along the rock glacier (Fig. 6). Because of the location of the reference electrode (settled to 0) downslope of the rock glacier, the rise of the SP at the front can be interpreted as an important negative residual anomaly of several hundred mV.

A VLF-R tomography performed with the 2LayInv software (Pirttijärvi 2006) allows us to know approximately the active layer depth and the permafrost resistivity. The parameters of the profiling inversion are presented in Figure 6. Maximal VLF-R resistivities are found at the front of the rock glacier, and a decrease of the values toward upslope can be observed. Between 30–70 m, the decrease in the resistivities coincides with a decrease of the active layer depth. At 75 m, an important groundwater runoff has been perceived beneath the surface.

Data from the Piancabella active rock glacier show a connection between changes in SP, changes in active layer properties (particularly, its depth), changes in permafrost structure and/or in bulk resistivity structure (as shown by the VLF-R tomography). Indeed, the correlation between SP and active-layer depth is -0.74, whereas it is -0.85 between SP and permafrost resistivity. The correlation between SP and altitude (in m) is 0.54, which confirms that SP is partially independent from topography.

The permafrost resistivity depends on ground temperature, permafrost ice resistivity and content, and unfrozen water resistivity and content (Haeberli & Vonder Mühll 1996). Thus, it is difficult to separate the effect of change in water conductivity on SP from those on bulk resistivity.

The good connection between SP and permafrost resistivity probably indicates that there is a constant and continuous groundwater flow of constant water electrical conductivity and constant temperature throughout the active layer, and that SP changes are due to changes in the bulk resistivity structure of the rock glacier. This would confirm that the suprapermafrost groundwater runoff is supplied by the melt of annual névés at the root of the rock glacier and by the addition of incidental rainfall (see Tenthorey 1992). It is difficult to know the proportion of ice melt in the active layer and/or at the permafrost table, which is probable for a rock glacier situated at the lower limit of discontinuous permafrost.

Finally, the negative SP residual anomaly at the foot of the rock glacier front evidences an important groundwater runoff. This groundwater runoff is probably linked to suprapermafrost and intra- and subpermafrost water flow, which concentrates at the foot of the rock glacier front (Haeberli 1985).

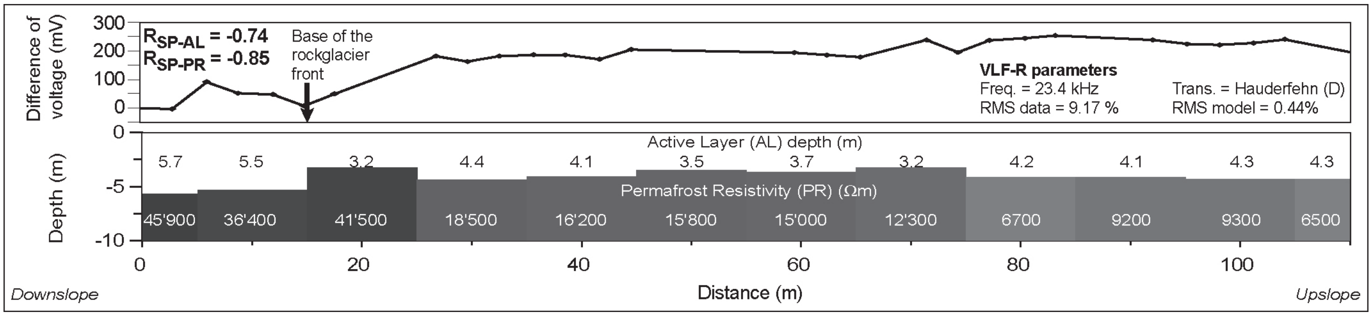

Figure 6. Profile SP-20 (at the top) and VLF-R tomography (below) on the Piancabella rock glacier. The VLF-R profiling inversion was performed with the 2LayInv (©University of Oulu) software (Pirttijärvi 2006).

Gana Rossa talus slope

SP prospecting of the Gana Rossa talus slope (Fig. 7) shows two negative residual anomalies in the lower part of the landform and an important and well-developed positive anomaly between 60–160 m distance. Another positive anomaly is present in the upper part of the talus slope. VLF-R prospecting shows relatively high apparent resistivities (over that 10,000 Ωm) in the lower part and in the middle of the talus slope. According to DC-resistivity, EM-31 and thermal prospecting (Scapozza 2008), permafrost is present only in the lower part of this talus slope (Fig. 7).

The streaming potentials are weakly positively correlated with altitude (R = 0.54), which contrasts with the theory of the TE (see *Data treatment*). Indeed, a test made in the Sasso di Luzzone talus slope (Fig. 3), where permafrost is absent, gives a very high negative correlation between streaming potentials and altitude (R = -0.97). Some results were pointed out by other studies carried out in high declivity slopes (e.g., Jackson & Kauahikana 1988).

Comparison between SP measurements and permafrost distribution shows, for the lower part of the talus slope, a connection between SP residual anomalies and permafrost occurrence. A possible hypothesis to explain this SP positive residual anomaly is the following: the presence of saturated or partially under-saturated permafrost may create a relatively impermeable surface of water runoff, which may modify the direction of the natural streaming potential linked to the slope (which is present between 120–200 m, as pointed out by the negative correlation between streaming potentials and altitude) by the canalization of groundwater flow at the base of the active layer. Following this hypothesis, the negative SP residual anomaly situated at a distance of 25 m may be related to an important water infiltration in the porous sediments, supplied by the melt of annual névés and by the addition of incidental rainfall. Whereas, the negative SP residual anomaly situated at a distance of 50 m may be related to the presence of a talik that would permit an intrapermafrost groundwater flow. The important groundwater runoff in the lower part of the talus is also proved by a spring (Fig. 3). Finally, in the upper part of the talus slope, the SP variations are probably due to the topography of bedrock, which is located only a few meters below the slope surface.

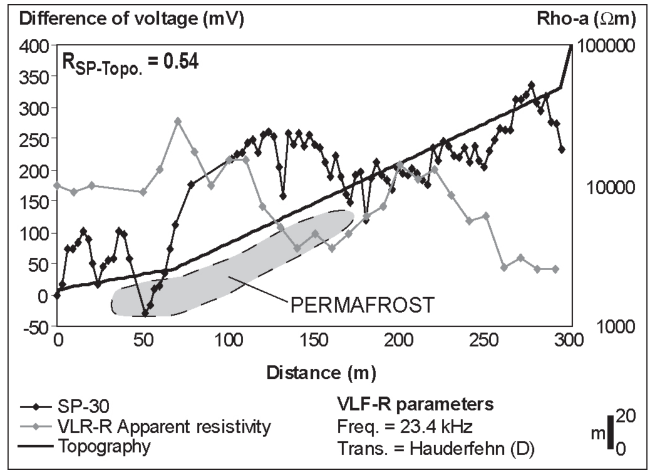

Figure 7. SP profile across the Gana Rossa talus slope.

In conclusion, it is very difficult today to better detail the hydrological and glaciological behavior of this talus slope without short, medium, and long-term thermal and geophysics monitoring at the surface and in boreholes.

Conclusions and Perspectives

The examples discussed show that measurement of streaming potential change on periglacial landforms offers good possibilities for assessing changes in water content and migration. Self-potential measurement could be useful for studying, in accordance with other geophysical methods, the importance of groundwater runoff generated by water infiltration and/or ice melting in permafrost terrains. The repetition of the same SP profile ten months later on a relict and an active rock glacier gave the same results; this confirms that streaming potential monitoring in periglacial landforms is possible. Self-potential monitoring associated with thermal and Electrical Resistivity Tomography (ERT) monitoring could be interesting for quantifying the processes correlated with permafrost degradation in high mountain environments.

Abstract

Accurate land cover, such as meso-scale to high-resolution digital elevation models (DEM), is needed to obtain reliable inputs for modeling the hydrology and the exchange between the surface and atmosphere. Small format aerial photography can be used to acquire high-resolution aerial images using balloons and helicopters. This method presents a low-cost, efficient method to construct a DEM of the polygonal patterned ground on Samoylov Island in the Lena Delta, Northern Siberia (72.2°N, 126.3°E). The DEM should be the foundation for modeling meso-scale hydrological processes on the island and identifying locations of discharge. The whole island could be covered with images taken from heights between 600 m and 800 m. All points of the DEM, with a resolution on the ground of 10 m, have a horizontal and vertical accuracy better than 1.0 m. This accuracy and the resolution depend on the survey height, the resolution of the camera system, the number and the quality of the images, and the algorithms used in the analysis. All listed parameters are explained and discussed in the paper.

Keywords: aerial photography; balloon; digital elevation model; polygonal patterned ground; Samoylov Island.

Introduction

The application of small format aerial photography to acquire high-resolution aerial images is still challenging. Balloons, kites, and helicopters are interesting and valuable tools for aerial photography. Several techniques with their advantages and disadvantages are briefly introduced and discussed in Bigras (1996) and Henry et al. (2002). Boike and Yoshikawa (2003) showed the successful use of balloon aerial photography for mapping snow, ice, and periglacial landforms around Fairbanks and Ny-Alesund, Svalbard. Recently, Vierling et al. (2006) successfully employed a tethered balloon with an altitude up to 2 km to acquire remotely sensed data. Further application fields are briefly explained in Aber and Aber (2002).

The goal of our work was to generate a digital elevation model (DEM, regular or irregular distributed points) of the polygonal patterned ground on Samoylov Island in the Lena Delta, Northern Siberia (72.2°N/126.3°E). The DEM should be the foundation for the modeling of meso-scale hydrological processes on the island for answering questions like: where are polygonal seas, how big are they, and where does the water drain into the Lena?

The landscape of the island is shaped by the micro topography of the wet polygonal tundra. The development of low-centered ice-wedge polygons results in a prominent micro relief with the alternation of depressed polygon centers and elevated polygon rims with elevation differences of up to 0.5 m over a few meters distance. Satellite images with resolutions between 15 m and 30m, such as Landsat (Aber & Aber 2002), do not represent this micro relief sufficiently. Difficulties of using satellite images are discussed in detail by Dare (2005). It is, however, the most important factor for small-scale differences in vegetation type and soil moisture, and is therefore a major variable when considering heat and trace gas fluxes on the meso-scale.

Depending on the general conditions, feasible equipment, cost, and available measurement time, the required horizontal and vertical accuracy of the DEM should be better than 1 m. Since remote-control-aircraft and drones are not permitted in Siberia, we used a tethered helium balloon. In addition it was also possible to take images from a helicopter. The photogrammetric equipment consists of a Nikon D200 with a 14 mm lens, 26 fabric-made targets for ground control points (GCPs), and additional geodetic equipment (tachymeter Elta C30).

This paper presents a low-cost, efficient method to acquire high-resolution aerial images using helium filled balloons. It discusses (1) different steps of obtaining aerial images from a balloon and a helicopter, (2) data analysis, (3) advantages and disadvantages of different assimilation platforms and (4) further improvements to increase the resolution of the DEM and the horizontal and vertical accuracy of the coordinates of each point.

Methods

The motivation mapping of the patterned ground on Samoylov Island was achieved using photogrammetric methods on aerial images with overlapping areas, allowing the determination of 3D coordinates (stereoscopy). There are different methods available ranging from simple stereoscopic methods with two images to a bundle block adjustment (Henry et al. 2002) over all taken images. Here

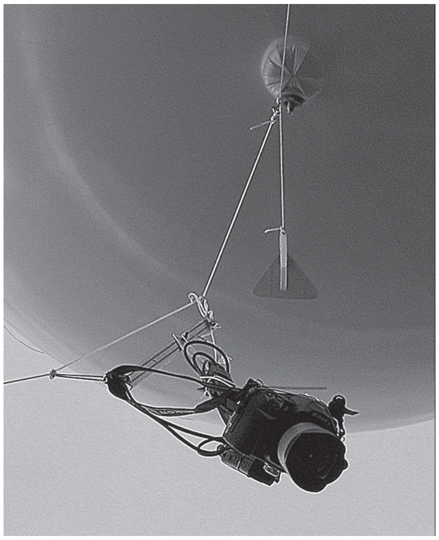

Figure 1. Camera system: Nikon D200, hanging at the tethered helium filled balloon.

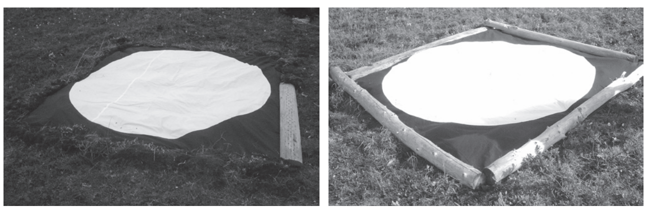

Figure 2. Fabric-made targets used as ground control points with a diameter of 2.5 m.

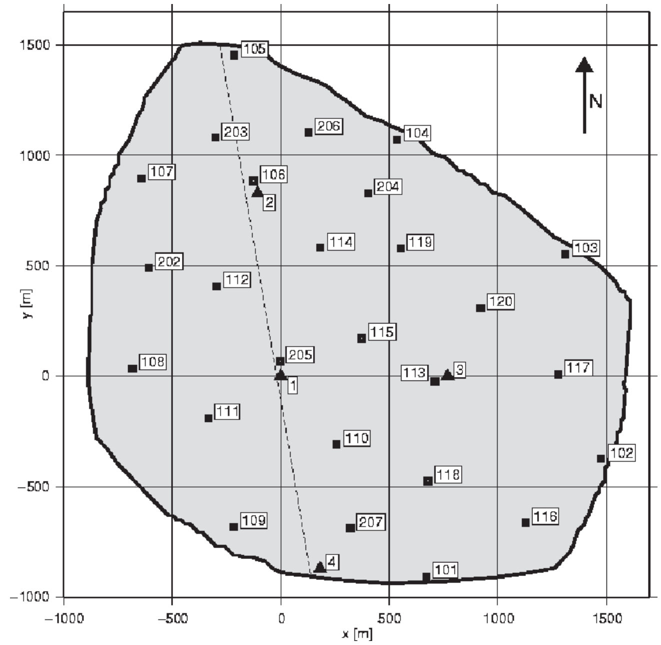

Figure 3. Schematic illustration of Samoylov Island: Network of 26 ground control points (squares); The coordinate (0,0) shows the origin of the local coordinate system with a fixed height of 100 m. The 4 datum points are displayed as triangles. The dashed line separates the flood plain (western part) and the plateau (eastern part).

the former method was used, since the flight path, height, and orientation of the balloon and thus the resulting images were somewhat unpredictable. The data analysis then consisted of two important steps: firstly a separate backward intersection for the calculation of the image orientation and secondly a forward intersection for the calculation of the 3D coordinates of the points of the DEM.

Before the fieldwork was carried out, the optimal camera system and the number of the GCPs was determined. The pre-condition for the DEM was a resolution on the ground better than 10 m with an accuracy in coordinates better than 1 m. Thus prior calculations were done on flight height, the size of the GCPs, the distance between them, and the required number of images covering the whole island. The survey height and the number and size of the GCPs finally were a compromise between the available time for measurement, the investment for the camera system, and the mentioned optimal conditions for resolution and accuracy.

Equipment

The equipment for the aerial photography consists of a Nikon D200 camera with a 14 mm lens (Fig. 1) and 26 fabric-made targets used as GCPs (Fig. 2). The Nikon D200 is a digital mirror reflex camera with a CCD sensor of 10.2 megapixel. With the calculated flight height of 800 m, one pixel maps an area of ~0.12 m² on the ground.

Depending on the flight height, the focal distance of the lens, and the condition that each GCP should represent an area of at least 6 x 6 pixels in the digital images, their diameter had to be greater than 2.0 m (Fig. 2).

To precisely calculate the image orientation, it was necessary to set up enough GCPs on the island to get a minimum of 4 points within each image. Considering the calculated flight height of 800 m, this resulted in at least 20 GCPs (called 101–120) with a spacing of about 500m to get an optimal coverage of Samoylov Island (~5 km²). Six control targets with a diameter of 1.0 m were additionally laid out to condense the point network (point IDs 202–207). The entire network of GCPs is shown in Figure 3.

A local coordinate system on Samoylov Island was fundamental to the photogrammetric fieldwork. Therefore 4 datum points (Fig. 3, point IDs 1–4) were set up, each marked with a 1m iron pipe in the permafrost soil. The distances between these points reached from 800 m to 1200 m. In Figure 3 the coordinate (0, 0) shows the origin of the local coordinate system with a fixed height of 100 m. For setting up the coordinate system we used the tachymeter Elta C30. The repeatability of the coordinates of the datum points was better than +/-2 cm.

Fieldwork

The fieldwork was divided into two parts. Firstly, GCPs were laid out, and their coordinates were surveyed in the local coordinate system. Secondly, aerial photographs were taken using a tethered balloon and a helicopter.

After laying out the GCPs, their registration was conducted

Figure 4. Tethered balloon, filled with helium, diameter 2–3 m.

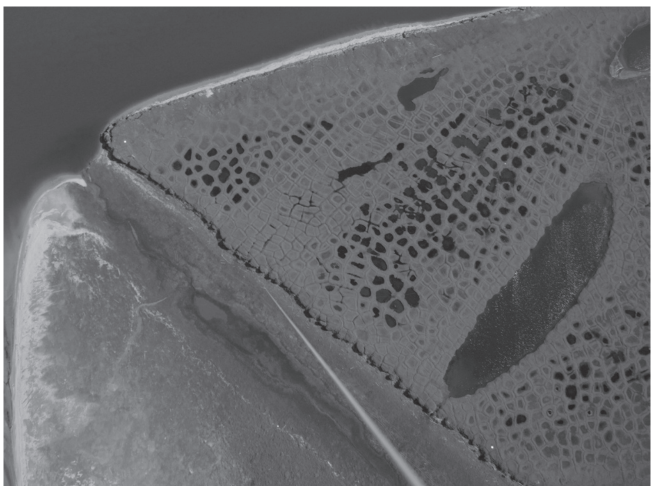

Figure 5. Polygonal patterned ground admitted from a height of ~750 m, in front the rope to the balloon.

in the local coordinate system with help of the tachymeter. The accuracy of the distances between the datum points and the GCPs was better than 1 cm. The coordinates of all GCPs had an absolute accuracy better than +/-5 cm. These accuracies depended on the determination of the center of the GCPs, the accuracy of the angle measurements with the tachymeter, and the distances to the survey points.

The balloon used in mapping the patterned ground on Samoylov Island is depicted in Figure 4, and an example image is given in Figure 5. The interval timer of the camera was adjusted to 1 minute, so the camera could take images for nearly four hours. Using the tethered balloon, one third of the entire island (western part, flood plain, Fig. 3) could be covered from a height of about 800 m.

Additionally, images were captured from a helicopter from altitudes between 600 m and 900 m. Using the helicopter, the middle part of the island could be covered with a flight height of ~600 m, the eastern part with flight heights of nearly 800–900 m.

Calibration of the camera system

For the subsequent data analysis it was necessary to determine the parameters of the inner orientation of the camera system (interior parameters: principal distance c, coordinates of the principal point x_0, y_0, parameter of distortion dx, dy). The calibration of the camera system as specified in Luhmann (2000) was conducted before the fieldwork at the Institute of Photogrammetry at the Dresden University of Technology (Table 1).

To verify these camera parameters, a calibration-field was set up on Samoylov Island. Using the Elta C30, the coordinates of these points were measured with a relative accuracy of a few millimeters. The parameters of the inner orientation, that were consecutively determined, were nearly the same as in the laboratory, so the relation between the body of the camera and the objective can be assumed as stable.

Data Analysis

To analyze the collected data, a program was generated based on the algorithms of Luhmann (2000) and Schwidefsky & Ackermann (1976). The program includes the collinearity equations, which correlate the image coordinates (x,y) and the object coordinates (X,Y,Z) for each point:

$$x = x_0 - c \cdot \frac{r_{11}(X - X_0) + r_{21}(Y - Y_0) + r_{31}(Z - Z_0)}{r_{13}(X - X_0) + r_{23}(Y - Y_0) + r_{33}(Z - Z_0)} + dx \qquad (1)$$

$$y = y_0 - c \cdot \frac{r_{12}(X - X_0) + r_{22}(Y - Y_0) + r_{32}(Z - Z_0)}{r_{13}(X - X_0) + r_{23}(Y - Y_0) + r_{33}(Z - Z_0)} + dy \qquad (2)$$

First, a backward intersection was calculated for each single image to determine the outer orientation (perspective center (X_0, Y_0, Z_0) and rotation matrix $\underline{R}$). Approximated parameters of the outer orientation were necessary and could be calculated applying a special algorithm developed by Schwidefsky and Ackermann (1976). The calculation of the outer orientation was successful for all images, which had minimized 4 GCPs.

Second, approximated coordinates for the points of the DEM were determined with help of a regular raster with a step size of 10 m based on the local coordinate system. The height of each point was set up to the average height of all GCPs. With the known outer orientation of the images a backward intersection could be determined for each preliminary point of the DEM, so the approximated positions could be found in the images. Then a search patch was defined around these locations and a matching-algorithm (with sub pixel accuracy) was implemented to locate precisely the same patch in other images. The matching algorithm was calculated with a cross-correlation:

$$k = \frac{\sum_{x'}\sum_{y'} g_1(x',y') \cdot g_2(x+x', y+y')}{\sum_{x'}\sum_{y'} g_1(x',y')^2 \cdot \sum_{x'}\sum_{y'} g_2(x+x', y+y')^2}$$

$$-1 \le k \le 1$$

At each position (x', y') a correlation coefficient k was determined depending on the gray scale value g of each pixel. The output consisted of a correlation image with all calculated values of k. Then, an algorithm was implemented which fitted an ellipsoidal paraboloid in the correlation image to find the exact position of the correlation maximum. At the end a forward intersection was calculated as a least square adjustment to get the exact 3D-coordinates for the points of the DEM.

The output dataset consists of all calculated coordinates, the standard deviation, and the correlation factor for the matching of one point between different images. If the correlation factor is greater than 0.7, and if the accuracy of the coordinates (horizontal and vertical accuracy) is better than 1 m, the point is stored as a point of the resulting DEM of Samoylov Island.

Results

Figure 6 shows the triangulated DEM. The horizontal and vertical accuracy of the coordinates of each point is better than 1.0 m (1σ, i.e., confidence interval of 68%). Polygonal lakes are easy to distinguish, because the algorithm was not able to match over the uniform water surface. Also, areas with bad data coverage are recognizable, for example in the southeastern part of Figure 6. The main reason for this is that the helicopter height changed very fast during the taking of the subsequent images, resulting in changing scaling factors of these images and smaller correlation factors. Other reasons for degraded correlation are poor illumination conditions and insufficient contours. As a result, only few points were found with a correlation larger than 0.7, whereas for most points the correlation factor was lower than 0.5. The island's center and the western and northern part have the best coverage of points. The helicopter was flying over the center at a nearly constant height of 600 m. In addition, the height of the tethered balloon over the flood plain (western part, Fig. 6) was nearly constant, which made the calculations (in particular the matching algorithm) really successful. The estimated points from both datasets could be matched with correlation factors up to 0.99 and with horizontal and vertical accuracies partially better than 0.5 m.

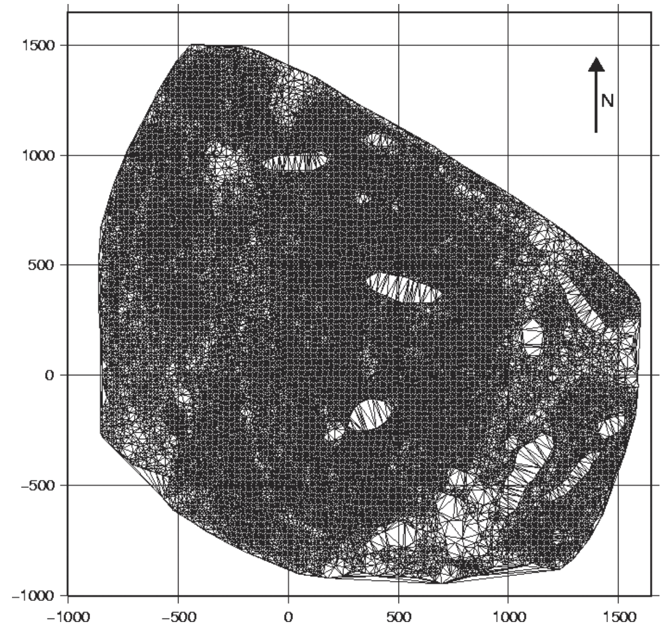

Figure 6. Triangulated irregular DEM with an approximated step size of 10 m of Samoylov Island: x- and y-coordinates are in a local coordinate-system (scale in m).

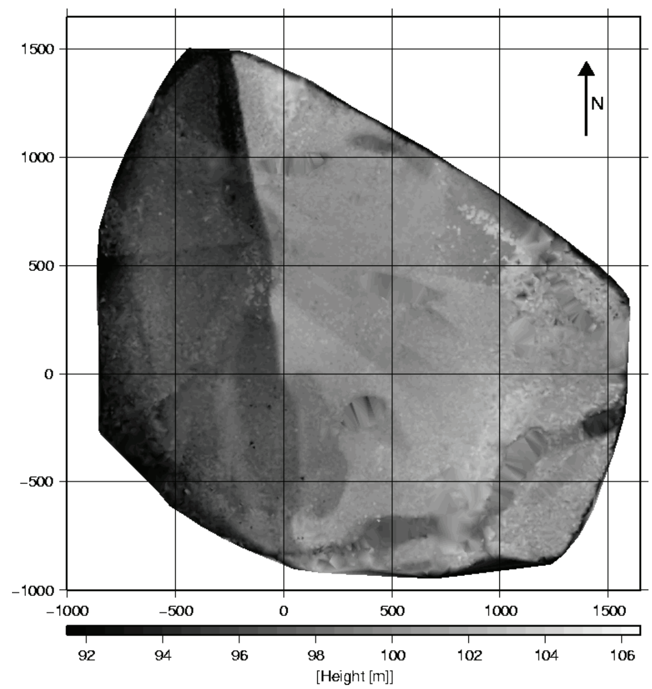

Figure 7. Surface of Samoylov Island: x- and y-coordinates are in a local coordinate system (scale in m). The heights of the points of the DEM are relative heights with respect to the origin of the local coordinate system (0.0) with a height of 100 m.

In Figure 7 the triangulated network from Figure 6 is shown as a surface for the whole island. The flood plain is easy to distinguish, as well as the ridge between the flood plain and the plateau and the cliff line with height differences up to 8 m.

Discussion

The goal of this project was to generate a DEM of the whole of Samoylov Island. The short observation period and the cost of and permission for the equipment formed the boundary conditions for the field work, under which a trade-off between the resolution, accuracy, and practicable amount of work for the acquisition and evaluation of photos had to be found. We finally decided to use a tethered, helium-filled balloon and a camera with a high precision lens (Nikon D200 with 14 mm lens). On the ground, 20 fabric-made targets with a diameter of 2.5 m and 6 targets with a diameter of 1.0 m spanned a network of GCPs.

Taking aerial photographs with a balloon is a low-cost and efficient method to acquire high-resolution aerial images. However, to take images with a balloon-borne camera, a calm day with good illumination conditions is required. Especially the wind speeds limit the observation time – during the 3 weeks of the field work on Samoylov Island we had only 2 days with good weather conditions. Taking images from a helicopter is independent from wind conditions and more stable in maintaining the height and the flight path. But this application is very expensive, and it is also dependent on good illumination conditions.

A sensitive step within the data analysis is the matching algorithm, because different illumination conditions like cloud shadows and different scaling factors of the images are a disadvantage. Also the search patch has to be big enough to get sufficient correlations between different images with high correlation factors. To avoid correlations between neighboring points of the DEM (this would degrade the accuracy of coordinates) the step size has to be at least twice the size of the search patch. Depending on the survey height of 800 m and a search patch of 24 x 24 pixel, the resolution on the ground of the DEM was set to 10 m. Therefore, all points of the generated DEM should be independent from each other.

Under these terms each point of the DEM has a horizontal and vertical accuracy better than 1 m. Naturally there are improvement possibilities to retrieve the micro relief of the polygonal wet tundra, such as the use of more and smaller targets for GCPs concomitant with a lower flight height and thus a higher resolution and accuracy. Furthermore the standard deviation of the coordinates of the DEM improve, if the points can be found in more than 2 images. Therefore, a better and regular image-coverage of the whole island from the same survey heights and good stereoscopic bases (relation between survey height and image-spacing) are a requirement for high resolution DEMs.

Conclusions

The method described in this paper is, depending on the measurement time, cost, and equipment, very useful to measure typical permafrost landscapes with the desired resolution and accuracy. Depending on the survey height and conditions described above, the horizontal and vertical accuracy of each point in the generated DEM of Samoylov Island shown in Figures 6 and 7 is better than 1.0 m for nearly 70% of all triangulated points. The obtained resolution of the DEM amounts to 10 m. Additionally, the combination of images from balloon and helicopter was successful if the flight height was approximately equal.

The meso-scale DEM discussed in this paper is now utilized (at the Alfred Wegener Institute for Polar and Marine Research in Potsdam) to determine the channel routing in a spatially distributed hydrologic model for Samoylov Island. Additionally, it is also possible to generate a orthomosaic (Bitelli & Girelli 2004) with the known parameters of the outer orientation of the images. This methodology provides a good basis for quantification of fluctuating coastlines in permafrost landscapes.

Acknowledgments

This work was funded by the Alfred Wegener Institute for Polar and Marine Research in Potsdam, Germany. We are thankful for the logistical and financial support of the Russian-German research station on Samoylov that made this study possible. We also thank Günter Stoof, Moritz Langer, and Maryvonne Landolt for their assistance in the field and for data discussion and analysis.

Abstract

The Yedoma Suite is well exposed along coasts and riverbanks in the northeastern Siberian Arctic. The cryotexture of these mostly ice-supersaturated deposits is similar at most sites—ice bands and reticulated ice lenses. The Yedoma Suite is considered a sequence of buried cryosols, formed under predominantly subaerial conditions. It represents an important terrestrial carbon reservoir (TOC 2–5-wt%). The multimodal grain size distribution does not reflect primarily aeolian accumulation, but rather a mixture of various periglacial transport and accumulation processes based on the concept of nival lithogenesis. The Yedoma Suite age lies in the MIS-3 and MIS-2 periods and, in rare cases, already starts during MIS-4. The palaeoecology of the Yedoma Suite can be summarized in the term "Tundra Steppe," combining both tundra and steppe environmental features. The present occurrence of the Yedoma Suite remains is closely related to low mountain ridges surrounding the northern and northeastern Siberian shelves. The concept of nival lithogenesis is presented, explaining the origin of source material and transport medium.

Keywords: cryolithology; late Pleistocene; northeastern Siberia; palaeo-environment; yedoma.

Introduction

The term *yedoma* is often associated with describing possible reactions of permafrost to global warming (Zimov et al. 2006, Walter et al. 2006, Walker 2007). The word *yedoma* probably originated in Kamchatka and described a boggy site or an elevated meadow-like flat plain. It entered science via the expeditions of Vitus Bering in Siberia during the 18th century. Initially, the term *yedoma* was of geomorphologic origin and described the hills separating thermokarst depressions in East-Siberia, especially in the Yana-Indigirka and Kolyma Lowlands (Kolosov 1947, Baranova & Biské 1964, Mursaev 1984, Tomirdiaro 1980). These mounds were considered to be erosional remnants of former accumulation plains. In this sense, yedoma described a special geomorphological relief type in Siberian permafrost regions, directly formed by thermokarst and thermoerosion (Solov'ev 1959, 1989).

The stratigraphical term *Yedoma Suite* was later adopted for middle Pleistocene horizons in the northeastern Siberian Lowlands (Lavrushin 1963, Vas'kovsky 1963). This stratigraphical position was moved to the late Pleistocene based on faunal studies at the Duvanny Yar site in the Kolyma Lowlands (Sher 1971), which became the stratotype for the Yedoma Suite. This categorization was finally confirmed by the decision of the Interdepartmental Commission on Quaternary Stratigraphy of the Soviet Union in Magadan in 1982 (Sher 1987).

Early genetic conceptions of the Yedoma Suite include glacier-dammed basin sediments (Grosswald 1998), alluvial genesis (Rozenbaum 1981), deltaic formation (Nagaoka et al. 1995), proluvial and slope deposits (Slagoda 2004, Gravis 1969), cryogenic-aeolian (Tomirdiaro et al. 1984, Tomirdiaro & Chernenky 1987), and nival deposits (Galabala 1997) as well as polygenetic origins (Sher et al. 1987).

The deposits of the Yedoma Suite represent unique late Pleistocene palaeoenvironmental archives for a large region of the Northern Hemisphere lacking major glacial records. Within the Russian-German project, System Laptev Sea, these deposits were studied with a multidisciplinary approach (cryolithology, sedimentology, palaeontology, palaeobotany, geochronology, mineralogy, isotope geochemistry, GIS, remote sensing) during the last ten years. We here present a first review of some general results on the overarching features of the Yedoma Suite in the Laptev Sea region and a concept of its formation.

Study Region

Since 1998, we have studied the characteristics of the Yedoma Suite at 15 well-exposed sites on the Laptev Sea and the East Siberian Sea coasts, and in the Lena Delta (Fig. 1). These sites are situated in the lowland plains of the continental shelf on both sides of the current seismically active boundary of the Eurasian and the North American continental plates.

Characteristics of the Yedoma Suite

Occurrence and geomorphology

The occurrence of the Yedoma Suite in the study region is closely related to low mountain ridges (ca. 200 to 400 m a.s.l.) surrounding the northern and northeastern Siberian shelves, which are the major sediment sources for the Yedoma Suite. In the western Laptev Sea and the Lena Delta region the occurrence of the Yedoma Suite is strongly connected with the coastal mountains of the Pronchishchev, Chekanovsky, and Kharaulakh Ridges. Heavy mineral studies at various sites have shown that these ridges are a main source of sediment (Siegert et al. 2002, Schwamborn et al. 2002, Schirrmeister et al. 2003). Therefore, foreland accumulation plains were the areas of the formation of the Yedoma Suite. In the eastern part of the study region, the exposed granite and basalt intrusions on Bol'shoy Lyakhovsky Island and Cape Svyatoy Nos as well as the fault ranges on Bel'kovsky, Stolbovoy, and Kotel'ny Islands serve as source areas for sediments of the Yedoma Suite. The distribution of the ice-rich sequences is easily identified by frequent thermokarst depressions or lakes (Grosse et al. 2005, 2006, 2007).

The Yedoma Suite exposes permafrost cliffs in 10- to 40-m-high horseshoe-shaped thaw slumps or thermocirques along sea coasts and riverbanks (Fig. 2).

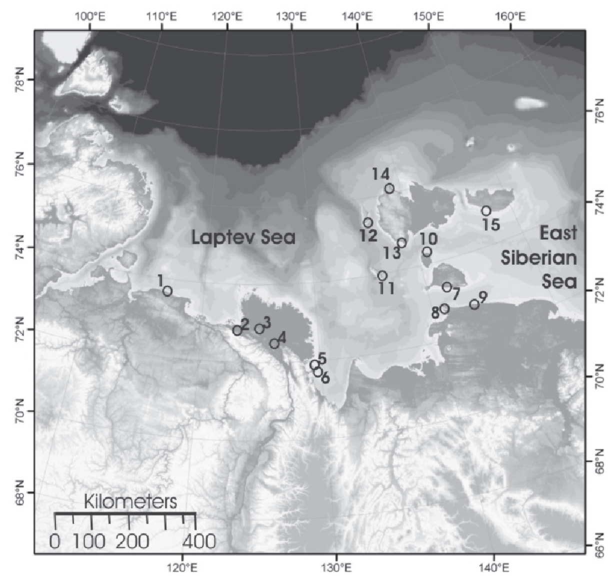

Figure 1. Study sites of the Yedoma Suite between 1998 and 2007. 1: Cape Mamontov Klyk. 2: Ebe Basyn Sise Island. 3: Khardang Island. 4: Kurungnakh Island. 5: Bykovsky Peninsula. 6: Muostakh Island. 7: Bol'shoy Lyakhovsky Island. 8: Syatoy Nos. 9: Oyogos Yar coast. 10: Maly Lyakhovsky Island. 11: Stolbovoy Island. 12: Bel'kovsky Island. 13: Kotel'ny Island. 14: Cape Anisy. 15: Novosibir Island.

Cryolithology

The cliffs are composed of ice wedge bodies and columns of frozen deposits between them, representing vertically or diagonally cut polygonal ice wedge systems. Therefore foliated syngenetic ice wedges of 2–5 m width and 10–40 m height, and separate thermokarst mounds of 2–5 m in diameter and up to 10 m height are the most characteristic features of Yedoma Suite erosion cliffs. Compared to the ice wedges, the intrapolygonal deposits are more resistant to thawing processes because they have a smaller ice content and contain stabilizing peaty paleosol layers alternating with silty-sand layers. These features of continuous permafrost sequences are the result of long-lasting and stable cryogenesis and landscape conditions.

The cryotexture of the Yedoma Suite is quite similar at all of the study sites. The general texture is layered. Ice bands (1–10 cm) alternate with sediment interlayers of variable thickness. These interlayers contain numerous small ice lenses as well as reticulated ice lenses. The frozen sediment sequences are frequently ice-supersaturated, resulting in gravimetric ice contents of 60 to 120% on average (Fig. 3).

Such cryotextures are typical for sediments formed in poorly drained landscapes with a near-surface permafrost table. The formation of these ice bands is a sign of stable surface conditions and stable active-layer depths over a certain time period, resulting in ice aggradation at the top of the permafrost table. The stable isotope signature of ice wedges shows light values for all study sites (site mean

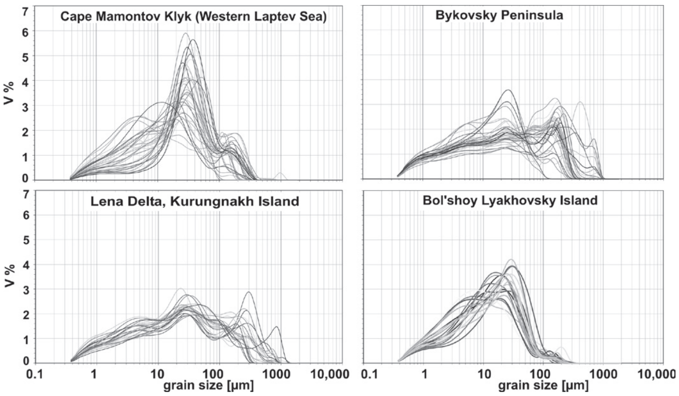

Figure 4. Typical grain-size distribution patterns of the Yedoma Suite at various sites.

values: δD -230 to -260‰, $\delta^{18}O$ -28 to -31‰, d-excess about -6‰) reflecting very cold winter temperatures and moisture sources which are isotopically different from Holocene and modern ones (Meyer et al. 2002a, b).

Organic carbon and grain-size parameters

The Yedoma Suite includes buried cryosols marked by brownish horizons, as well as peat inclusions and/or numerous twigs and leafs. Cryoturbation patterns of 0.5 to 1 m thickness are very common. The organic carbon content is relatively high (1 to > 20 wt%, in average 2 to 5 wt%). Wood fragments and peat are present, with numerous small filamentous rootlets and dispersed organics detritus.

The fine-grained sediments composing the Yedoma Suite are poorly sorted and differ in grain-size parameters from site to site (Fig. 4). Multimodal grain-size distribution patterns reflect a mixture of transport, accumulation, and re-sedimentation processes. Therefore, we conclude that this type of sediment in the Laptev Sea region is not primarily of aeolian origin, a view that is still widely reflected in the scientific literature using the generalizing term "Arctic loess" (e.g., Tomirdiaro 1982, Walker 2007).

Summarizing the special cryolithological and sedimentological characteristics, it is concluded that the frozen deposits of the Yedoma Suite accumulated in a special periglacial facies. The term "Ice Complex" (Soloviev 1959, p. 49) is used for these deposits.

Age determination and stratigraphy

The age of the Yedoma Suite was determined by radiocarbon AMS analyses of about 300 samples and some luminescence datings (Schirrmeister et al. 2002a, 2003, 2008, Grosse et al. 2007, Andreev et al. 2008). The geochronologically determined onset of the Yedoma Suite accumulation varies between about 55 ky BP at the New Siberian Islands and 27 ky BP at the western Laptev Sea coast. The latest deposition is dated between 28 ky BP at the New Siberian Islands and 17 to 13 ky BP in the western Laptev Sea. Unconformities are frequent, up to 20 ky, and probably caused by thermokarst and thermoerosion. The Yedoma Suite predominantly covers the Kargin and Sartan period of the Russian late Pleistocene stratigraphy, which corresponds to the MIS-3 and MIS-2 of the global classification. At Bykovsky Peninsula, the Yedoma Suite is somewhat older, and already started during the Zyryan period (MIS-4) (Meyer et al. 2002a, Schirrmeister et al. 2002b). In general, the lower boundary contrasts sharply with the underlying deposits, which often are fluvial sands with peat layers or loess-like floodplain deposits. These deposits are U/Th and luminescence-dated between 60 and 100 ky). The upper boundary is characterized by separate, locally confined Holocene deposits on top of the Yedoma Suite (Andreev et al. 2004, Krbetschek et al. 2002, Schirrmeister et al. 2003, Grosse et al. 2007).

Table 1. Palaeoenvironmental stages of northeastern Siberian Arctic lowlands during the late Quaternary (inferred from multiproxy analysis of permafrost records, Andreev et al. 2002, 2008).

Allerœd 12 ky	• Tundra with higher bioproductivity • Warming climate • First thermokarst depressions
Sartan 30 - 12 ky	• Sparse grass-sedge tundra • Cold and dry summers, very cold winters • Ice Complex formation
Kargin ca. 50 - 30 ky	• Tundra steppe with high bioproductivity • Relatively warm summers, cold winters • Ice Complex formation
Zyryan ca. 100 - 50 ky	• Sparse grass sedge tundra • Extreme cold and dry climate • Widespread fluvial, lacustrine, and floodplain deposits • Begin of local Ice Complex formation

Palaeoecology (Table 1)

New data for the faunal and floral composition during the formation of the Yedoma Suite in the study region were collected and analyzed within our project "System Laptev Sea" and described in numerous palaeoecological papers (e.g., Andreev et al. 2002, Bobrov et al. 2004, Kienast et al. 2005, Kuznetsova et al. 2003, Sher et al. 2005, Wetterich et al. 2005). The findings are in good agreement with studies; e.g., of Anderson & Lozhkin (2001). The special floral and faunal communities that existed during Yedoma Suite formation disappeared approximately at the Pleistocene-Holocene transition. The palaeo-biosceonosis is called Mammoth Steppe or Tundra Steppe, combining both tundra and steppe features. The climate was more continental in the late Pleistocene Arctic than today, with colder winters and warmer summers and, therefore, stronger seasonal gradients in temperature and precipitation (Meyer et al. 2002a/b, Kienast et al. 2005, Schirrmeister et al. 2002b, 2003, 2008, Wetterich et al. 2008).

Formation of the Yedoma Suite

To explain the formation of the Yedoma Suite, we use the concept of nival lithogenesis proposed by Kunitsky (2007). Several geological processes are important for its formation and can be summarized in four stages (Fig. 6):

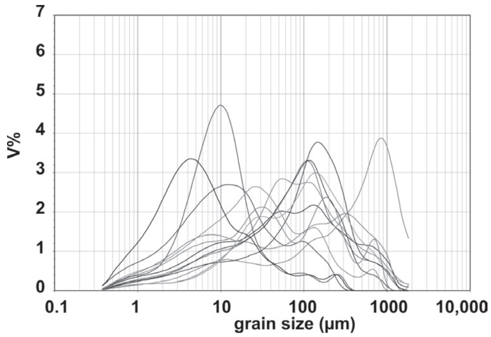

Figure 5. Grain-size distribution curves of clastic remains in various modern snow patches studied around the Laptev Sea.

1. Accumulation of windblown snow together with plant and mineral detritus in numerous perennial snowfields (névés) in topographic features of hills and low mountain ranges (e.g., steep slopes, valleys, cryoplanation terraces, Fig. 6a). Similar processes, but at a smaller scale, are observed today at numerous sites in northeastern Siberia, where nival processes are an essential relief-forming factor (Kunitsky et al. 2002).

2. A concentrated detritus mat forms due to repeated thawing of accumulating snow, transport of detritus by meltwater, and downslope accumulation of plant and mineral debris. Intense freeze-thaw cycles and wet conditions around and below the perennial snowfields support the formation of fine-grained material by frost weathering (Fig. 6b). Such processes are also observed in modern snowfield areas. Grain-size analyses of modern clastic material show similar multimodal patterns as the Yedoma Suite (Fig. 5).

3. Discharge of clastic and organic detritus proceeded by snowfield meltwater runoff. Fine-grained debris was subsequently distributed by alluvial, fluvial, proluvial, and partly also aeolian transport to piedmont plains, cryoplanation terraces or large alluvial fans (Fig. 6c).

4. Ice Complex formation consisted of concurrent processes of sediment accumulation, ground ice segregation, syngenetic ice wedge growth, sediment reworking, peat aggradation, cryosol formation, and cryoturbation (Fig. 6d).

The formation of huge polygonal ice wedge systems and thick continuous sequences of frozen deposits is closely related to the persistence of stable, poorly drained, low-topographic gradient accumulation plains.

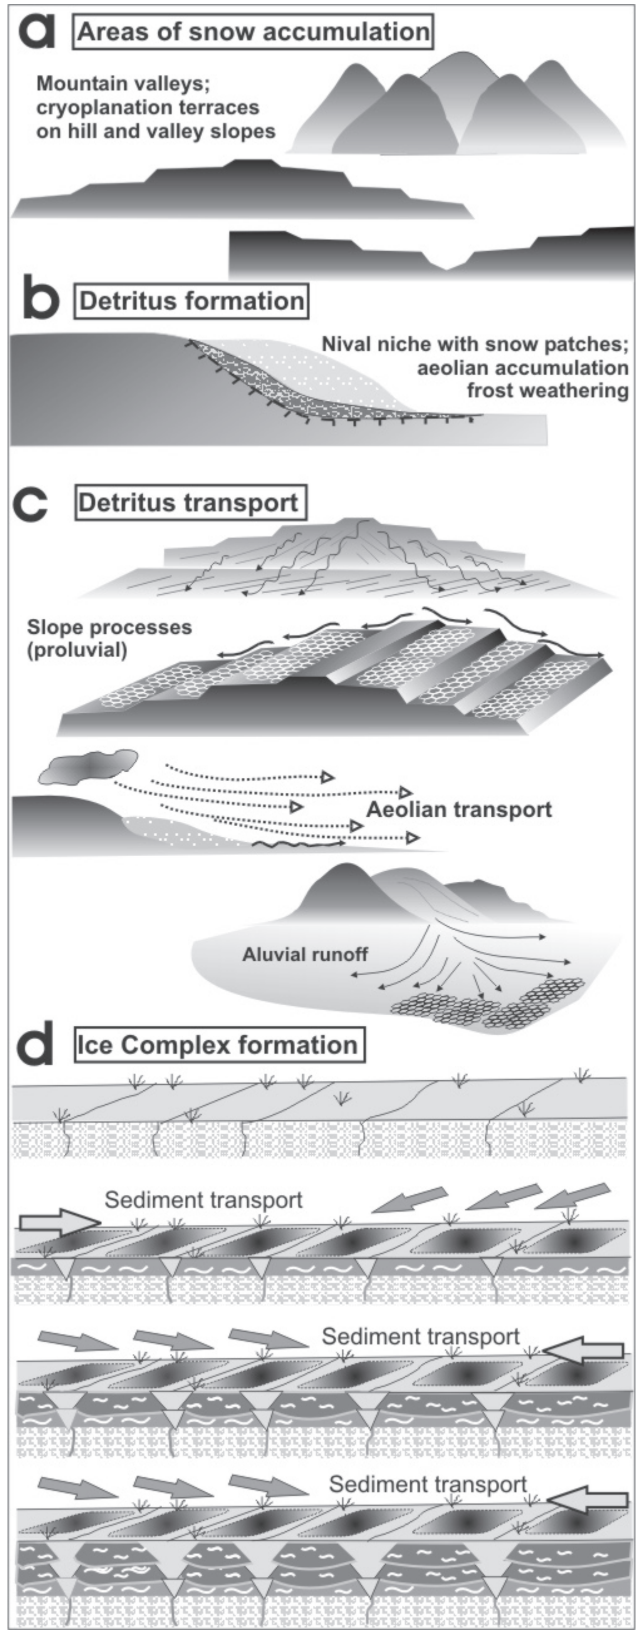

Figure 6. Scheme of Yedoma Suite formation.

Conclusions

The Yedoma Suite is an important paleoenvironmental archive that spans large regional and chronological gaps in the proxy information of the late Pleistocene Arctic. Consistent cryolithological, sedimentological, and palaeo-ecological features (Tab. 2) reflect similar environmental conditions for a wide variety of sites, representing a special periglacial facies.

Concluding, the Yedoma Suite includes a massive carbon and freshwater reservoir susceptible to release by global warming. In order to estimate and calculate the role of these widespread ice- and organic-rich frozen deposits in Siberia in a future warming Arctic, we must improve our knowledge of their characteristics and origin. The specific combination of strongly continental climate and the local landscape permitted syngenetic formation of ice wedges and organic-rich, ice-supersaturated sequences, called Ice Complex or the Ice Complexes of the Siberian Arctic.

Table 2. Typical features of the Yedoma Suite in the shelf region of northeastern Siberian.

Cryolithology	Ice-supersaturated, syngenetic ice wedges, segregation ice
Sediment	Poorly sorted, organic-rich silty sand
Formation age	80 to 12 ky BP
Stratigraphy	(MIS-4) to MIS-2
Palaeoecology	Tundra Steppe/Mammoth Steppe
Climate	High continental, arid
Genesis	Nival lithogenesis, alluvial, proluvial, and aeolian accumulation
Landscape	Lowland plains and cryoplanation terraces
Terminology	Ice Complex deposits compose the Yedoma Suite, which is preserved in Yedoma hills

Acknowledgments

This paper is based on the joint Russian-German science cooperation "System Laptev Sea" supported by the German Ministry of Education and Research. The Russian as well as the German Science Foundation promoted these environmental studies with several projects. We thank all Russian and German colleagues who help us during field work and laboratory studies, but especially S. Kuzmina, M. Grigoriev, W. Schneider, V. Tumskoy, A. Sher, V. Rachold, G. Schwamborn, F. Kienast, P. Tarasov, A. Eulenburg, and U. Bastian. In addition, we thank P.P. Overduin for the native speaker correction as well as D. Froese and one anonymous reviewer for their helpful hints.

Abstract

Two sediment-mineralogical properties were tested as proxy data reflecting the intensity of cryogenic weathering. They were applied to lake sediments from Elgygytgyn Crater Lake in Chukotka, Siberia, and to frozen deposits from the catchment that serve as a reference for in situ weathering conditions. (1) The relative amounts of quartz and feldspar in different silt fractions yield the so-called cryogenic weathering index (CWI). High CWI values, as deduced from the samples, are related to the mineralogically selective weathering resulting from freeze-thaw cycles in the upper permafrost. (2) Image analysis of scanning electron micrographs (SEM) of quartz particles allows characterization and semi-quantification of grain morphology and surface features stemming from frost weathering (i.e., flaky surfaces, microcracking). The constant presence of cryogenic weathering signals both in lake sediments and frozen deposits suggests the long-term prevalence of stable permafrost conditions in the area at least since 220 ka.

Keywords: cryogenic weathering; quartz-feldspar ratio; microtextural properties; paleoenvironment reconstruction.

Introduction

Today, the majority of Siberian landmasses are subject to permafrost conditions. This is also the case for most of the Quaternary (Kaplina 1981, Brigham-Grette 2004, Hubberten et al. 2004). Nonetheless, until now no continuous record has been available that could be used to demonstrate variability of permafrost conditions for that time, nor have any suitable proxy data been tested. Such a sediment record could now become available through studies at Elgygytgyn Crater Lake in northeastern Siberia.

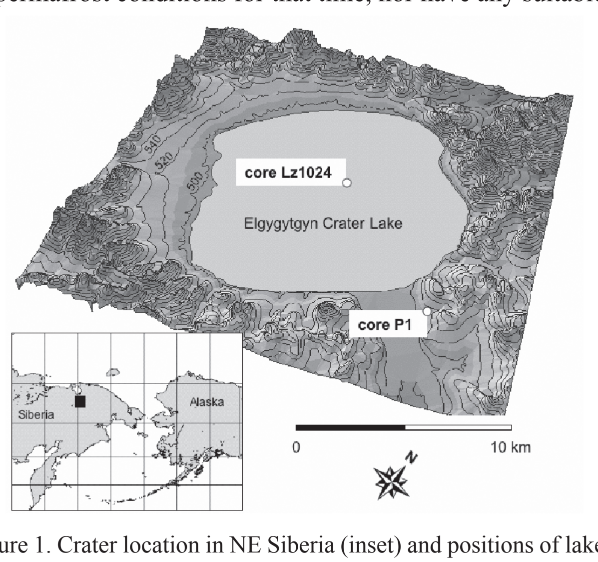

Figure 1. Crater location in NE Siberia (inset) and positions of lake sediment core Lz1024 (67°30.13′N,172°06.46′E) and permafrost core P1. The shoreline is 495 m above sea level.

Frost weathering, slope dynamics, and fluvial outwash are among the main surface processes, and they trigger erosion and detrital sediment transport into the lake basin. Continuous periglacial denudation is assumed for the Quaternary (Glushkova & Smirnov 2007). Tracing signals of cryogenic weathering from the catchment into the lake basin provides a direct land-to-lake linkage within paleoenvironmental reconstruction and will enlighten the permafrost history of non-glaciated NE Siberia. The development of a sediment-mineralogical approach to obtain proxy data for cryogenic weathering is the content of this paper. We use material from former coring into the lake and frozen deposits of the catchment (Melles et al. 2005).

Environmental Setting

Elgygytgyn Crater Lake, 12 km in diameter and 170 m in water depth at maximum (Fig. 1), holds sediments that mirror glacial to interglacial cyclicity and regional environmental change at millennial time resolution (Nowaczyk et al. 2002). The sediments consist of clayey silts and silty clays with occasional sand layers (Asikainen et al. 2007). Based on sedimentological data (physical properties, organic, and isotope geochemistry), distinct climate-related sediment units have been identified that are primarily controlled by fluctuating carbon, nitrogen, and opal contents and linked to a changing extent of lake ice cover; i.e., "cold + moist," "cold + dry," "warm," and "peak warm" (i.e., Eemian interglacial) (Melles et al. 2007). The sediment units alternate in the last 250 kyr, the time span that is covered by the first recovered sediment cores (Juschus et al. 2007, Nowaczyk et al. 2007). We assume a fairly constant surface denudation processes in the confined catchment of the crater lake, which makes the site a natural laboratory for studying the production of weathering debris in the catchment and its subsequent deposition in the adjacent lake sediment column. Longer core retrieval is planned (Melles et al. 2005), which will yield a climate record more than 3 million years old, since the origin of Elgygytgyn Crater is attributed to a meteoritic impact 3.6 M yr ago (Layer 2000). Thus, there will be the potential to identify the assumed onset of permafrost conditions across the Pliocene/ Pleistocene boundary. The altitude of the lake is 495 m above sea level (a.s.l.), and the highest peaks forming the crater walls are about 900 m a.s.l. Local basement rocks are of volcanic origin and are part of the Late Cretaceous Okhotsk-Chukotka volcanic belt (Belyi 1998, Layer 2000, Ispolatov et al. 2004). The rocks consist largely of andesitic to rhyolitic tuffs and ignimbrites of primarily acidic composition. Some subalkaline basaltic andesites have been identified framing the crater lake to the southwest.

Methods

Indicator data for paleo frost weathering: (I) mineral composition

In terms of sedimentology, the destruction of quartz grains is a basic process during the formation of cryogenic debris. As established in experiments, cryogenic disintegration promotes a relative accumulation of quartz grains in the silt fraction (10–50 microns); whereas fresh feldspars and heavy minerals accumulate in the sand fraction (50–100 microns) (Konishchev 1982). This mineralogically selective weathering is active under water-saturated freezing-thawing cycles (Minervin 1982). Expressed in a so-called *Cryogenic Weathering Index* (CWI), the role of cryogenic weathering in frozen soil formation can be estimated (Konishchev 1998):

$$CWI = (Q_1 / F_1) / (Q_2 / F_2) \qquad (1)$$

where Q_1 is quartz content (%) in the fine fraction; F_1 is feldspar content (%) in the fine fraction; Q_2 is quartz content (%) in the coarse fraction; and F_2 is feldspar content (%) in the coarse fraction.

CWI values greater than 1.0 argue for cryogenic weathering that influences the grain-size dependent mineral composition. Comparison of measurements from regionally distributed sediment samples of Arctic Siberia show that warm-climate sediments clearly can be discriminated from cold-climate samples (Konishchev & Rogov 1993). According to that study, Palaeogene-aged samples have CWI values ranging clearly below 1. Towards the Late Neogene and the Early Quaternary, the CWI values reach 1.7. In the lower and middle Pleistocene, values become as high as 3.3. The Eemian has falling values down to 1.7, before values rise again to a maximum of 3 at Weichselian time. Holocene CWI values range from 1.6 to 2.1. Indication of cryogenic weathering according to the CWI has already been implemented into permafrost modeling spanning the last 400 kyr (Romanovskii & Hubberten 2001). In our study, relative quartz and feldspar contents have been determined using standard x-ray diffractometry methods (Ehrmann et al. 1992, Vogt 1997) on a Philips PW 1820 goniometer that used a CoKα radiation (40 kV, 40 mA).

Indicator data for paleo frost weathering: (II) grain morphology and grain surfaces

Grain shapes and grain surface microtextures of mostly quartz and feldspar are well-established means to characterize sedimentary deposits and infer the environmental history from single grain morphology (Krinsley & Doornkamp 1973, Diekmann 1990, Mahaney 2002). Whereas single grain features are well-defined in the case of aeolian, glacial, and fluvial sediments, comparable features associated with mechanical encroachment in frozen ground is only sparsely documented, but appears distinctive (Konishchev & Rogov 1993, Van Hoesen & Orndorff 2004). Angular outlines and micromorphology such as high relief, sharp edges, and articulate steps are most frequent. They have been found in Holocene samples of Elgygytgyn Crater slope deposits (Schwamborn et al. 2006). Here, considerable amounts of grains are characterized by weathered surfaces; flakiness and microcracks were common features when inspected on SEM imagery. The grain surface features are particularly diagnostic for frozen ground sediments, since their production can be directly linked to the destructive effect of thaw-freeze alternation.

Sedimentary material

Lake sediments from core Lz1024 (Fig. 1) down to 12.2 m sediment depth were first measured for grain size distributions of 43 non-turbidite samples using a laser particle analyser (LS200, Beckman Coulter, Inc.). The studied interval spans the last 220 kyr according to the age model of Juschus et al. (2007). In contrast to Konishchev & Rogov (1993), CWI measurements are based on fractions 2–20 microns and 20–63 microns, since first grain size measurements revealed that lake sediments have a major mode at about 20 microns (Fig. 2). Grain shape and grain surface features have been characterized on at least 20 randomly selected quartz grains in each of 28 lake sediment samples. Chemical treatment of the samples followed standard techniques that are outlined elsewhere (Schwamborn et al. 2006). Hereafter, CWI calculations and SEM analysis have been applied.

Frozen deposits were recovered down to 5 m depth in a slope at the crater margin (P1 in Fig. 1). The dated core material shows a correct age-to-depth relation back into the Late Pleistocene (Schwamborn et al. 2006). For CWI calculation, seven samples have been selected that extend over the Holocene. They serve as a reference of in situ cryogenic weathering of the periglacial landscape.

Results and Discussion

Mineral composition

The clayey silts and silty clays from lake sediment core Lz1024 yielded a mean CWI value of 1.6, whereby the minimum value is 1.0 (11.7 m depth), and the maximum value is 3.5 (11.2 m depth) (Fig. 3). The silty sands and sandy silts from permafrost core P1 have a mean CWI value of 1.1, whereby the minimum value is 0.9 (0.7 m depth), and the maximum value is 1.4 (3.7 m depth) (Fig. 3).

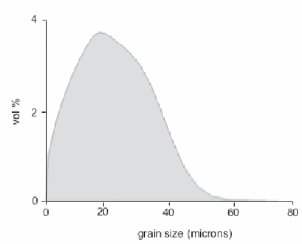

Figure 2. A typical grain size curve of lake sediments displaying the mode at 20 microns (sample from 10.64 m core depth).

All lake sediment CWI values are higher than 1.0 and thus fit well into the range of sediments from the glacial cycles. This argues for the presence of cryogenic conditions throughout the studied time interval. The variability around the mean is independent from sediment units and glacial to interglacial modes (Fig. 3). Several aspects are considered, which influence grain break-up and mixture of cryogenic detritus in the basin. (1) Warm periods are associated with higher temperature gradients in the active layer, thus increasing thermal stress to the grains and subsequent mechanical break-up. (2) Increasing moisture promotes the frequency of microcracking, when water migrates into fissures and subsequently disrupts the grains when crystallizing to ice. Both aspects (1 and 2) are also taking place in soil layers with fluctuating negative temperatures, but to an unknown degree. (3) Varying microclimates at rock surfaces, varying salt concentrations, and biotic encroachment (i.e., lichen growth) contribute to rock fragmentation to an unknown degree (Miotke 1988, Hall & André 2003, Guglielmin et al. 2005). (4) The particle size of source material may vary through time. (5) Soil weathering products that have been eroded and transported into the lake basin are reworked in the

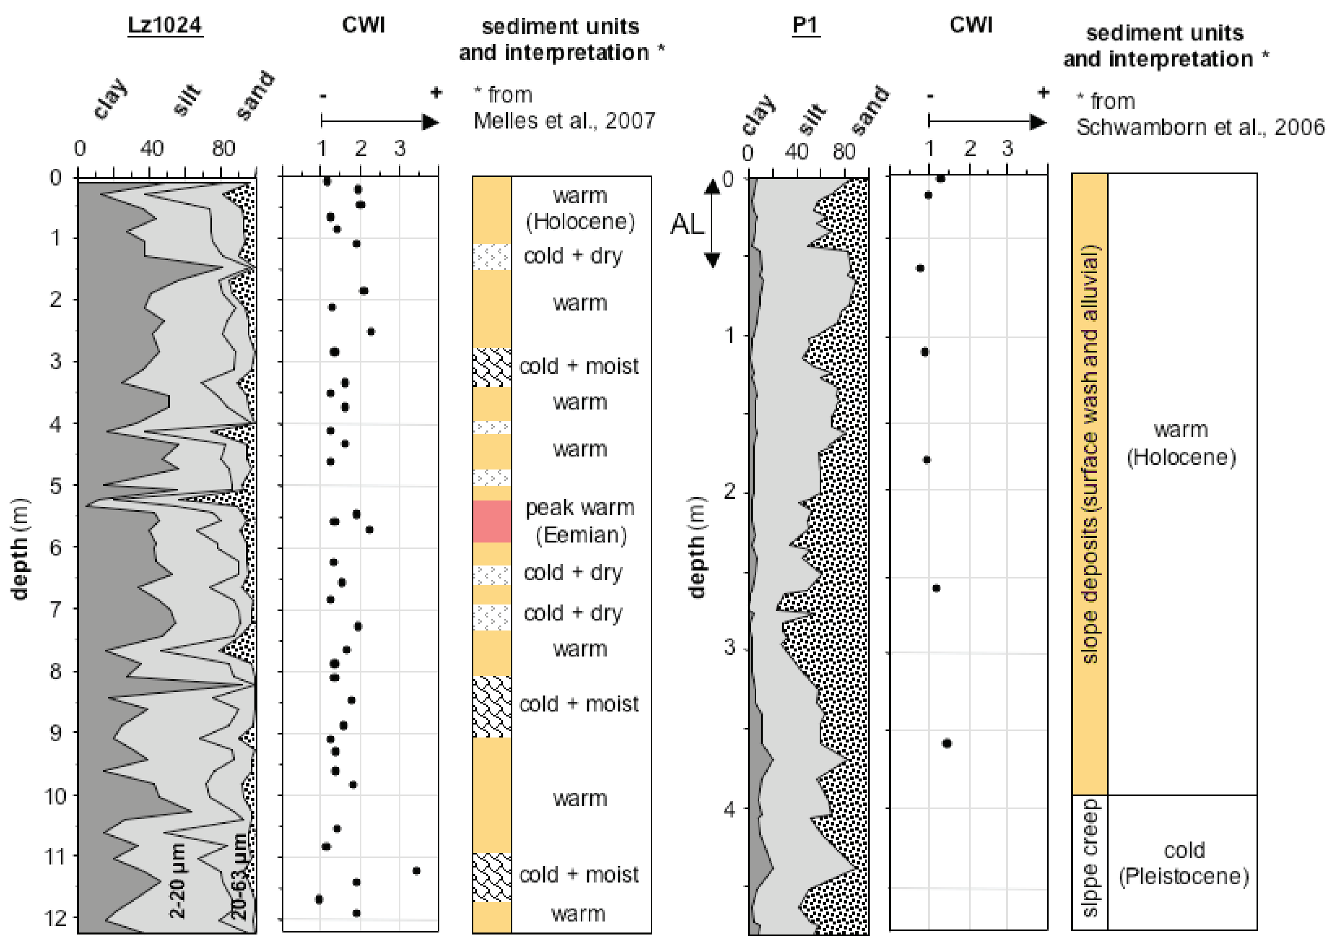

Figure 3. Values of the cryogenic weathering index (CWI) calculated for lake sediment core Lz1024 and permafrost core P1. Basic sediment interpretation schemes are added (see references). AL = Active layer.

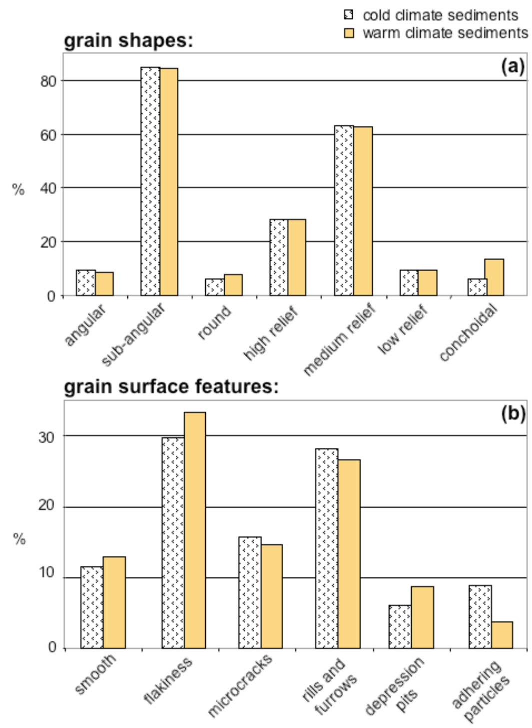

Figure 4. Grain shapes (a) and surface features (b) counted with quartz grains (63–125 microns) from lake sediment core Lz1024 (n=560).

shoals when strong winds from NW or SE lead to a thorough turbulence of the uppermost water column during the open water season. This leads to sediment mixing in the marginal shoals that also may add to blur the original CWI signal. (6) Changing lake levels contribute to sediment mixing, since the exposed and subsequently eroded areas around the lake have changed through time (Glushkova & Smirnov 2007, Schwamborn et al. 2007).

The near-surface permafrost around the lake produces low CWI values under Holocene warm-climate conditions (~1.0). Minor sediment mixing due to transport and reworking processes are associated with the environmental setting of P1 deposits (e.g., hill creep, slope wash, alluvial deposition), since the weathering debris is accumulated in a piedmont setting (Schwamborn et al. 2006).

Grain morphology and grain surfaces

Subangular grains are most common, but angular and round grains can also be found at all lake sediment core depths (Figs. 4, 5). Grains with conchoidal fractures, with smooth surfaces, brittle surfaces, and microcracks occur throughout the lake sediments, but to a lesser extent. Irregular, angular shapes (Fig. 5-1) argue for a short-distance transport, whereas conchoidal features (Fig. 5-4) suggest that pressure occurs either during in situ rock fragmentation or hill creep. Rounded grains (Fig. 5-3) represent the eolian portion that is drifted and deposited in the lake basin. However, estimates of the modern eolian input into the lake sediments yield a portion smaller than 5% (Fedorov pers. com.). V-shaped depression pits occur occasionally and point to grain-to-grain percussion during aquatic transport.

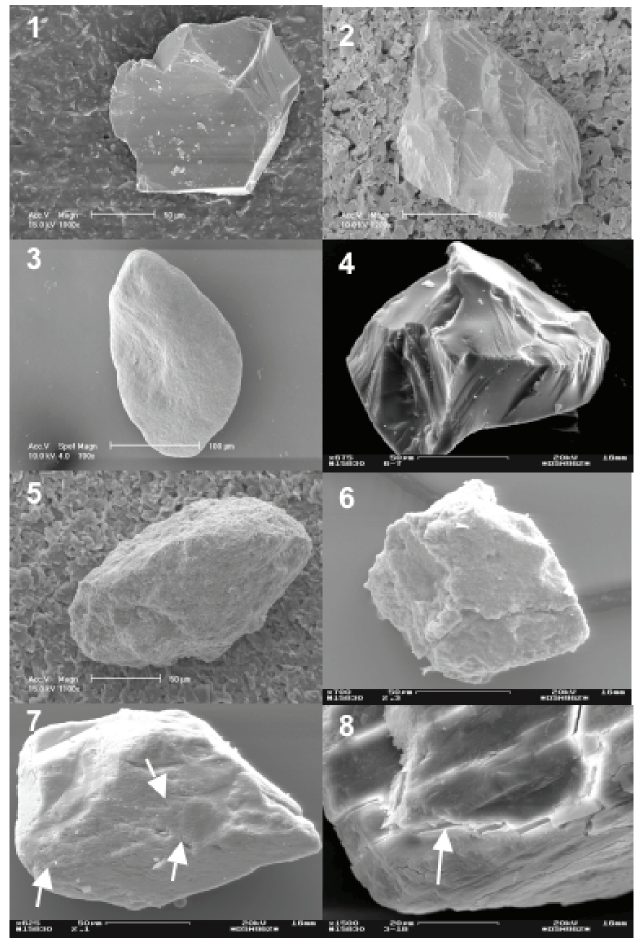

Figure 5. Examples of SEM micrographs from lake sediment quartz grains (63–125 microns); grain shapes: angular (1), subangular (2), rounded (3), conchoidal (4); grain surface features: brittle and flaky surfaces (5 + 6), cryogenic microcracking (7 + 8, see arrows).

Quartz grains exhibit abraded and softened areas, which can act as source areas for silt particles (Figs. 5-5, 5-6). Likewise, microcracks promote separation of silt-sized fragments and conspicuously display the destructive effect of cryogenic widening in the microscale to a varying degree (Figs. 5-7, 5-8). Descriptions of brittle grain surfaces along with microcracks are associated with cryogenic destruction within the thaw-freeze cycles in the uppermost permafrost (Konishchev. & Rogov 1993), or they have been described as crushing features (Van Hoesen & Orndorff 2004). They are present in Elgygytgyn lake sediments, and when medium- to high-relief grains become fragmented due to cryogenic cracking, the connection between SEM and CWI analysis is most obvious.

The discrimination between cold-climate and warm-climate sediments (Fig. 4) does not exhibit prominent quantitative differences between the two. All characteristics can be identified to varying degrees at all sediment depths. Frost weathering features like brittle surfaces and microcracking demonstrate that traces of cryogenic destruction inherited from permafrost processes are well-preserved within the lake sediment column.

For frozen deposits from the catchment, grain micromorphology assessments are already available (Schwamborn et al. 2006). Angular outlines and microfeatures such as high relief, sharp edges, and articulate steps were most common and were consistently observed for all samples. This was linked to short transport distances from their source rocks. Many grains were characterized by rough and weathered surfaces. Flakiness and microcracks were common features. The grain surface textures appear particularly diagnostic for frozen ground sediments, since their production can be directly linked to the destructive effect of thaw–freeze alternation. Frost weathered surfaces and cryogenic cracking point to the sandy grains as the source areas of silt particles. This highlights in situ disintegration, especially of quartz grains, after they were subject to thaw–freeze dynamics (Konishchev and Rogov, 1993).

Conclusions

Despite some blurring effects (e.g., mixing of detritus resulting from weathering and from depositional processes, and sediment reworking in the lake margins due to lake level changes) CWI and SEM analysis can link lake sediments and frozen slope deposits for paleoenvironment interpretation. The studied sediment properties suggest that cryogenic weathering was persistent around Elgygytgyn Crater Lake for at least the last 220 kyr.

An unknown temporal offset between the creation of cryogenic features in the catchment and the material deposition in the lake has to be taken into account when interpreting the timescale within the paleoenvironmental archives.

The combination of grain size, CWI, and SEM results is considered a helpful technique to identify on- and off-set of permafrost conditions in the area when inspecting future drill cores that go beyond 3 M yr back in time.

Acknowledgments

Martin Melles and Olaf Juschus, Cologne University, provided access to the lake sediment samples, Helga Kemnitz, GFZ Potsdam, helped with the SEM facilities. Their assistance is greatly appreciated. Financial support has been granted by the BMBF (German Ministry of Science and Education). The reviewers' comments helped to improve the paper.

Abstract

Geoelectrical methods are recommended for identification and location of seepage zones in permafrost areas. These include vertical electric sounding, and profiling of apparent electric resistances and self-potential. Methods are based on significant specific electric resistance difference between frozen and thawed soils, and self-potential is generated by filtrating flows. Changing the distance between points of vertical electric sounding allows us to build 3D fields of electric resistance $\rho_a(x_i, y_i, z_i)$. Filtration zones appear with low ρ_a values and low (negative) self-potential. Comparison of ρ_a fields measured in different periods allows use to monitor the temperature changes and state of the frozen material, and to forecast and prevent possible seepage with minimum financial effort. Use of the described techniques demonstrate their high efficiency during technical condition determination of water reservoirs dams, technical water retention dams at gold and silver mining enterprises, and at diamond mines.

Keywords: control; dam; filtration; geoelectrical methods; monitoring; permafrost.

Introduction

Northeastern Russia is part of the cryolithozone, with its permafrost base stretching from tens to hundreds of meters in depth. Despite this, the upper soil layer has fluctuating temperatures, often above the melting point. This balanced natural process causes no negative environmental changes. Under technogenic influence, geochemical and thermal changes are much greater then natural factors. In northeast Russia, such negative technogenic effects on soils are caused by hydrotechnical facilities such as tailings and water reservoirs.

Use of cyanide process for gold and silver extraction in Northeast Russia brings up the problem of massive toxic waste storage in permafrost zones. Besides tailings facilities, there are varieties of clean and technical water reservoirs, reservoirs for thermal and hydro-electrical plants, tailings facilities of diamond mines, and more. All these hydrotechnical structures are formed with dams, and are mostly situated in river valleys. Depending on the object's use, dams could be permeable or water retaining. Large volumes of water affect the temperature of the frozen material up to its thaw. Lowering the melting point of frozen material in contact with highly mineralized technical solution can also lead to solution seepage. Investigation of such seepage zones, the determination of their location, and monitoring of technical status of hydro technical structures is successfully performed with use of geoelectrical methods.

Geotechnical Characteristics of Dams and Underlying Base Rock in Permafrost Zones of Northeast Russia

Most rivers at Northeast Russia follow tectonic fault zones. Besides tectonic fracture, vertical cracking as a result of cryogenic deformation appears even in solid bedrock. For example, at Kupol Mine (Central Chukotka), such cracks in basalt are 50–70 m deep and can be traced for hundreds of meters on the surface. Similar cracking in a different rock type were observed in Saha (Yakutia), when tailings facilities for diamond mines were in construction. Granites in the area of the Kolyma River Hydroelectrical Plant have very similar block type form. The absence of tectonic mirrors on joint surfaces within fault zones testifies to the cryogenic genesis of these fractures, as does the absence of tectonic displacement. Such cracks, as a rule, are not filled with ice, but just "capped" with delluvial material 1–2 m at the top. Mostly, such cracks were found during removal of the upper delluvial layer. Filling these cracks at road crossings was not successful, nor was filling with concrete as large amounts were simply draining in.

Basic Technical Peculiarities of Dam Structure in the Russian Northeast

Currently in Northeastern Russia (Yakutia, Chukotka and Magadan Regions), there are number of operating and abandoned tailings facilities and reservoirs. Places in Magadan Region, where geoelectrical investigations were performed, are shown on Figure 1.

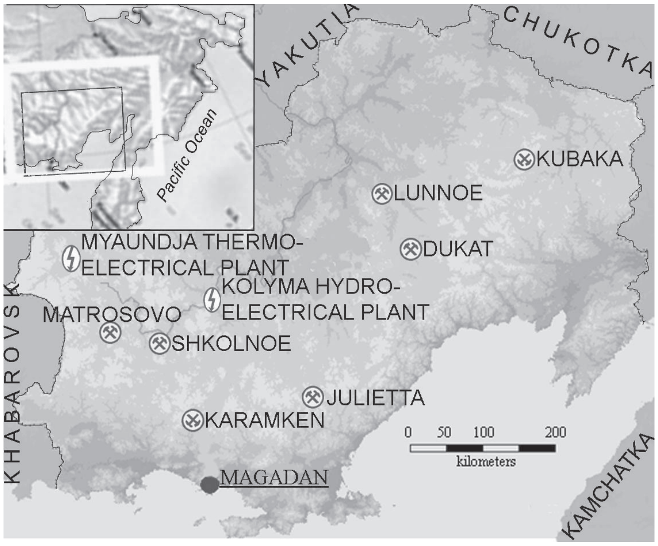

Figure 1. Location of sites where geoelectrical methods were applied to investigate the dam status.

Regardless of design, dams in Russian Northeast are constructed of local materials. Depending on the dam's purpose, there are two different types: permeable (filtering) and watertight (water retaining) (Biyanov 1983) Permeable (filtering) dykes are designed to separate technical solutions and solid parts from sludgy tailings. Sometimes, additional filtering dykes are built on the surface of the tailings for the same reason. Below the filtering core, reclaimed technical water is taken back into the process.

What follows is a general overview of tailings facilities structural peculiarities at various mining enterprises. As a good example, we will describe Kubaka gold mine, the first joint-stock gold mining enterprise with a foreign investor in Magadan Region. During operation from 1997 to 2006, over 90 tons of gold were mined and extracted using the cyanide process. During exploitation, dams were raised to increase the tailings facility capacity. It was situated on the valley side, so no upper dam was needed (Fig. 2). Cleared water was draining through the filtering dyke into a reclaimed water pond, where it was taken into the process again. The water retention dam had a frozen core, formed by over 100 thermo siphons inserted through the dam into bedrock. These were installed in 1998, when geoelectrical sounding showed that dam's core and underlying bedrock had melted zones and technical solution was seeping through. Pipes were filled with carbon dioxide. Foreign engineering companies were developing most sufficient variants of Kubaka deposit mining and foreign investors were implementing them. Kubaka's tailings facilities are example of good handling of a variety of technical challenges. Tailings facilities were inspected with geoelectrical methods several times during operation.

The Kubaka mine was performing a closure procedure during 2007; tailings were caped with 1.5 m of waste rock, 0.5 m of silty shale and 0.3 m of top soil for vegetation. Since waste rock was placed during winter time on frozen tailings, it remained frozen during summer and heavy mining equipment was hauling material on top of capped tailings without sinking. This is a unique example of full reclamation of a tailing facility in Northeast Russia.

Karamken Gold Mine (operated from 1978 to 1995) is situated 100 kilometers north of Magadan. Karamken Mine Tailings facility is situated in the mid-flow of Tumanniy creek. There was a need to prevent inflow of upper creek water into the tailings facility. An impermeable upper dam was guiding into a diversion channel.

In order to maintain impermeability of the upper dam, a row of holes with pipe casing was emplaced. A refrigerator was pumping the cooling agent ($CaCl_2$). Freezing the dam's core created an impermeable barrier. The diversion channel was originally made of concrete U-shaped sections which deformed quickly, and steel lining was placed inside to maintain the level needed for water flow. Its abandoned tailings facility used a different approach for separation of water from the slurry then used at the Kubaka mine. The technical solution was settling and seeping through the dykes and tails and was accumulating at the sump, which was dug at the deepest point of the wooden tunnel and down to the bedrock below the dam.

Currently, despite shut down of the Karamken mine, liquid waste from the Kolyma Refinery is frequently discharged in the Karamken tailings facility.

Tailings facilities at other Magadan region gold and silver mines which use the cyanide process were constructed later then the Karamken and Kubaka facilities. Mostly, they have polymer lining. Tailings facilities of the Vetrenskoe mine was very similar to Kubaka, with reclaimed water sump in the old bed of the diverted creek.

Tailings facilities of Saha (Yakutia) diamond mines have only one watertight dam, the frozen core providing its impermeability. The core is kept frozen by pipes filled with kerosene. Reclaimed water was accumulating in the pond next to the dam.

There are many more plains in Saha (Yakutia) then in the Magadan region, so the areas occupied by diamond mines in Saha (Yakutia) are greater, and dams are lower but longer then tailings facilities in Magadan region mines.

Besides mining enterprises, there are a variety of hydrotechnical structures in the region such as reservoirs for domestic use near towns, and technical water reservoirs for hydro and thermoelectrical plants. The largest volume of water is held by a major dam 150 m high at the Kolyma River Hydroelectrical Plant. The dam is constructed in highly fractured granite, where the fractures have different genesis.

Miaundja Thermo Electrical Plant, built in the early 1950s, has a technical water reservoir. It has a frozen core, which is cooled with air circulating through a wooden tunnel throughout the dam's center during the winter period. The dam is constructed on highly fractured shales.

Dams have a shape of trapezium in cross-section, with the lower face terraced with benches.

Another peculiarity of the Russian Northeast that affects hydrotechnical structures besides permafrost is the high seismicity of some areas in the region.

Tailings facilities, water reservoirs and other hydrotechnical structures bring a local influence to a surrounding frozen material. This includes heat brought with highly thermo conductive water or technical solutions. To protect a dam from melting, extra material is placed from its influenced upper face. This material protects frozen material from heat exchange with water. In addition, heat exchange tailings facilities are influenced by mineralized solution which lowers the ice melting point.

These would be two main reasons for infiltration appearance; through the dam's core as well as through fractured bedrock. A variety of technical accidents on hydrotechnical facilities in Chukotka emphasizes the seriousness of such infiltrations. Roughly every reservoir was loosing water because of infiltrations (Demchenko et al. 2005).

Localizing infiltration zones using non-geophysical methods like drilling is slow and costly, and introduces additional heat to dam's material.

Geoelectrical Methods of Controlling and Monitoring Dams in Northeast Russia

Geoelectrical methods of determining filtration zones is widely used in permafrost free regions; e.g., for mudslides sounding (Bogoslovsky & Ogilvy 1970). Their localization is determined by self-potentials survey, their minimums show the object.

Physical Basis of Geoelectrical Methods for Detection of Seepage and Melting Zones

In permafrost regions, the first applications of geoelectrical methods for determining melted zones in dams and bedrock where performed after several accidents involving water reservoirs (Kadykchan town, Miaundja Thermo Electrical Plant) occurred in permafrost areas of Northeast Russia. Geoelectrical methods from geophysics were used for localization of melting areas and filtration zones. Water flow in a filtration zone creates a field of self-potentials; the magnitude increases with an increase of mineralization level and flow speed. During methods development, the fact of low self-potentials in fresh water filtrations was discovered. Soil resistivity in permafrost studies showed that melting soils increases their conductivity by three orders of magnitude (Frolov 1998, Yakupov 2000). In the case of mineralized solution, resistivity of melted soils is near zero Ω-m. Later, during investigation of seepage zones at the Northeastern (permafrost zone) mining enterprises' tailings facilities, highly mineralized solutions were stated as significant sources of self-potentials as well.

Complex of Geoelectrical Methods for Detection of Dams' Melting and Seepage Zones

Geoelectrical methods from geophysics are used by our team for determination of filtration zones through dams and bedrock, during technical control and monitoring at Northeast Russia (Saha (Yakutia) and Magadan Regions) (Muslimov & Sedov 2006). They include vertical electric sounding (VES), electrical profiling of CD (Schlumberger array), very low frequency (VLF) and self-potential (SP) profiling; all performed on standard equipment. VES uses a symmetrical Schlumberger array (C_1O = 1,5; 2,0; 3,0; 4,5; 6; 9; 12; 16; 20; 30; 40; 80; 110; 150; 200 and 300 m, P_1P_2 = 2; 10 m, C_2 - ∞). Lateral profiling used a half Schlumberger array P_1P = 2.0 m. In winter, we have electrode contact problems and then VES and electric profiling are replaced by alternate current (AC) methods. Time domain electromagnetic survey (TDEM) is search conductor mineralized filtrate. Configuration uses central loop mode and transmitting loop of 20x20 m. The seepage zone has very low resistance. TDEM is faster and cheaper, and can be used all year round since grounding is not needed. Electrical profiling is typically performed on two feeder distances or two different frequencies. This gives the apparent resistances typical for two different depths.

VES, electrical profiling, VLF and TDEM with measuring stations on the dam's crest, benches and lower face is performed as an initial step. Stations interval is 20 m. Electrical profiling of the perimeter may be done as well, if needed. VES measurements are done on dam's crest and benches, as well as at locations which showed low resistances on initial electrical profiling.

Depending on the approach used, geoelectrical sounding results are presented as graphs with resistivity profiles - $\rho_a(x_i)$, pseudo depth plot - $\rho_a(x_i, z_i)$, apparent resistivity contours - $\rho_a(x_i, y_i)$, profile and contours in mV SP, VES curves - $\rho_a(z_i)$ and its interpretation. For technical monitoring of dams, VES provides the most interesting data. It is presented as three dimension (3D) coordinates ρ_a (x_i, y_i, z_i). The developed software allows one to use any "slice" of the collected data for determination of the filtration zones. Mostly, apparent resistance profiles ρ_a (x_i, z_i) and ρ_a (y_i, z_i) along and across the dam body are used. Lateral sections $(z_к)$ ρ_a for different depths ρ_a (x, y, z_n) can be done. Quantitative interpretation (determination of true specific resistance ρ_n) at a certain point with (x_i, y_{ii}, z_i) coordinates is very difficult. This statement is based on the fact that a dam's structure, even if it would be made out of material with invariable resistance, is very complex and does not correspond to conditions required for quantitative interpretation of VES, developed for horizontal stratum of infinite stretch (Hallof 1981). This limitation of VES is valid for any other geological task. The accuracy of the quantitative interpretation is determined by intersecting VESs. Coinciding resistance curves testify that the stratum is horizontal and infinite. Despite quantitative interpretation of VES is not possible, the technical monitoring task was fulfilled successfully, as experimental works results show. Let us describe this statement with the following example. Despite any misrepresentations caused by a complex dam profile, apparent resistances along or across dam's axis will be similar if there are no filtration zones. Only along the dam's flanks, where interfacing environments have some influence, will variations be seen. Abnormally low resistances in the cross section will appear in the filtration (melting) zones, despite their scale, and are very well distinguished on the apparent resistance minimum cross sections. The coordinates of the filtration zone is determined by tracing this zone of low resistances in the row of profiles for the dam's body, or in the bedrock beneath. Besides VES, self-potential profiling along the dam's axis is performed during summer and early autumn. Filtration zones are seen as negatives anomalies. This anomalies SP depend on flow velocity and increases with higher flow velocity.

Examples of Determining Location of Filtration and Melting Zones by Geoelectrical Methods for Controlling and Monitoring Dams in Permafrost Regions of Northeast Russia

Using geoelectrical methods described above to locate melting and seepage zones, we will discuss results on specific hydrotechnical structures of different genesis and use. As a very positive example, we will discuss results of monitoring at Kubaka Mine tailings facility (Fig. 2).

It includes thickened tailings (1), filtering dyke (2), reclaimed water pond (3) and water retention dam (4), which holds highly mineralized technical solution.

During seven years, the filtering dyke was built up several times to increase projected capacity. The first year of water retention dam surveying indicated dam instability, and signs of minor seepage of technical solution into the creek below. After geoelectrical control in 1998 was performed on both structures, seepage zones were identified. For seepage zones

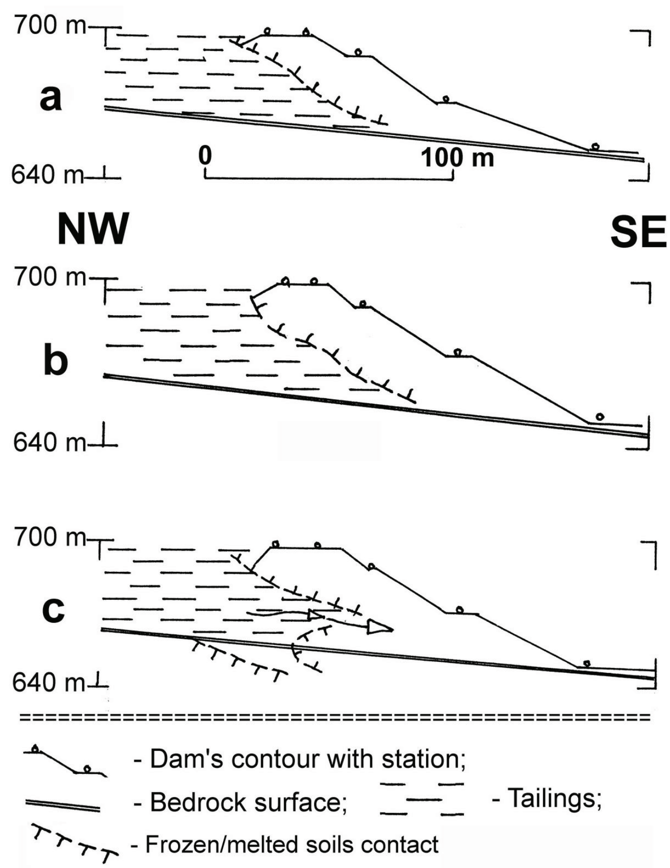

Figure 5. Seepage locations in the upper (filtering) dyke, according to the cross section resistances profiling. Geoelectrical control performed in year 2003.

determination, longitudinal VES profiling was performed (Fig. 3).

Seepage zones were marked with self-potential minimums on the profile, which was compared with VES stations. Later, melted and seepage zone distribution in the dam was confirmed during drilling work to install thermosiphons. The distance between thermosiphons pipes was around 2.0 meters, and they were nailed through the dam into the bedrock. Their bottom line is shown as a step-looking straight line. Figure 4a shows the location of melting and seepage zones four months after the thermosiphons were installed in 1998. Technical solution seepage was stopped after melted zones froze. Soil freezing increased ρ_a (x_i, z_i) and showed clearly during VES. Bedrock resistivity changed insignificantly (Figure 4b). Ceased seepage was marked by negative anomalies of SP disappearance. Geoelectrical methods (VES, SP TDME) were used for melting zones and filtration location in the filtering dyke, as well. Geoelectrical data complex interpretation allowed us to determine the location of filtration zones, pointing out areas blocked with compacted pulp (Fig 5a and 5b). Filtration zones were marked not only with low resistivity ρ_a, but with significantly low SP (Fig. 5c).

On the pseudo plot, melting and seepage zones were shown as areas with minimum apparent resistances.

A 3D apparent resistivity model indicates the distribution of dyke and dam melting zones. Upper face material is influenced with technical solution, and has zones with temperatures above the melting point. This zone is shown as an area with low electric resistance (Fig. 6). The melting and seepage zones pseudo plots for longitudinal profile across Kubaka Mine tailings facility is shown in Figure 7.

Geoelectrical methods of investigation used at others dams in the Magadan Region allowed us to determine seepage zones and to perform adequate measures for their elimination.

Yakutia diamond mine tailings facilities hold low mineralized technical water. A frozen core is usually created with thermosiphons filled with kerosene, and seepage zones appear either in fracture zones of bedrock, or where thermosiphons are not functioning. Seepage of fresh water there is indicated the same way as seepage of technical solution described above; these places demonstrate low electric resistivity (Fig. 8).

A complex of geophysical approaches consisting of VES, apparent resistivity and self-potential profiling were used for seepage determination at Marha' tailings dam ALROSSA. Seepage elimination was achieved with kerosene filled

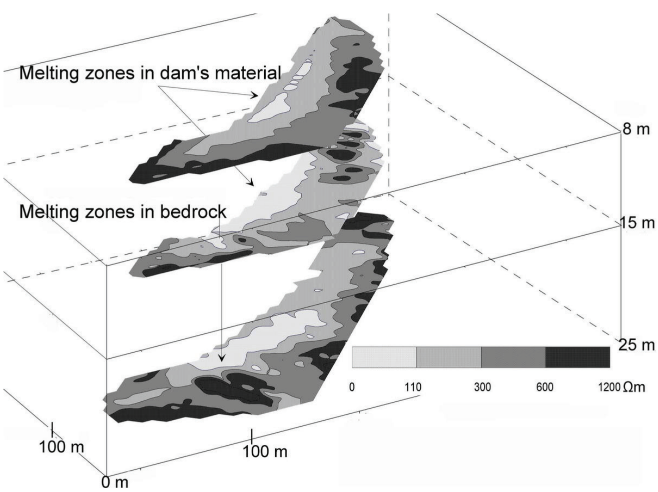

Figure 6. 3D model of showing low resistivity of melted material zones in the dam and bedrock.

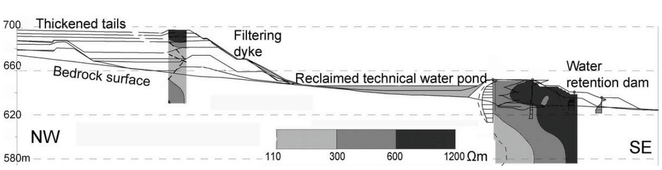

Figure 7. Pseudo plot for longitudinal profile of apparent resistivity across Kubaka Mine tailings facilities.

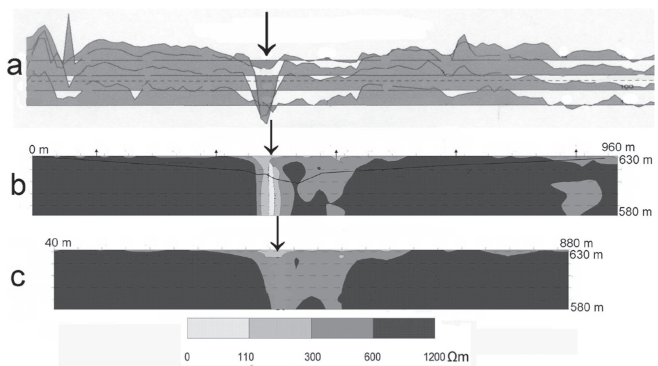

Figure 8. Seepage zone determination with VLF profiling along the crest (Marha Dimond Mine, Saha (Yakutia), ALROSSA). VLF resistivity profiles (a), pseudo plot with melted zone, June 2003 (b), pseudo plot after melted zone congealing, July 2003 (c). Arrows show seepage zone location.

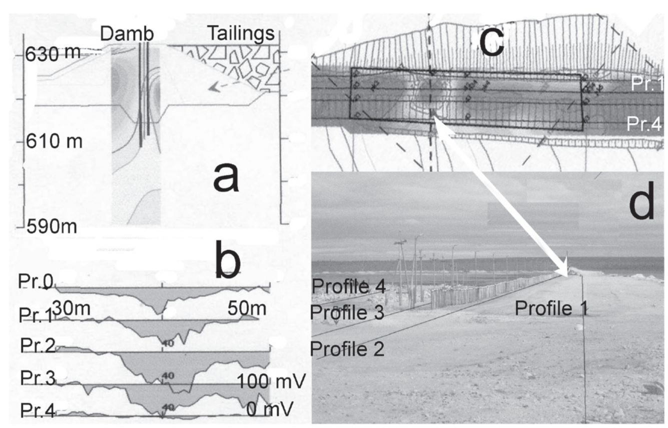

Figure 9. Seepage zone determination with geoelectrical methods (Complex VES, SP and resistivity profiling). Apparent resistivity distribution with depth (a) and on the dam's surface (c) indicates that melted material zone with electric conductivity formed around non-operating thermo needle. Since the dam was constructed with coarse material, seepage occurred in a melted zone, which was distinctly indicated with negative SP anomalies (b). SP and electric resistivity profiles were along the dam's crest (d). Profiles were done using 10 m spacing.

thermo needles and graphical interpretation of achieved results (Fig. 9).

In order to eliminate seepage determined with geoelectrical methods, a new thermo needle was installed and the location refroze. Graphs show self-potential minimums above the seepage zone. The pictures show the dam crest with thermo needles and seepage location with formed depression across.

Conclusions

Experience obtained during several years of using geoelectrical methods for monitoring and controlling the technical status of hydrotechnical structures in the permafrost zone shows high efficiency compared to other methods. They are fast and productive. High resolution mapping allows us to detect melted material zones with volumes as small as 0.1 m^3, in the dam or bedrock beneath it. Measurement can be performed on solid surfaces as well as on the water. Geoelectrical methods of control are remote and do not influence sampled material by introducing heat or highly mineralized technical solutions. This fact is very important for rock material containing ice, when contacting the solution can significantly change the melting point. With all benefits, the described methods are much cheaper then any other.

Acknowledgments

We express our gratitude to JSC “Ecogeophysics” director Alexander Sadikov for fruitful discussions on theories, methods, implementation, and sharing results obtained during geophysical control of structures in permafrost zones of Magadan Region, Chukotka and Saha (Yakutia).

Abstract

The presence or absence of permafrost plays a significant role in balancing the infiltration process between surface water and groundwater. These interactions between surface water and groundwater are poorly understood, yet will have a significant affect on the winter base flow discharge of most Arctic rivers as permafrost degrades. To better understand the base flow variability within the Arctic freshwater system, it is important to document and analyze the geochemical characteristics of groundwater. Spring water from 16 aufeis sites in the foothills of the Alaskan Brooks Range was collected during the summer of 2006. Results indicate that three distinct aquifer systems or hydrologic pathways exist in this region. Major ion chemistry of the waters is dominated by Ca^{2+} and HCO_3^-. Geothermal waters are dominated by SO_4^{2-}. Increased knowledge of geochemical characteristics of base flow will provide more insight into the long-term changes of the hydrologic cycle on the Arctic North Slope of Alaska.

Keywords: Brooks Range; geochemistry; groundwater interactions; PCA; infiltration.

Introduction

The hydrology in the Arctic is responding to an already changing climate. One of the major changes is the degradation of permafrost. As permafrost degrades, surface water and precipitation will infiltrate into the deeper sub-permafrost aquifer for the first time in recent geologic history (Clark et al. 2001). These interactions between the surface water and groundwater are poorly understood and will affect the amount and type of winter base flow reaching the Arctic Ocean. These interactions will also introduce new irregularity into an already sensitive hydrologic cycle. In an effort to better understand the base flow variability within the Arctic freshwater system, it is important to document and analyze the geochemical characteristics of groundwater in the dynamic hydrologic system of the Brooks Range.

Water balance studies are integral to quantifying the amount of water entering the Arctic Ocean from runoff, aufeis fields, and springs of the northern Brooks Range. Traditional thought surrounding water balance studies is that water enters the system from topographic highs and exits at topographic lows. The presence of faults, fractures, and permafrost in this study region introduces complexity to the water balance studies being performed. One of several working hypotheses for this research project is that water enters the watershed from the southern slope of the Brooks Range and then travels through the complex fracture system to emerge on the northern slope as spring water and aufeis fields. Geochemical characteristics, as well as dating, of the water will lead to knowledge of flow paths as these characteristics are indicative of specific water-rock interactions (Gomez et al. 2006).

The spatial expanse and remoteness of the eastern Brooks Range has resulted in a limited number of detailed geological studies, whereas much work has been done on the western and central Brooks Range as a result of the development of Red Dog Mine and National Petroleum Reserve – Alaska (NPRA) (Dumoulin et al. 2004, Kelly et al. 2004, Morelli et al. 2004, Slack et al. 2004). At this time, extrapolation of the subsurface stratigraphy from the drill logs in the west and central Brooks Range has been used in conjunction with limited subsurface evidence from the eastern Brooks Range to conceptualize the subsurface pathways and corresponding water-rock interactions in the study area.

One objective of the project is to collect spring water emerging from known aufeis sites in the foothills of the eastern Brooks Range. Aufeis sites are evidence for subterranean water channels that remain open due to the combination of adequate flow rates and warmer water temperatures. Spring water samples collected during the summer of 2006 were analyzed for major chemical characteristics. The data obtained will later be compared to previous chemical data of similar spring sites in an effort to distinguish whether changes have occurred in the hydrologic system of the Brooks Range. However, this paper will address interpretation of results from only those waters collected during 2006 and their geochemical properties, as well as those of several surface precipitate phases collected at the surface exposures. It is believed that these precipitates will lead to a better understanding of the subsurface water-rock interactions, as they are an indicator of the fluid chemistry (e.g., mineral saturation indices) immediately upon exposure at the surface.

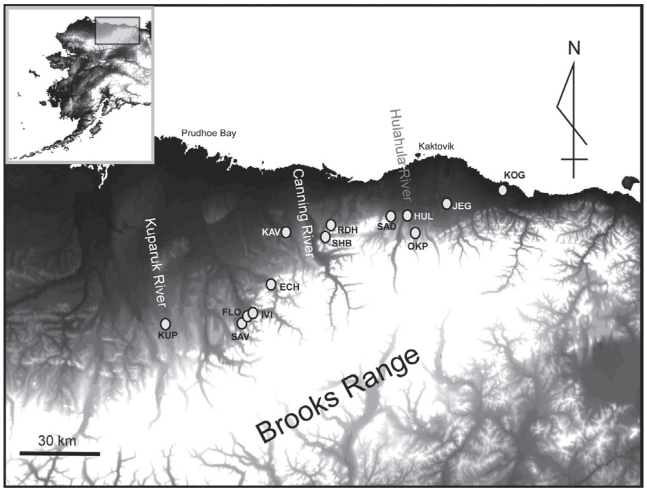

Figure 1. Location map with spring water sites and identifying features.

Methodology

Spring water samples were collected in July of 2006 (Fig. 1). Measurements of pH were conducted in situ with a hand-held meter calibrated at ambient temperatures with pH 4 and pH 7 buffers before and after the sampling trip. Spring water temperature was collected using the same meter. Several liters of water were collected in 1-L HDPE Nalgene bottles. One liter was reserved for alkalinity tests, while the remaining sample volume was then brought back to the lab, filtered through a 0.45um filter, and acidified, if necessary, for further analyses. Alkalinity was determined using HACH method 8203 WAH. Dissolved major cations (Ca^{2+}, Mg^{2+}, Na^{+}, and K^{+}) were analyzed with a Perkin Elmer AAnalyst 300 Atomic Absorption Spectrophotometer; Sr^{2+} was analyzed with an Aglient 7500 CE Inductively Coupled Plasma-Mass Spectrometer. Major anions (Cl^{-}, F^{-}, B^{-}, and SO_4^{2-}) were analyzed with a Dionex LC20 Ion Chromotograph. Hydrothermal precipitates were collected as grab samples in the summer of 2006 at 2 of the 12 spring water sites. The major element compositions of the hydrothermal precipitates were analyzed using a PANAlytical Axios wavelength dispersive x-ray fluorescence (XRF).

Results

Geochemical results indicate that spring waters in the eastern Brooks Range are characterized by varied and distinct water-rock interactions (Table 1). Emerging water temperatures varied by nearly 50°C and pH ranged by a factor of 3. Waters were found to be dominated by either Ca-HCO_3 or SO_4 signature, indicative of the predominant type of water-rock interactions.

Identifying potential flow paths

Principal component analysis (PCA) was used to investigate the underlying relationships among samples. This multivariate statistical analysis reduces the number of variables of a complex system to a lower dimension (from 12 variables to 2 in this case) (Güler et al. 2002). Unscrambler® software was used in calculating principal components (PCs). An initial PCA was created using all sites listing in Table 1. Due to the significant separation between the geothermal springs, OK, RDH1 and RHD2, and the decreased resolution for the remaining spring water sites, it was decided to exclude the geothermal springs to increase the resolution of the remaining spring water sites. The inputs were all those data listed in Table 1, excluding temperature and pH. Figure 2 is the score plot based on these inputs. Principal component one (PC1) explains 50% of the variance and PC2 explains 22% of the variance. PC1 is interpreted to represent flow path interactions. Those samples in the extreme (+) x-direction are subjected to more interactions with material surrounding the flow path while those in the extreme (-) x-direction has little interaction with surrounding material. Those sites lining up on the x-axis indicate site with moderate to limited interactions with surrounding material. The relative distance between sample site SAD and all other sites indicate water at this site interacts with a different type of material or an additional layer than the other sites. SAD water samples have high concentrations of Mg^{2+}, Sr^{2+}, and SO_4^{2-} relative to the others included in this computation.

PC2 is interpreted as segregating the spring sites into groups. Group I sites (IVI, FC, and SAV) not only have similar geochemical characteristics but also spatial proximity (refer to Fig. 1). The same is true for Group II sites (ECH, SHU, and HUL). Sample sites identified to be Group III sites (KUP, JEG, and KAV) are those with a shorter flow distance and, therefore, decreased interactions with more individual, site-specific characteristics.

Precipitates

Several spring water sites had physical evidence of fracture flow through a limestone bedrock formation. Upon surface exposure, the fluids are concentrated during ice-formation, leading to formation of an amorphous precipitate. Spring water site KAV was the most prominent with several mounds of 30 cm in diameter and height. Spring water sites RDH and HUL also had water with a milky-white appearance at the sample site. XRF analysis indicated precipitates at KAV and RDH to be composed principally of CaO (63.76%; 58.24 %), SiO2 (18.6%; 14.9%), and S (17.51%; 26.56%), respectively. The CaO fraction is most likely derived from

one of the several limestone lithologies. The emerging temperatures and geochemical characteristics at the spring water sites suggest S and SiO_2 portions are preferentially removed from the flow path as the water reaches the surface. Without more specific subsurface lithologies, it is difficult to determine how similar the flow paths are for the KAV and RDH. Preliminary results based on interpolated subsurface information and multivariate statistical analysis, indicate the two sites do not share flow paths.

The oxide percentages, dominated by CaO, seem to be further evidence of water-rock interaction with carbonate rocks. As the projected infiltration region of the Brooks Range is composed of carbonate rock, it is of little surprise to see a large percentage of the hydrothermal precipitates as CaO. Also of little surprise are the remaining two dominant components, SiO_2 and S. The assumed geothermal properties in the subsurface suggested by well log data, as well as concentrations of Si and S in the spring waters, imply a definite heat source and interaction with sulfide minerals (likely pyrite). Elemental concentrations of Zn, Pb, Zr, Sr, and Ba suggest further comparisons with stratigraphy connections with the region surrounding the Red Dog Mine in the western Brooks Range (Dumoulin et al. 2004, Kelly et al. 2004, Morelli et al. 2004, Slack et al. 2004).

Conclusion

All 12 spring water sites sampled exhibited unique geochemical markers as a result of specific water-rock interactions as the water reached the surface. Using a multivariate statistical technique, PCA, spring water samples were differentiated into groups based on these unique geochemical markers. Precipitate data suggest the type of water-rock interactions that dominate on the path to the surface. Further work is needed to identify potential correlation between spring water sites and fractures as well as subsurface lithologies among those spring water sites grouped according to PCA score plot results.

Interactions Between Human Disturbance, Demographics of *Betula fruticosa* Pall., and Permafrost in the Vitimskoye Upland, East Siberia

I.R. Sekulich
Institute of General and Experimental Biology SB RAS, Ulan-Ude, Russia

Abstract

The demographic structure of coenopopulations of *Betula fruticosa* Pall. in birch-shrublands is described in relation to off-road vehicle and agricultural disturbance and changes in terrain at the southern limit of continuous permafrost. It was determined that the degree of change in the demographic structure of the shrub affects the dynamics and processes of the permafrost condition. Heavy use of vehicles and ploughing lead to loss of shrubs and to grassy pasture. These changes contribute to major changes in soil temperature, moisture, and drainage conditions, followed by thermokarsting and solifluction. In the case of slight anthropogenic impact, such as the single passage of a tracked vehicle, the birch populations recover and the soil and terrain environment returns to the original condition.

Keywords: anthropogenic disturbances; *Betula fruticosa*; coenopopulations; demography.

Introduction

The major ecostabilizing element in a permafrost ecosystem is vegetative cover. However, the influence of human activity becomes more and more noticeable, and this, first of all, has an effect on vegetation. In this connection, research on the structure of vegetative cover, its stability in relation to anthropogenic disturbances, and its ability to self-recover has become most important.

The study of plant species coenopopulations gives the possibility to reveal the actual reaction of plants to various ecological factors on two levels: the individual level and the populations level.

According to Harper's studies in England (Harper & White 1974, Harper 1977, Harper 1992, etc.) and Rabotnov's, and Uranov's in Russia (Rabotnov 1950, 1964, 1969, 1975, 1978, 1985; Uranov 1960, 1975, 1977) the coenopopulation approach is widely developed, particularly in Russia.

The demographic structure of a plant's coenopopulations is one of the basic criteria of estimation of the modern state of species in coenosis, the level of vital condition of its coenopopulations, the degree of their stability and prospects of development.

Study Area

Our research was performed on the central part of the Vitimskoye upland, which is located in Eastern Siberia in the depths of the Eurasian continent to the east of Lake Baikal (Fig. 1). It is a large isolated area situated at the southern limit of continuous permafrost. The permafrost is the major ecological factor which determines the character and distribution of vegetation here.

Larch forests (from *Larix gmelinii* [Rupr.] Rupr.) and communities formed of low birches or birch-shrublands (in Russia termed *yernik)* are the most widespread here.

The capacity of permafrost in the research area is from 50 m to 250 m with temperatures from 0°C to -3°C, and depth bedding of permafrost in birch-shrublands and lighted larch forests in August-September is about 1.0–1.6 m (Vtorushin & Pigareva 1996).

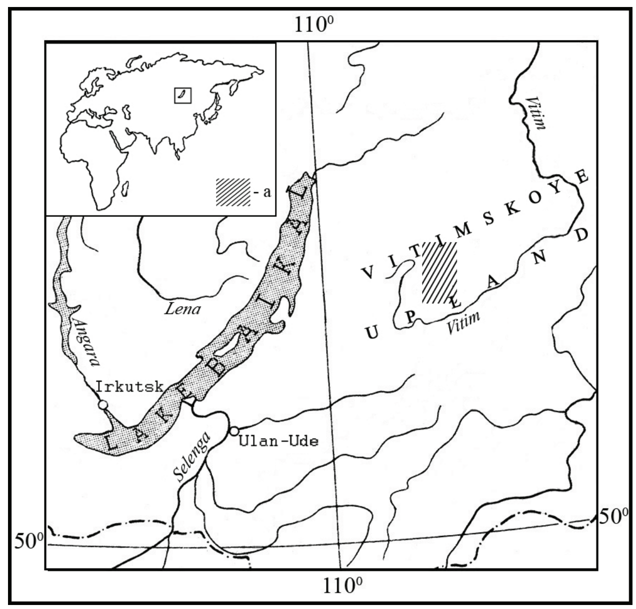

Figure 1. Map of location of research area.

The character of anthropogenic impact on birch-shrublands is developed in the following directions: their total destruction at strip-mining of minerals and ploughing up the earth, influence of track-type transport, and pasturing.

Material and Methods

The object of our research is *Betula fruticosa* Pall. subsp. *montana* M. Schemberg, the basic dominant of birch-shrublands, which occupy hollow inclined slopes, above the floodplain terraces, high parts of valley bottoms; that is, just those sites which are widely used by humans on the Vitimskoye upland.

Research was carried out, spent on model area in 100 square meters on which continuously calculated individuals on age groups.

The whole life cycle of plants can be divided into the age stages and age groups (Rabotnov 1950) submitted in Table 1. The letter code of each age group has been offered by Uranov (1960).

Determination of age groups is based on a number of complex signs, such as seed or root nutrition of plants, presence of juvenile or adult structures and their quantitative parities at the individuals, seed or vegetative reproduction, a parity and intensity of these processes, a parity of processes of new growth and dying, and degree of basic signs of biomorph generated at the individual.

The age level of the coenopopulations is estimated by the index of age (Δ) proposed by Uranov (1975) and by the index of effectiveness of the populations (ω) proposed by Zhivotovsky (2001). Values of Δ and ω were calculated by the following formulas:

$$\Delta = \sum n_i m_i \Big/ \sum n_i \qquad (1)$$

$$\omega = \sum n_i e_i \Big/ \sum n_i \qquad (2)$$

where n_i is the number of individuals of each age group; m_i is the coefficient of the age group, calculated by Uranov (1975); and e_i is the efficiency of plants of each age group, calculated by Zhivotovsky (2001). Values of m_i and e_i are submitted in Table 2.

Indexes Δ and ω vary from 0 to 1, and the highest value characterized the elder coenopopulation (Uranov 1975, Zhivotovsky 2001).

Results and Discussion

We studied the changes of demographic structure of the coenopopulations of *Betula fruticosa* on sites with partial destruction of vegetative cover as a result of the influence of track transport and pasturing. In estimating the degree of anthropogenic influence on the demographic spectrum of disturbed coenopopulations, it is necessary to compare them with a base spectrum, which, as considered Smirnova (1987), is the modal characteristic of dynamic balance of a coenopopulation. The base spectrum coenopopulations *B. fruticosa* on the Vitimskoye upland is full-constituent, has one peak, with absolute maximum on old generative individuals.

Two variants of modification of the demographic structure were marked.

One of them shows in increase of the quantity of pregenerative individuals at remaining big amount of generative individuals. An age spectrum of such coenopopulations has two peaks, the first maximum on immature individuals and the second maximum on old generative individuals. As an example, the age spectrum coenopopulation in a community of Multiherboso–Betuletum fruticosae is shown (Fig. 2). The community is situated near settlement along a highway and often exposed to influence of track-type vehicle.

At unitary passage of the cross-country vehicle according to mechanical influence, integrity of vegetative cover is broken, shrubbery and herbs are damaged, the moss and lichen cover are destroyed. As a result of these disturbances gaps formed, which are the microecotope for renewal *B fruticosa.* There is a rejuvenation of the coenopopulation at the expense of the big number of young individuals (Table 3). Short-term influence of transport does not effect adult individuals of *B. fruticosa* essentially. After termination of anthropogenic impact, individuals can quickly restore their habitus to former level. It is connected with formation of new suckers from sleeping buds which are on underground xylopodium parts. The growth of these suckers can reach 30–50 centimeters in the first year. At multiple or constant impact of track-type transports, the adult individuals finally perish, which leads to growth of grassy plants (cereals and sedges).

Replacement of birch-shrublands on grassy communities of meadow type leads to change of hydrothermal condition of soil. In space between ruts under the grassy vegetation, the depth of seasonal melting of permafrost is increased, raised soil temperatures, the moisture of soil is decreased. In ruts the temperature is decreased, which is connected with superfluous moisture of a surface (Moskalenko 1999).

Another variant of anthropogenic change occurs with pasturing. There are regressive changes in age structure. As a result of trampling and pasturing the young individuals of

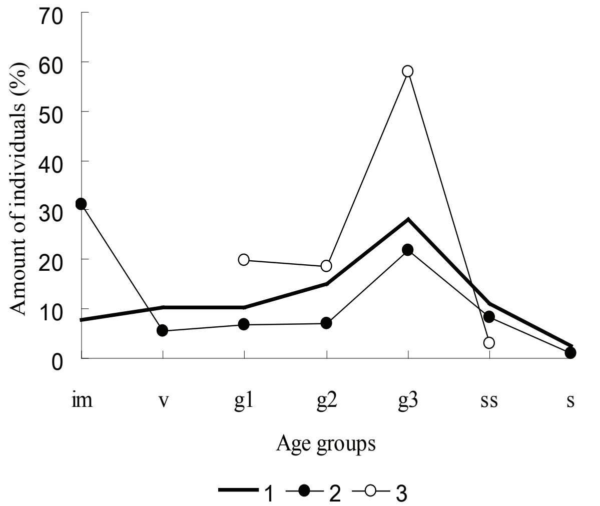

Figure 2. The age spectrums coenopopulations of *Betula fruticosa*. 1 – base spectrum; 2 – community of Multiherboso–Betuletum fruticosae; 3 – community of Kobresio filiformis– Betuletum fruticosae. Characteristic of age groups was explained above.

B. fruticosa disappear from structure of community together with grassy plants. The coenopopulation is presented by old-age plants. A community of Kobresio filiformis–Betuletum fruticosae located on an abrupt slope can be an example of such kind of coenopopulation. The age spectrum here has one peak, but differs from base spectrum. This age spectrum is not full-constituent and presented by old individuals (Fig. 2). This spectrum completely correlated with the regressive coenopopulations type of the spectrum, described by T.A. Rabotnov (1950). The quantity of individuals of *B. fruticosa* in this coenopopulation is small (Table 3). Gradual aging of coenopopulation without young individuals can lead to disappearing. The hydrothermal conditions of soil are changed on the bared sites, therefore cryogenic processes, such as erosion and solifluction, can develop.

The low index of age and index of effectiveness of coenopopulation of *B. fruticosa* occurred in community of Multiherboso–Betuletum fruticosae shows the invasive character of coenopopulation. The high index of age and index of effectiveness in community of Kobresio filiformis–Betuletum fruticosae show, that this coenopopulation mostly consists of old individuals and testifies decreasing of dominant role of species in coenosis (Table 3).

The coenopopulation in community of Multiherboso–Betuletum fruticosae it is considered as young, and the coenopopulation in community of Kobresio filiformis–Betuletum fruticosae – as becoming old according to "delta-omega" classification (Zhivotovsky 2001).

Thus, human-induced disturbances on the demographic structure of coenopopulation *B. fruticosa* in birch-shrublands on the Vitimskoye upland promote development of various geocryological processes, such as bogging, thermokarst, erosion, and solifluction. When the disturbances of demographic structure are slight, fast restoration of coenopopulation and ecological conditions occurs.

Table 3. The quantity, index of age (Δ), and index of effectiveness (ω) of anthropogenic disturbed coenopopulations of *Betula fruticosa*.

Abstract

Maritime conditions in the South Shetland Islands allow the presence of ice-cemented permafrost and an active layer from 25 cm to more than 1 m thick. In this work permafrost distribution has been studied from detailed geomorphological maps in 14 areas. Periglacial maps derived from the general ones allowed us to differentiate areas where permafrost-related landforms and processes occur and to compile permafrost distribution maps. Field observations and other methods have been used to check mapping interpretations. The spatial location of permafrost-related landforms allowed us to differentiate the following permafrost spatial-distribution pattern: (1) non-existing or sporadic permafrost at altitudes below 20 m a.s.l., (2) mainly discontinuous permafrost between 20 and 40 m a.s.l., and (3) mainly continuous permafrost at more than 70% of ice-free surfaces above 40 m a.s.l. Field observations pointed out important spatial and seasonal local variability in the presence of permafrost.

Keywords: ANTPAS project; geomorphology; Maritime Antarctica; periglacial landforms; permafrost distribution; South Shetland Islands.

Introduction

The South Shetland Islands are located in the Maritime Antarctica, between the Drake Passage and the Bransfield Sea, at 61°59′S/63°20′S, and 57°40′W/62°45′W (Fig. 1). The archipelago occupies about 4700 km^2 and only 10% are ice-free areas. The region has a cold maritime climate with annual mean surface air temperature at the coast line about -2°C, and daily summer temperatures above 0°C. Annual precipitation is between 400 mm/yr and 800 mm/yr and rain occurs in summer.

Studies on permafrost have been carried out on different places in the South Shetland Islands. There are works on Deception Island (López-Martínez et al. 1996, 2000, 2002), Media Luna Island (Corte & Somoza 1954, Serrano & López-Martínez 1997a), Robert Island (Serrano & López-Martínez 1997b, 1998), Nelson Island (Araya & Hervé 1972a, 1972b), King George Island (Simonov 1977, Barsch et al. 1985, Quinsong 1989, Zhu et al. 1996, Serrano & López-Martínez 2004) and Livingston Island (Thom 1978, López-Martínez et al. 1996, Serrano et al. 1996, Bergamín et al. 1997, Ramos 1998, Ramos et al. 2002, Ramos & Vieira 2003, Hauck et al. 2007). These studies provide information about the presence of permafrost and the active layer at different locations and altitudes in different islands. The aim of this work is to show an overview of the permafrost presence and distribution on ice-free areas of the South Shetland Islands from gepomorphological mapping and field observations. It is a contribution to the ANTPAS projects for compiling a map of permafrost in Antarctica. Bockheim (1995) pointed out the necessity to better know the extent of permafrost linked to the soils evolution and the recent global change.

Methods

This work is mainly based on the use of periglacial landforms as indicators of permafrost existence and distribution. Periglacial landforms and processes have been used as indicators of permafrost environments on Arctic and mountain environments with useful results (Black 1976, Washburn 1979, Harris 1982, Karte 1983, Clark 1988, Bockheim 1995, Barsch 1996). On the active layer a widespread group of landforms and processes are developed and relations between landforms, processes, existence, and extension of permafrost have been established (Harris 1982, French 1996). Rock glaciers, patterned ground, protalus lobes, frost mounds, frost creep, and gelifluction features point out the existence of mophodynamic and environmental conditions

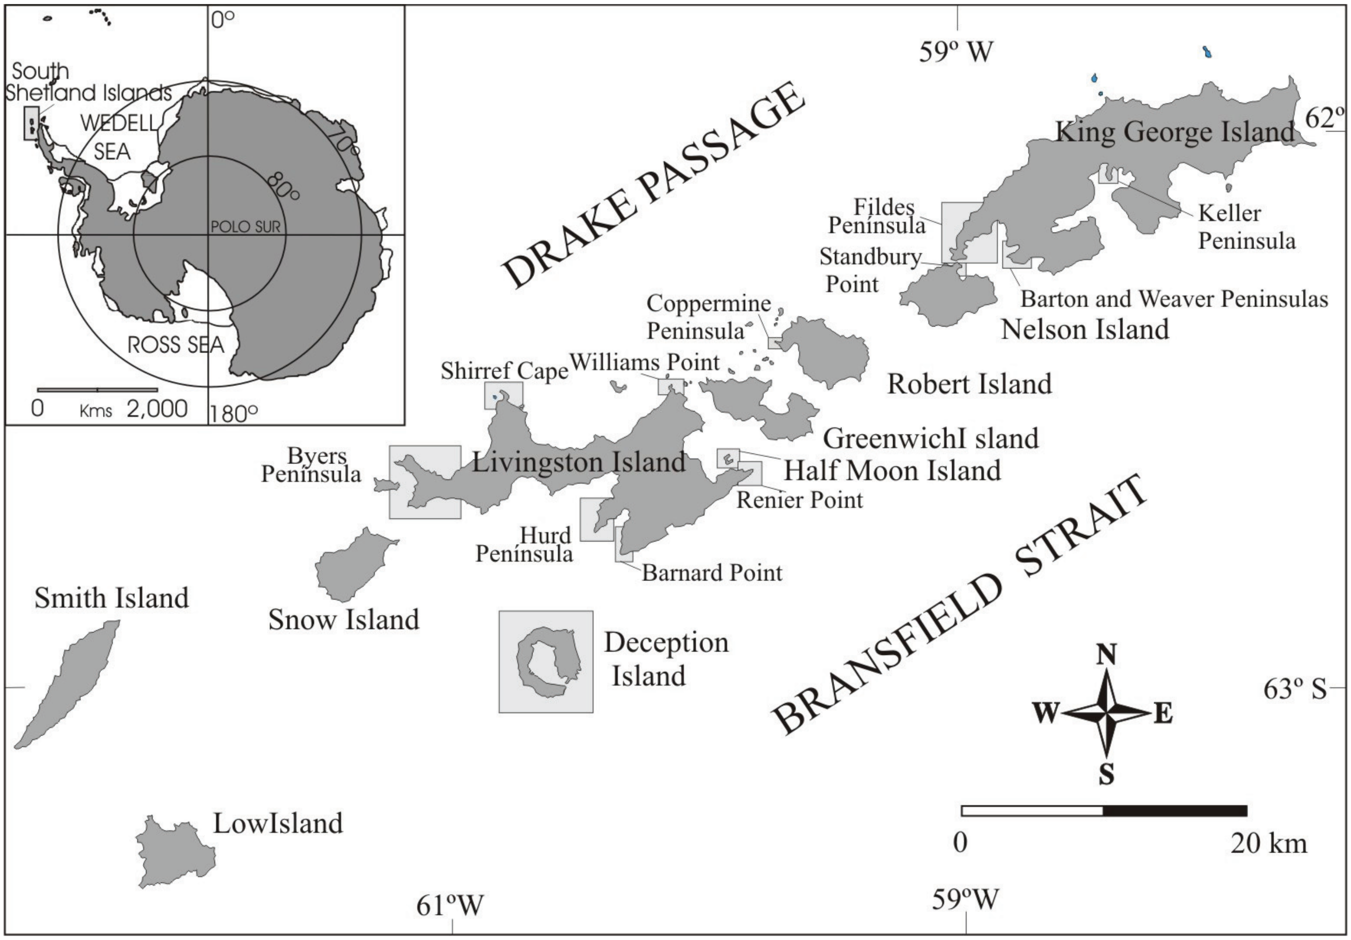

Figure 1. Location map of South Shetland Islands and places where geomorphological maps have been made by our group. Elephant Island not included in the map.

linked to permafrost (Black 1976, Barsch 1978, 1996, Harris 1982, Karte 1983, Haeberli 1985, Clark 1988, Huizjer & Isarín 1997). Differences between permafrost-related periglacial landforms and those periglacial landforms not related to permafrost occurrence have been used in this work to study the distribution and nature of permafrost in the South Shetland Islands. In addition and in order to check the validity of the interpretations in several places other techniques such as BTS measurements, vertical electric sounding, slope transects, mechanical sounding, active layer measurements, and water and permafrost analysis have been used.

Our group has compiled fourteen geomorphological maps between 1:25,000 and 1:10,000 scales (Table 1).

From the geomorphological maps simplified periglacial maps, showing such type of information only, have been made. Landforms valid as indicators of permafrost existence have been selected to deduce permafrost occurrence. The location and altitudinal distribution of permafrost-related landforms have been quantified to produce synthetic simplified maps of permafrost distribution.

Results: Permafrost Distribution

In the study region there is ice-cemented permafrost and the active layer is in general from 25 cm up to more than 1 m thick. Buried or ground ice has been recognized in several places at different altitudes.

Twelve types of landforms related to permafrost have been inventoried in the study areas in the South Shetland Islands and used for permafrost mapping (Table 2). Landforms related to frost heave and frost creep are the most common periglacial landforms in the archipelago. Patterned ground occurs in a wide altitudinal range, mainly between 10–100 m a.s.l. and being the dominant landforms above 25 m a.s.l. Stone fields are located mainly between 10–118 m a.s.l. The permafrost-related landforms and processes comprise 80% of the surface occupied by periglacial shapes on ice-free areas of the South Shetland Islands. Rock glaciers and protalus lobes are indicators of continuous or discontinuous permafrost, and are spread in several peninsulas and other places of the archipelago. Eight active rock glaciers have been identified in the South Shetland Islands but protalus lobes located between sea level and 300 m a.s.l. are more common features (Birkenmajer 1981, 1997, Barsch et al. 1985, Serrano & López-Martínez 2000). The rock glacier fronts have as a mean altitude 13 m a.s.l. and the upper ends 67 m a.s.l. and they are mainly developed below 70 m a.s.l. (Serrano & López-Martínez 2000). The mean altitude of rock glacier upper ends and protalus lobes point out the existence of continuous permafrost, although the fronts are located in

Table 2. Processes and landforms related to permafrost inventoried in the South Shetland Islands.

PROCESSES	LANDFORMS	LANDFORMS ELEVATION
Frost creep Gelifluction	- Protalus lobe - Rock glaciers - Block streams - Ploughing blocks - Gelifluction sheets - Gelifluction lobes - Debris lobes	40-100 m 0-300 m 30-100 m 10-90 m 0->100 m 10-300 m 0-100
Frost heaving Cryoturbation Sorting	- Stone stripes: Coarse stone stripes Fine stone stripes - Stone fields - Patterned ground: Stone circles Earth circles Stone polygons Earth polygons - Frost mounds	45-90 m 10-90 m 10-300 m 45-50 m
Thermokarst	- Melting hollows	40-100 m

areas without permafrost-related landforms.

The altitudinal analysis point out that at very low altitudes (between 0–20 m a.s.l.) patterned ground exists only occasionally. Three rock glacier fronts reach the sea or lowest beaches, permafrost occur at 2.5 m a.s.l. in Deception Island and at 7 m a.s.l. in Livingston Island (López-Martínez et al. 1996, Bergamín et al. 1997). Below 10 m a.s.l. the permafrost indicator features occupy only 12% of the surface with periglacial landforms, insufficient to be considered as discontinuous permafrost. From these data and the mentioned periglacial maps it is possible to deduce that on the lowest beach levels permafrost is sporadic or non-existing. Above 20 m a.s.l. landforms and processes related to permafrost are dominant (72% of periglacial landforms are permafrost-related) and point out a mainly discontinuous permafrost environment. Above 40 m a.s.l. debris lobes, protalus lobes, patterned ground and frost creep processes are dominant and the mean altitude of rock glacier upper ends and the location of all the protalus lobes point out a mainly continuous permafrost environment from 40–300 m a.s.l.

The distribution of the mentioned features allows to differentiate the following altidudinal distribution of permafrost:

- Between 0–20 m a.s.l. Non-existing or sporadic permafrost environments are dominant.
- Between 20–40 m a.s.l., mainly discontinuous permafrost environments are developed.
- Above 40 m a.s.l. mainly continuous permafrost environments are common, being at those altitudes more than 70% of ice free areas surface occupied by permafrost-related landforms and processes.

Field observations pointed out the important spatial and temporary variability in the presence of permafrost. Altitude plays an important role but also topography, soil characteristics, and orientation. Variations in meteorological conditions and snow coverage may change the active layer thickness in different years.

Conclusions

The analysis of permafrost related landforms and processes allowed us to establish the wide distribution of permafrost in the South Shetland Islands but also to assert that not all ice free areas in the archipelago have permafrost environments. The altitudinal analysis of the periglacial landforms denotes a distribution of permafrost environments in three areas with different morphodynamic systems:

- A sporadic permafrost environment (from 2.5–20 m a.s.l.), where less than 15% of the surface is occupied by permafrost related landforms.
- A mainly discontinuous permafrost environment (between 20–40 m a.s.l.)
- A mainly continuous permafrost environment (above 40 m a.s.l.) where more than 70% of periglacial landforms are related to permafrost.

From geomorphological maps it is possible to point out an altitudinal distribution of periglacial landforms and processes characterized by the lack of intense periglacial processes near the sea level, and the domain of permafrost related landforms on higher heights, dominated by the presence of patterned ground.

Abstract

In this paper we present initial results from observations of the effects of a series of natural vegetation covers and several experimental plots manipulated to mimic local grazing practices on soil temperatures, moisture content, and active-layer thickness in the Dalbay ILTER (International Long Term Ecological Research) study site in the Hovsgol Mountain forest steppe zone, northern Mongolia. We set up experimental plots with three types of treatments—control plot and plots that mimicked light and heavy grazing by clipping vegetation cover. The results show that both live and dead plants (especially moss, shrubs, forest, and dense grass) produce considerable insulation effects, maintaining low permafrost temperatures and protecting soil moisture from high evaporation. Therefore, both natural vegetation cover characteristics and grazing practices are important factors in preventing permafrost degradation in arid mountain environments.

Keywords: active layer; Hovsgol; soil moisture; soil-surface temperatures; soil temperatures; vegetation cover.

Introduction

The mountain forest steppe zone along the eastern shore of Lake Hovsgol Mongolia is characterized by mountains with altitudes of 1700 to 2200 m a.s.l. It is located in the southern fringe of the Siberian continuous permafrost and taiga forest zones. The forest is predominantly Siberian larch (*Larix sibirica*), distributed on crests and north-facing slopes. South-facing slopes and valley bottoms are generally dominated by *Poa* and *Carex* species. Shrubs, lichens, and thick grasses with abundant dead plant materials are widespread on gentle north-facing slopes and along river channels. There are 2–15 cm thick moss layers in the forest and 5–30 cm thick layers of peat in some valley bottoms (Goulden et al. 2006). Discontinuous permafrost is characteristic of the region near the lake. Active-layer depths are highly variable, ranging from 1 to 5 m depending on the topographic setting and vegetation cover. Permafrost thickness is between 5 to 20 m in the valley bottoms and thicker on the forested north-facing slopes. Permafrost is absent on south-facing slopes without forest (Etzelmuller et al. 2006, Heggem et al. 2006).

Permafrost degradation under the influence of climate warming in the Hovsgol region has been more intense during the last 15 years (1991–2006) than the previous 20 years (Sharkhuu et al. 2007). Mean annual air temperature at the Hatgal weather station, located on the most southern shore of the Lake Hovsgol, has increased by 1.86°C during the last 40 years (Nandintsetseg et al. 2006). Within the framework of the International Hovsgol Project supported by the Global Environmental Facility and implemented by World Bank (GEF/WB) in 2002–2006, Norwegian and Mongolian permafrost researchers studied the distribution and thermal conditions of permafrost in the region characterizing topography, snow and vegetation cover, soil texture, and soil moisture. The rate of increase in mean annual permafrost temperature varies from 0.02 to 0.04°Ca^{-1} per year, depending on landscape and ground conditions (Sharkhuu et al. 2007). In addition, human activities such as livestock grazing, anthropogenic forest fires, and some engineering works have led to local intensive degradation of permafrost. In some valleys of the study area especially,, livestock grazing has had negative effects not only on the permafrost but also on the ecosystem. The objective of this study was to estimate these anthropogenic effects, focused on grazing and forest fires. Hence studies on vegetation cover, soil-surface temperature, and active layer thickness were conducted in the Dalbay and Borsog Valleys between 2004 and 2007.

Study Area

The study area includes six valleys (Borsog, Dalbay, Sevsuul, Noyon, Shagnuul, Turag) on the eastern shore of Lake Hovsgol (Fig. 1).

Parts of the eastern shore area have been extensively used for grazing by nomadic families. Grazing is most intense

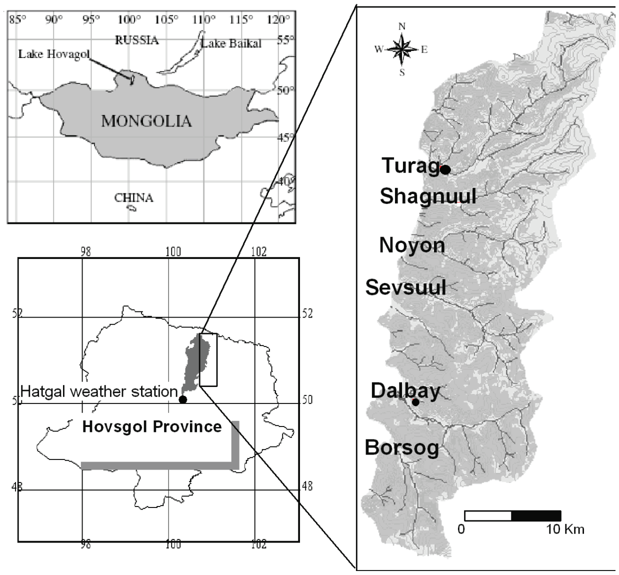

Figure 1. Location of the study sites along the eastern shore of Lake Hovsgol, Mongolia.

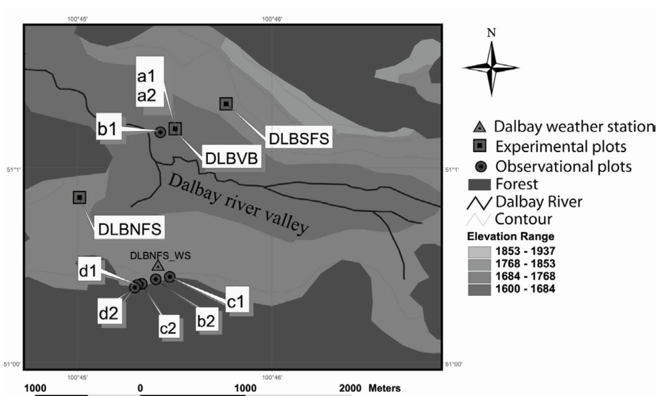

Figure 2. Topographic map of Dalbay Valley showing the locations of the eight plots used to study the effects of natural land-cover types. Points indicate locations of dataloggers used for SST measurements. Several points are overlaid on this map due to the short distance between them (e.g., *a1* and *a2*). Plots used for experimental study were shown as rectangular, labeled DLBSFS (plots on south-facing slope), DLBVB (plots in valley bottom), and DLBNFS (plots on north-facing slopes). Weather station location is illustrated with a triangle, labeled DLBNFS_WS.

in the northern valleys, especially in Turag and Shagnuul Valleys. Sevsuul and Noyon Valleys are only moderately grazed; whereas, Dalbay and Borsog Valleys have little or no pastoral use. Compared with Turag Valley, the present shallow active layer and low permafrost temperatures in Dalbay Valley are apparently insulated from thaw by the thicker vegetation cover (Table 1)

Methods

Natural land-cover plots

In order to estimate the thermal insulative effect of a range of naturally occurring vegetation cover year-round (October 2004–October 2005), soil-surface temperature (SST) recordings at eight observation plots in the Dalbay

Table 1. Vegetation cover and land-use characteristics in the study valleys.

Valley	Borsog	Dalbay	Shagnuul	Turag
Livestock numbers (sheep units)	51	530	3001	3330
Dry plant biomass, gm^{-2}	660	585	48	116
Active-layer thickness, m	2.1	1.4	4.3	4.8
Mean annual permafrost temperature, °C	-0.91	-1.25	-0.56	-0.42
Estimated permafrost thickness, m	35	45	25	20

Valley (Fig. 2) were made. All soil-surface temperature recordings were made at 2–5 cm depth under soil-surface in order to prevent temperature recordings affected by direct sun radiance. These plots represent the range of vegetation available within the valley.

In addition, some observations on the effects of forest fire on soil-surface temperature were made on north-facing slopes with larch forest in Shagnuul Valley Soil-surface temperatures at 2–5 cm depth and ground temperatures at 1 m depth were recorded by UTL-1 datalogger year-round.

Experimental plots

In order to explore effects of grazing on soil temperature, moisture and active layer, three 2×6 m^2 experimental grids were established along a topographic transect (south-facing lower slope, valley bottom, north-facing lower slope) in Dalbay and Borsog Valleys (Fig. 2). Within each grid six 2×2 m^2 plots were established with three different treatments: (*CO*) dead plant material and vegetation cover were both left intact, as control plots; (*CL*) vegetation cover was clipped but dead plant material was not removed (hereafter referred to as clipped plots); and (*CR*) vegetation cover was clipped and dead plant material was removed (hereafter referred to as cleared plots).

Soils within the active layer in valley bottoms and on north-facing gentle slopes consisted of gravelly silt and sands, covered by a 10–20 cm layer of humus. In summer, supra-permafrost waters are usually formed with a thickness of 10 to 30 cm, depending upon the amount of precipitation. Gravelly sands are characteristic of the south-facing slope.

Soil-surface temperature observations at 2–5 cm at each of the experimental plots began in October 2005. Unfortunately, these stopped in late March 2007 after 1½ years of observations, due to low battery power in the loggers. However, during each field season, measurements of soil temperatures and active layer thickness were made in the experimental plots.

UTL-1 dataloggers (interval 1.5 h, accuracy ±0.25°C) were used to record soil surface and soil temperatures for both natural and experimental plots. In addition, the MMT-4 thermistors and probes (accuracy ±0.1°C) were used. Mean winter temperature was calculated from mean December, January, and February temperatures, while mean summer temperature was calculated using June, July, and August means.

Live and dead plant biomass in each experimental plot was sampled from a 0.5×0.5 m^2 area in late June and early September–October of 2006. Biomass was determined after drying the sampled plants at room temperature for more than 48 hours. Dry plant biomass at each Dalbay plot is shown in Table 2. Clipped and cleared (CL and CR, respectively) plots were manually clipped monthly during the summer months of 2006.

Soil moisture in each experimental plot was determined by weight method monthly during summer. Soil samples were taken at each 50 cm depth from surface 0.1 m depth to a depth of 2 m. In addition, we determined soil density by core method to use for a model estimation. Soil samples were obtained using a hand drill (augur) and weighed using a digital balance with an accuracy of 0.1 g. Active layer thickness was measured using a 1.85 m long steel probe and several thaw tubes placed in some of the boreholes in early September and October, 2005–2006.

Table 2. Dry plant biomass (gm^{-2}) at each experimental plot in the Dalbay Valley

Vegetation cover at each site	CO	CL	CR	
			CR_{bj}	CR_{aj}
Grass, forb dry steppe on south-facing slope	340	135	96	118
Forb, grass meadow in valley bottom	625	375	135	160
Grass, forb wet steppe on north-facing slope	560	485	62	36

CO-unclipped control plot; CL-clipped plot with litter left in place; CR-cleared plot (vegetation cover was clipped and litter was removed): CR_{bj}-before July; CR_{aj}-after July.

Results and Discussion

Effect of natural vegetation on soil-surface temperatures

Initial results of quantifying the thermal insulation effect of different vegetation covers on soil-surface temperature are presented in Table 3. In particular, 10 cm thick (*Rhytidium rugosum*) moss cover decreased soil-surface mean summer temperature by 6.4°C as compared to plot without moss cover. Dense 1.8 m (*Salix* sp.) shrubs decreased soil-surface summer temperature by 1.4°C as compared to 0.5 m shrubs, and young dense larch forest decreased soil-surface mean summer temperature by 1.1°C as compared to sparse larch forest. Dense grass decreased soil-surface summer temperature by 2.2°C as compared to mown grass plot. In general, all types of vegetation cover decreased soil-surface summer temperatures by 5–9°C as compared with mown grass plot. Summer temperature differences (R_s) between different types of vegetation cover and mown grass plot are shown in Table 4. The temperatures under sparse forest, 50 cm high shrubs, and dense grass are reduced by 2–4°C. However, mean winter temperatures under dense vegetation cover were increased considerably, due to the accumulation of relatively loose and thick snow. Values of the mean annual temperature and the annual temperature amplitude under

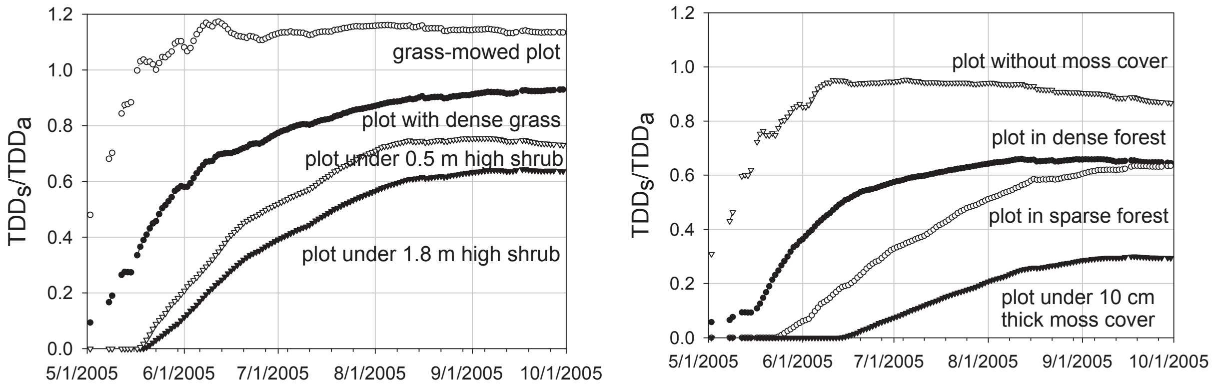

Figure 4. Daily n-factors (ratio of soil-surface to air temperatures) over the course of summer 2005 at each of the eight study plots.

Table 3. Mean soil-surface temperatures, temperature amplitude, summer temperature reduction (Rs) and summer n-factor in plots of different natural land cover in the Dalbay Valley (Oct. 2005 to Oct. 2006).

Plots	Land cover	Mean temperatures, °C			Temperature amplitude	R_s	Summer n-factor
		winter	summer	annual			
d2	10 cm thick moss	-8.6	3.4	0.29	6.8	9.0	0.29
b1	1.8 m high dense shrub	-7.4	7.4	0.63	7.8	5.0	0.63
c2	Dense forest	-11.7	7.5	0.64	10.5	4.9	0.64
c1	Sparse forest	-14.8	8.6	0.72	13.0	3.8	0.72
b2	50 cm high dense shrub	-11.4	8.8	0.73	11.3	3.6	0.73
d1	On moss surface	-11.5	9.8	0.86	11.9	2.6	0.86
a2	Dense grass	-11.1	10.2	0.93	11.9	2.2	0.93
a1	Grass mowed	-13.7	12.4	1.13	14.7	0.0	1.13
Air temperature at Dalbay		-23.9	10.8	-5.3	18.8	-	-

different land-cover types differ by 0.5 to 2.0°C and 3.0 to 7.0°C, respectively.

Linear least-squares regressions between daily air temperatures from the Dalbay automatic weather station and soil-surface temperatures under different land-cover types at the experimental plots were fitted. The linear regression analysis shows that the presence of thick moss is a major factor in insulating the ground from the heat. While slope value of linear regression between daily air temperature and soil-surface temperature under moss cover is 0.35, slope value of regression between air temperature and soil-surface temperature in mown grass plot is 0.70 (Fig. 3). *P* values for r^2 and slopes of all regression analyses were significant (P<0.0001).

Seasonal n-factors (Lunardini 1978), the ratio between thawing degree-days at the soil-surface (TDD_s) and in the air (TDD_a), were calculated for each day at plots of different land covers in Dalbay Valley and are shown in Figure 4. Usually n-factors are calculated using seasonal degree-day sums (Smith & Riseborough 1996). Here, n-factor was calculated using running sum of thawing degree-days at the soil surface and the air to show the seasonal progression.

These observations, though based on just one season of data, clearly demonstrate the importance of vegetation cover on ground thermal regime. In addition, in Shagnuul forest the mean annual surface temperatures were -3.1°C and -3.9°C in burned and unburned forest, respectively.

Effect of vegetation cover manipulation on soil temperatures

The initial results from the experimental plots are presented in Table 5. Compared to the control plots CO, the mean monthly summer soil-surface temperatures in the CR plots (clipped and litter removed) were higher by 0.7–1.7°C on the north-facing slope, by 2.3–2.7°C on the south-facing slope, and by 3.2–5.6°C in the valley bottom, depending upon plant biomass and surface wetness. Meanwhile, the undisturbed presence of dead plant matter (litter) in the valley bottom decreased the temperatures by 0.7–2.0°C. As compared to control plot CO, mean winter soil temperature at a depth of 1.2 m in the CR plot of the valley bottom was higher by 0.3°C, due to accumulation of summer heat into soil. However, the temperature at depth of 0.1 m was lower by 4.3°C due to relatively thin and dense snow accumulation in the clipped and cleared plot. Differences in near-surface soil temperatures between CO and CR plots were higher in summer than in autumn. The difference also decreased gradually with depth. In general, mean annual active layer temperatures in CR plots were significantly warmer than in CO plots.

Effect of vegetation cover manipulation on soil moisture

Not only live vegetation but also dead vegetation reduces near-surface soil moisture evaporation. Soil analysis shows that soil moisture content in CO and CL plots were always

	0.5	30.5	23.3	18.1	4.6	4.4

higher than in CR plots (Table 5). Due to plant biomass, hydrology, and soil characteristics, the differences in soil moisture content between CO and CR plots ranged from 5% to 20% in the valley bottom and did not exceed 2%–3% on south-facing slope. The difference decreased with depth.

Effect of vegetation cover manipulation on active layer thickness

In 2006 and 2007, the second and third years of the experiment, the thickness of the active layer in the CR plots in the valley bottom and the north-facing slope increased by 40–60 cm due to increased soil-surface temperatures and amplitudes, and decrease in soil moisture content. Each year, active layer thickness increased, though the rate of change decreased after the second year. Active layer thickness in CL plots also increased by about 15 cm (Table 6).

Conclusion

Vegetation cover acts as a cooling factor and reduces mean annual soil-surface temperatures. As compared to the mown

June 2006	35	49	61	13	20	29
Oct 7, 2006	125	138	177	102	113	143
Sep 7, 2007	123	140	185	101	116	147

grass site, mean summer soil-surface temperatures decreased by about 2.2°C under dense grass, 3.6°C under sparse forest and dense shrubs, 4.9°C under dense forest and bushes, and by 6.4°C under 10 cm thick moss at the Dalbay observation sites. As compared to Turag Valley where livestock grazing removes vegetation, the low grazing pressure maintains shallower active layer and lower permafrost temperatures in Dalbay Valley. Moss cover, dense grass, and forest are natural insulators, protecting soil moisture from high evaporation and maintaining low soil temperatures. The shallower active layer and low permafrost temperature found in the control (CO) and clipped (CL) plots, in contrast to the cleared plots are caused by live and dead vegetation cover. Thus, the main approach for preserving permafrost and ecosystems, especially in the Hovsgol forest steppe zone, must be based primarily on protecting vegetation cover.

Acknowledgments

These observations were conducted within the framework of the International Hovsgol Project, supported by a grant from the Global Environmental Facility and implemented by the World Bank to the Geo-Ecology Institute, Mongolian Academy of Sciences.

Two anonymous reviewers provided stimulating and helpful comments and suggestions on the draft manuscript. We want to thank all the mentioned persons and institutions.

Abstract

The thermal state of permafrost (TSP) in Mongolia is studied within the framework of mapping and monitoring of permafrost. Main parameters for estimating TSP are mean annual surface temperature (MAST), mean annual ground temperature (MAGT), or mean annual permafrost temperature (MAPT), and permafrost temperature gradient obtained during borehole temperature measurements by movable thermistors and data loggers. In this paper we will analyze and summarize initial data on estimating (1) changes in MAST and MAGT, depending on different natural factors, and (2) trends of increase in MAPT, based on data from 38 GTN-P and CALM borehole measurements in Mongolia. According to the results, the average rate of increase in MAPT in the Hentei and Hangai regions is 0.01°C–0.02°C a year, and in the Hovsgol region it reaches 0.02°C–0.03°C a year. Permafrost degradation under influence of climate warming was more intense during the last 15–20 years than during the previous 15–20 years (1970–1980s).

Keywords: boreholes; ground temperature; Mongolia; permafrost monitoring; soil surface temperature.

Introduction

Mapping and monitoring of permafrost is based mainly on the study of the thermal state of permafrost (TSP) (Kudrayvtsev et al. 1974). Main parameters for estimating TSP are mean annual surface temperature (MAST), mean annual ground temperature (MAGT), or mean annual permafrost temperature (MAPT), and permafrost temperature gradient (PTG). Values of MAGT are estimated by yearly average temperatures at depths of permafrost table or zero amplitude temperatures. They have a close relationship through thermal offset in active layers. For the last 40 years, Sharkhuu (2000) has measured ground temperatures in hundreds of shallow to deep boreholes in Mongolia. The data of borehole temperature measurements are useful for modeling and mapping distribution and thickness of permafrost in Central Asia. During the last 12 years Sharkhuu (2003 and 2005) also conducted permafrost monitoring in Mongolia within the international framework of GTN-P and CALM program (Burgess et al. 2000, Nelson et al. 2004). Initial results on CALM and GTN-P programs in Mongolia are presented in a number of publications (Brown et al. 2000, Sharkhuu 2003, Sharkhuu & Anarmaa 2005, Anarmaa et al. 2007). In addition, the Mongolian Expression of Intent #1129, main components of CALM and GTN-P programs in Mongolia, are part of the Thermal State of Permafrost IPY Project 50. According to the Expression, in 2007–2008 we are to extend boreholes and observations, improve quality of borehole temperature measurements, and generate new permafrost researchers. In this paper we analyze and summarize initial data obtained for mapping and monitoring of permafrost in Mongolia.

Permafrost zones occupy almost two-thirds of Mongolia, predominantly in the Hentei, Hovsgol, Hangai, and Altai Mountains and surrounding areas (Gravis et al. 1974). The territory is characterized by mountainous arid-land permafrost, sporadic to continuous in its extent, and it occupies the southern fringe of the Siberian permafrost zones (Fig. 1). In the continuous and discontinuous permafrost areas, taliks are found on steep south-facing slopes, under large river channels and deep lake bottoms, and along tectonic fractures with hydrothermal activity. In sporadic and isolated permafrost areas, frozen ground is found only on north-facing slopes and in fine-grained and moist deposits. The lower limit of continuous permafrost on south-facing slopes ranges from 1400 to 2000 m in the Hovsgol and Hentei Mountains, and from 2200 to 3200 m in the Altai and Hangai Mountains. The lowest limit of sporadic permafrost is found between 600 and 700 m a.s.l. Most of the permafrost is at a temperature close to 0°C, and thus, thermally unstable. However, average thickness and mean annual temperature of continuous permafrost is 50–100 m and -1°C to -2°C in valleys and depressions, and 100–250 m and -1°C to -3°C on mountains, respectively.

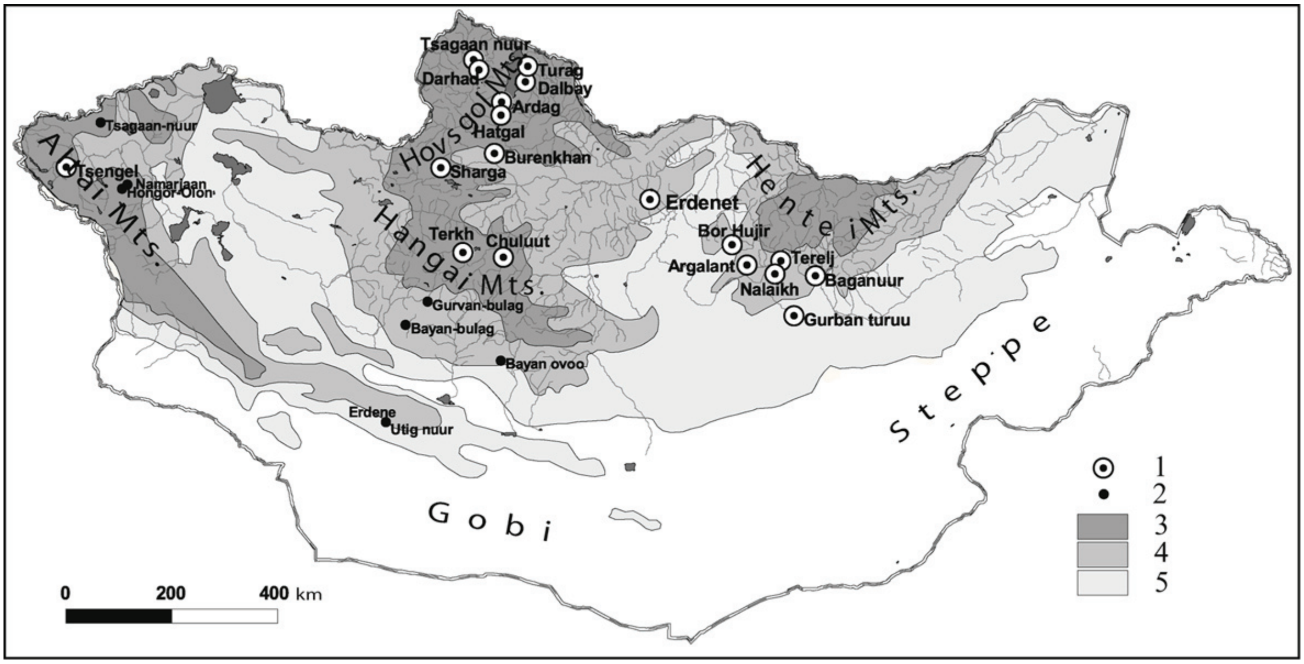

Figure 1. Location of permafrost monitoring boreholes in Mongolia 1 – Permafrost monitoring sites with GTN-P; 2 – Boreholes, planned to drill for permafrost monitoring; 3 – Continuous permafrost and discontinuous permafrost; 4 – Isolated permafrost; 5 – Sporadic permafrost.

Permafrost in Mongolia is characterized mainly by low and moderate ice content in unconsolidated sediments. Ice-rich permafrost is characteristic of lacustrine and alluvial sediments (Gravis et al. 1974, Sharkhuu 2003).

Permafrost in Mongolia is degrading under the influence of climate warming. According to the climate change studies (Natsagdorj et al. 2000), the mean annual air temperature has increased by 1.56°C during the last 60 years. Winter temperature has increased by 3.61°C. and spring-autumn temperature by 1.4°C–1.5°C. However, the summer temperature has decreased by 0.3°C. In the period from 1940–1990, mean annual air temperatures have increased by 1.8°C in northern and western Mongolia, 1.4°C in central Mongolia, and 0.3°C in southern and eastern Mongolia. For example, during the last 40 years mean annual air temperature at Hatgal weather station has increased by 1.86°C. Meanwhile, the air temperature trend was 0.61°C in the period from 1963–1989, and it reached 0.84°C in the period from 1990–2003 (Nandintsetseg & Goulden 2005).

Borehole Temperature Measurements

Methods

Ground temperatures in research boreholes have been measured by using movable thermistor strings and a digital multimeter of the MB-400 type. Temperature accuracy of thermistors of the MMT-4 type was 0.05°C. Temperature measurements in the permafrost monitoring boreholes are made using the same thermistors at the corresponding depths, and carried out on the same dates of any year. In addition, Stow-Away and HOBO, U-12 data loggers have been installed in most of the monitoring boreholes. UTL-1 and TR-52 data loggers have been used for measuring soil surface temperatures. Temperature accuracy of all the loggers is 0.25°C. Terrain and ground characteristics in most of the monitoring and research boreholes are determined in detail. Values of MAGT are estimated at depth of 10 m, although MAGT at depth of zero amplitude temperatures usually ranges from 10 m in fine-grained sediments with high moisture content to 20 m in bedrock and sandy sediments with course fragmental rock. A depth of MAGT also depends on yearly amplitude of soil surface temperatures. Mean winter temperature (MWT) is obtained by average value of air temperatures for December, January, and February. Mean summer temperature (MST) is estimated by the average value of air temperatures for June, July, and August. The frost number (FN) is calculated by a relation of values between thawing degree-days (TDD) and freezing degree-days (FDD) (Nelson & Outcalt 1987). A value of FN > 0.5 indicates more FDD than TDD, and is an indication of permafrost presence. This is, however, dependent on ground conditions, notably the thermal offset to the top of permafrost and therefore is not an absolute confirmation of permafrost existence (Heggem et al. 2006). Values of ground temperature gradient are estimated in the boreholes deeper than 30–50 m. Analysis of surface and ground temperature regime, or changes in MAST and MAGT depending on different natural factors, is made based on scientific methodology, developed at the Geocryology Department of Moscow State University (Kudrayvtsev et al. 1974).

Key study area

There are eight (Baganuur, Nalaikh, Argalant, Erdenet, Burenkhan, Hatgal, Ardag and Dalbay) key study areas with hundreds of geological and geocryological boreholes, where we measured and analyzed changes in MAGT depending on different natural factors. In addition, during the last 40 years ground temperatures have been measured in more than 100 geocryological and engineering-geological boreholes with permafrost in different areas of Mongolia.

Monitoring sites

Monitoring of permafrost in Mongolia, based on studies of TSP within the framework of GTN-P and CALM programs, has been conducted since 1996 and extended from year to year. At present, there are 17 monitoring sites, including 38 GTN-P and CALM boreholes in Mongolia. For the last 5–10 years, some boreholes with an average depth of 10–15 m were drilled in the locations with the temperature measurements which were made 15–40 years ago in old boreholes. We also plan to extend boreholes, especially in the Altai region (Fig. 1). All the monitoring boreholes are situated in natural conditions without thermal disturbance. Most of the monitoring boreholes are instrumented in order to decrease air temperature convection and to protect them from human damage. All the redrilled boreholes are cased by parallel steel and plastic pipes of 3–5 cm diameter with the mouth of the pipe at a depth of about 15–20 cm and covered by soil. The empty space outside of casing pipes is filled with fine sands.

Results and Discussion

Surface temperature regime

Soil surface temperatures in mountainous regions depend on mountain altitudes, slope aspect and steepness, and snow and vegetation covers. Selected data from soil surface temperature recordings on Tsengel (Altai), Solongot (Hangai), and Bogd (Hentei) mountain slopes are presented in Table 1.

Table 1. Year-round recordings of surface temperatures (°C), depending on topography and elevation (H).

Notes: Mean winter (MWT), summer (MST) and annual (MAT) surface temperatures; FN–frost number; A–amplitude temperature.

There are observed winter air temperature (MWT) inversions in some valleys and depressions which are located at altitudes of 1200 to 1800 m a.s.l in the Hentei Mountain region. A MWT inversion is not characteristic of the Altai high mountains. MST, MAT, and A in all the mountains are decreased in different gradients with mountain surface height. FN is increased with altitude. A south-facing slope, depending on its steepness, is warmer by about 0.5°C–2.0°C than a north-facing slope.

Thermal insulation of snow in severe climate conditions with high soil surface amplitude temperatures is essential (intensive), although average thickness of snow in Mongolia is about 5–20 cm. Experimental observations for studying the thermal insulation effect of snow cover on soil surface temperatures from November to March have been conducted in the Hustai and Terelj areas near Ulaanbaatar and at the Dalbay study site (See Table 2). Thick snow cover of 10–20 cm can warm mean winter surface temperatures by about 3°C–5°C. However, the thermal insulation effect of snow is gradually decreased with an increase in snow density and thickness which is more than 20–40 cm. It should be noted that the warming effect of snow on soil surface in the forest and with thick vegetation cover was more intensive than at open and bare sites.

Experimental observations for studying thermal insulation of different vegetation cover on soil surface temperatures have been conducted at the Dalbay and Hustai study sites (Heggem et al. 2006, Anarmaa et al. 2007). Data from Table 3 show that moss cover, dense grass, and forest are natural insulators, maintaining low soil temperatures. In particular, as compared with the grass mowed site, MSTs under different vegetation cover are decreased by 2°C–9°C. However, MWTs are increased 1°C–5°C, due to accumulation of relatively loose and thick snow in plants. Meanwhile, MSTs under dense

Sparse forest	-14.8	8.6	0.72	13
50 cm high dense shrub	-11.4	8.8	0.73	11.3
On moss surface	-11.5	9.8	0.86	11.9
Dense grass	-11.1	10.2	0.93	11.9
Grass mowed	-13.7	12.4	1.13	14.7
Air temperature	-29.3	10.8	-5.3	18.8

grass, forest, and 10 cm thick moss cover, are colder by 2.2°C, 4.2°C and 6.4°C, respectively. Therefore, the main factor in preserving permafrost and ecosystem in the Hovsgol and Hentei taiga zone must be based, first of all, on protection of vegetation cover (Sharkhuu & Anarmaa 2005).

Ground Temperature Regime

According to general regularities in TSP formation, MAGTs at depths of 10 m are decreased by about 0.4°C–0.6°C for each 100 m rise in mountain altitudes, and increased by 0.8°C–1.0°C for each 100 km moved from north to south. Ground temperature gradient varies from 0.01°C–0.02°C/m on mountain slopes and watersheds to 0.02°C–0.03°C/m in valleys and depressions. Meanwhile, the temperature gradient in unconsolidated sediments is more than in bedrock (Sharkhuu 2000). Changes in MAGTs, depending on different natural factors, are determined as follows:

Data from Table 4 show that forest cover can reduce MAGTs by about 0.5°C–1.2°C. Besides, as compared with south-facing slopes, MAGTs on gentle and steep north-facing slopes are colder by about 0.3°C–0.7°C and 0.8°C–1.5°C, respectively. Thus, north-facing slope and forest cover serve as favorable natural factors for TSP or permafrost existence.

Cold winter air temperatures are able to accumulate in rockfall and talus, which are widespread in the Altai, Hentei and Hovsgol Mountains. As compared with meadow, MAGTs at a depth of 2 m in talus and rockfall were colder by more than 1.7°C and 2.9°C, respectively. Value of low MAGTs in the course fragmental rocks such as rockfall and talus depends on porosity or the empty space in them (Table 5).

The thermal effect of underground waters on MAGT depends on river size, water stream, and water-bearing sediments. Data from Table 6 show that underground water streams along big and medium river valleys in continuous and discontinuous permafrost zones lead to taliks, due to an increase in MAGT. For example, as compared with large rivers, MAGT at a depth of 10 m in water-bearing sediments along medium and small river valleys and near brooks are colder by more than 2°C, 5°C, and 7°C, respectively.

Thermal offset enables permafrost to form and survive even when MASTs are positive (Osterkamp & Romanovsky 1999). Small patches and islands of permafrost in sporadic and isolated permafrost zones of Mongolia are formed as a result of thermal offset caused by differences of ground moisture content and thermal conductivity in the active layer (Sharkhuu 2000, Ishikawa et al. 2005). Observed values of MAGT for the thermal offset at Argalant borehole sites were typically 0.5°C to 1.5°C (Table 7).

Permafrost Temperature Monitoring

Main results on permafrost temperature monitoring in Mongolia are as follows: Permafrost in Mongolia is degrading at various rates, depending on climate and natural factors. In general, permafrost under influence of climate warming was degrading more intensely during the last 15–20 years than during previous 15–20 years (1970–1990). Permafrost degradation in bedrock is more intense than in unconsolidated sediments. For example, a rate of increase in MAPT in the Nalaih borehole with unconsolidated sediments does not exceed 0.02°C/year, but in the Burenkhan borehole with bedrock, it reaches 0.04°C/year (Fig. 2).

Moreover, the increasing permafrost temperature gradients with depth can be addressed as an indicator of recent and former degradation of permafrost (Harris & Haeberli 2003).

Table 4. MAGT depending on vegetation, slope aspect and steepness in Erdenet mountain area.

Slope aspect	Slope angle	Elevation, m	Vegetation	Ground	MAGT at 10 m, °C	Difference
South-facing	10°	1430	grass	bedrock	2.6	0.9

Figure 3 demonstrates that Darhad site would represent a warming trend during the early 1980s, while the Burenkhan site would respond to warming trends during the early 1960s. Both warming episodes are recorded according to climate data from the Muren, Hatgal, and Rinchinlhumbe weather stations (Anarmaa et al. 2007).

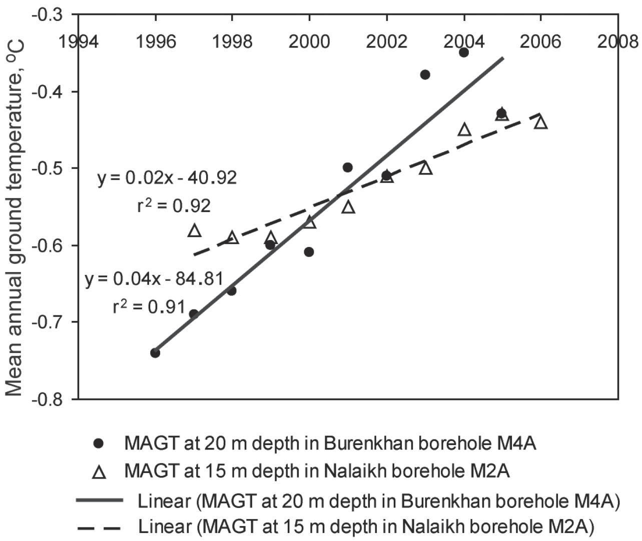

Figure 2. Trend of mean annual permafrost temperatures.

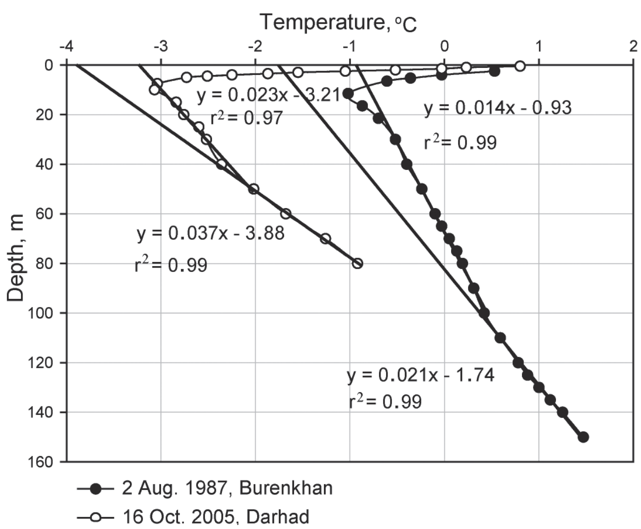

Figure 3. Change in permafrost temperature gradients with depth.

The average rate of increase in MAPT at 10 m depth in the Hovsgol Mountain region reaches 0.02°C–0.03°C/year, but in the Hangai and Hentei Mountain regions it does not exceed 0.01°C–0.02°C/year (Table 8). As compared with central Asia and European mountain territories, average trends of recent degradation of permafrost in Mongolia have almost similar values (Harris & Haeberli 2003, Marchenko 2007). However, as compared with eastern Siberia and Alaska, the average trends have smaller values (Osterkamp & Romanovsky 1999, Gavrilova 2003, Pavlov & Perlshtein 2006).

Conclusions

Main natural factors for determining thermal state and distribution of permafrost in the Altai, Hangai, Hovsgol, and Hentei Mountain regions are altitudes, slope aspect, and sometimes forest cover. The factors in arid land region surrounding the mountains are fine sediments with high moisture content and sometimes course fragmental deposits in mountains. Values of MAST and MAGT under influence of warming (5–20 cm thick snow cover and ground water stream) and cooling (forest and moss covers, fine-grained sediments with high moisture content and course fragmental deposits) factors are reduced within 0.5°C–2.5°C in every factor.

In general, permafrost under influence of climate warming in Mongolia is degrading at different rates. The permafrost in the Hovsgol Mountain region is degrading more intensely than in the Hangai and Hentei Mountain regions. Meanwhile, permafrost degradation under influence of climate warming was more intense during the last 15–20 years than during previous 15–20 years (1970–1980). Studies of TSP are of both scientific and practical significance for mapping and monitoring permafrost.

Abstract

An oil pipeline is to be constructed in northeastern China, which will transport oil from Russia to Daqing, China. Along the pipeline which runs from north to south, there exists continuous permafrost, discontinuous permafrost, sporadic permafrost, and seasonally frozen soil. A large number of undisturbed permafrost samples were collected to carry out thaw settlement tests in order to predict the potential deformation from thawing of permafrost. Test results include both thaw settlement parameters and the coefficients of compressibility dependent on total water content of samples. Regressive envelopes of the test results are suggested to analyze the relationships between the two parameters and water content for predicting the thaw settlement of permafrost for both fine- and coarse-grained soils. A comparison of thaw settlement parameters obtained using the proposed method and those estimated from specifications was carried out to clarify the thaw settlement behavior of permafrost along the pipeline.

Keywords: coefficient of compressibility; permafrost; pipeline; thaw settlement parameter.

Introduction

A pipeline is to be constructed in northeastern China to transport crude oil from Russia to China, in nearly a straight line in a north-to-south direction within a latitude range from 53°28′N to 46°30′N. The 960 km long, 914 mm diameter pipeline has been designed to be buried at a depth of 1.8 m (from ground surface to top of pipe) along most of the route. The pipeline has to traverse about 450 km of continuous permafrost, discontinuous permafrost, and sporadic permafrost zone from the most north to the south. The oil temperature at the inlet of the pipeline is estimated to be changing between -6°C to +10°C during the year. There will be no temperature control of the oil along the route. According to a preliminary estimate, the underlying permafrost would thaw to a depth of 1.5–4 m in the coming 30 years of service time, depending on the ice content of the permafrost.

Thaw settlement is one of the most critical design issues for a pipeline buried in permafrost. Uneven deformation of the pipe due to thaw settlement of permafrost may induce pipe breakage, especially in a large diameter pipeline. For many existing pipelines in permafrost regions attention was given to engineering permafrost problems in order to optimize design and maintain a good permafrost environment (Greenslade & Nixon 2000, Burgess 1988, Hanna & McRoberts 1988, Hanna et al. 1983, Nixon & Maclnnes 1996). Thaw settlement behavior of permafrost is an essential property for estimating the deformation of pipeline due to permafrost thawing. Some engineering specifications involving permafrost suggest values of thaw settlement based on the ice content of permafrost. However, measured results from tests are not always consistent with the estimated values suggested by the specifications because of the variety of soil type. Also, the compressibility after thaw of the permafrost is generally not considered in any specifications.

In the geological survey for the pipeline, many permafrost samples from boreholes were collected to study the thaw settlement behavior of permafrost. This paper documents the results of thaw settlement tests, which are proposed to be a reference in estimating the thaw settlement of permafrost along the pipeline.

Samples and Testing

Undisturbed frozen samples collected from boreholes were transported to a laboratory for testing. All thaw settlement tests were conducted in a confined condition using a cylinder of 79.8 mm ID and 40 mm height. Samples were carefully trimmed to fit to the test cell. Additional parts of the samples were used to measure their physical properties.

Samples were generally divided into two groups; these were fine-grained silty clay and coarse-grained soils including sand, sand with gravel and strongly weathered sandstone. Soil samples of both groups had a wide range of ice content and bulk density. The average plastic limit and liquid limit of the fine-grained soil were about 12.5% and 31.5%, respectively.

The total thaw settlement strain of a frozen sample generally consists of two components expressed as follows (Tsytovich 1975, McRoberts et al. 1978):

$$\alpha = A_0 + a_0 p \tag{1}$$

where

α is the total thaw settlement ratio, %;
A_0 is the thaw settlement parameter, %;
a_0 is the average coefficient of compressibility, 1/MPa;
p is the pressure applied to the permafrost sample, MPa;
A_0 and a_0 are determined using the thaw settlement test.

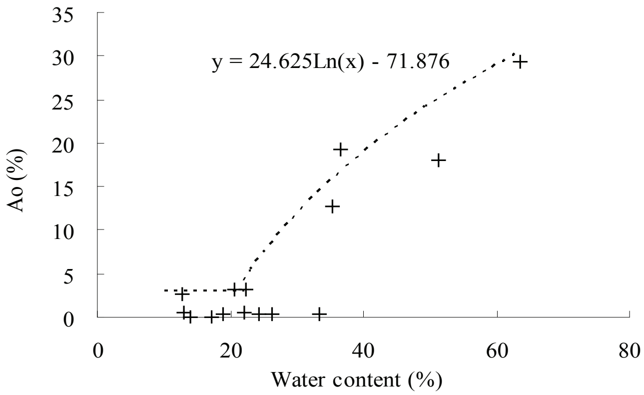

Figure 1. Thaw settlement parameter vs. water content for the fine-grained silty clay.

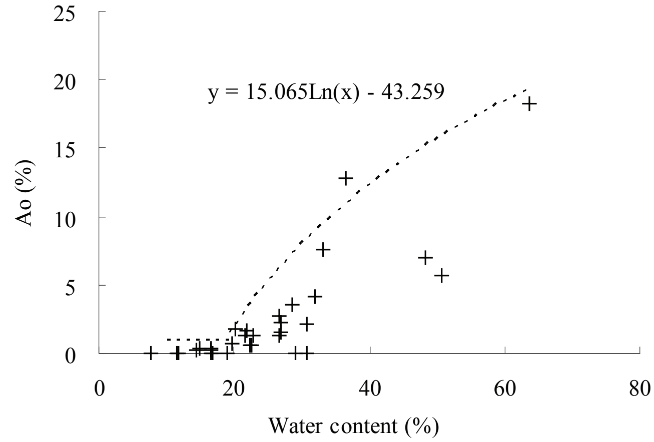

Figure 2. Thaw settlement parameter vs. water content for the coarse-grained soils.

After putting the sample into the test cell, the sample is allowed to thaw under uncontrolled conditions. For the thaw settlement parameter a pressure of about 1 kPa is maintained to overcome the friction between the sample and the cell wall. After the deformation stabilizes, subsequent increments of pressure are applied to determine the coefficient of compressibility. Three pressure stages, 50 kPa, 100 kPa, and 150 kPa are used in the tests. The coefficient of compressibility is determined as the average at the three pressure levels.

Test Results

Thaw settlement parameter A_0

The values of thaw settlement parameter are plotted against the initial water (ice) content of the samples as shown in Figure 1 for the fine-grained silty clay and Figure 2 for the coarse-grained soils. For both groups of soil, the relationship between A_0 and water content shows a two-stage phenomenon. There is a low and comparatively stable value when the water content is less than a certain value (defined as initial water content of thaw settlement for the soil type along the oil pipeline). Once the water content is greater than initial water content of thaw settlement, A_0 starts to increase considerably with the increase in water content. To be safe, it is not thought appropriate to fit a formula to all the test data. A regressive envelope of the data is, therefore proposed to predict A_0 for samples with high water contents. A logarithmic relationship was found to be a good choice (see dotted line in Figs. 1 and 2). The thaw settlement parameters for both soils can be predicted by the following relationships:

For fine-grained silty clay:

$$A_0 = \begin{cases} 3 & w \leq 21\% \\ 24.625\ln w - 71.876 & w > 21\% \end{cases} \tag{2}$$

For coarse-grained soil:

$$A_0 = \begin{cases} 1 & w \leq 19\% \\ 15.065\ln w - 43.259 & w > 19\% \end{cases} \tag{3}$$

where w refers to the initial water content of the samples.

Table 1. A_0 suggested in Specification GB50324-2001.

A_0 (%)	Total water content, w (%)	
	Silty clay	Coarse soil
< 3	$w < w_p+4$	$w < 15$
3~10	$w_p+4 \leq w < w_p+15$	$15 \leq w < 25$
10~25	$w_p+15 \leq w < w_p+35$	$25 \leq w$

Note: w_p is the plastic limit water content.

When the thaw settlement parameter is less than 3%, thaw settlement is generally considered to be negligible. In Equations (2) and (3), the first constant term corresponds to a water content range of less than the initial water content of thaw settlement. The initial water contents of thaw settlement are 21% and 19% for the fine-grained silty clay and coarse-grained soil, respectively.

Comparing Figure 1 with Figure 2, it is found that the value of A_0 for the fine-grained silty clay is greater than that for the coarse-grained soil at the same water content. This means that engineers should pay particular attention to silty clay permafrost soils with high ice content.

Comparison with specifications

In some specifications in China, thaw settlement parameters are suggested for different types of soil. Table 1 lists a typical summary of A_0 according to Specification for Survey of Frozen Soil Engineering Geology (GB50324-2001).

In terms of the classification of A_0 in the specification, water content ranges from test results can be calculated from the proposed predicting formulae. Table 2 lists the results.

It was found that the test results for the fine-grained silty clay roughly agreed with the suggestion in the specification, especially for the permafrost with high water-ice content. For the coarse-grained soils, test results indicated that the water content ranges generally had higher values than those suggested in the specification. In other words, the thaw settlement of coarse-grained permafrost soil would be much lower than that estimated in the specification.

Table 2. Water content ranges from test results in terms of the classification of A_0 in specification.

A_0 (%)	Total water content, w (%)			
	Silty clay		Coarse soil	
	Specification	Test	Specification	Test
< 3	<16.5	< 21	< 15	< 21.5
3~10	16.5~27.5	21~28	15~ 25	21.5~35
10~25	27.5~47.5	28~51	≥ 25	≥ 35

Coefficient of compressibility a_0

Results of the coefficients of the compressibility test are shown in Figures 3 and 4 for the fine-grained silty clay and the coarse-grained soil, respectively. It can be seen that there is a scatter in the test results. Although linear relationships can be used to approximate the test results (solid line in Figures), we suggest that the regressive envelopes of the data provide a reasonable and safe prediction. Logarithmic relationships are found to be quite appropriate for both fine-grained silty clay and coarse-grained soil (shown in dotted line in Figs. 3, 4). Therefore, the coefficient of compressibility for both soils can be predicted according to the following formulae:

For the fine-grained silty clay:

$$a_0 = 0.8514 \ln w - 1.5224 \tag{4}$$

For coarse-grained soil:

$$a_0 = 1.25 \ln w - 2.3146 \tag{5}$$

Although the thaw settlement parameter of the fine-grained silty clay is higher than that of the coarse-grained soil, the coefficient of compressibility of the coarse-grained soil appears to increase faster with increasing water content. This means that the frozen coarse-grained soil has more potential to deform than the fine-grained silty clay when loaded. The total thaw strain of permafrost depends on both A_0 and a_0 for different pressures. Based on the proposed estimate, the total thaw strain can be plotted as shown in Figure 5. It can be seen that if the pressure is less than 100 kPa, the silty clay deforms more than the coarse soil. For pressures greater than 100 kPa, the coarse soil deforms more than the silty clay.

The pipeline is designed to be buried at a depth of about 1.8 m; the depth at the bottom of the pipeline is about 2.7 m. Within the range of 4.0 m below the pipeline, where underlying permafrost may thaw, the soil pressure applied on permafrost is about in the range from 50–150 kPa, which falls within the pressure range of the tests. If an insulation layer is packed around the pipeline to reduce the depth of permafrost thaw, the thaw settlement should be comparatively low. In this case more attention should be paid to the deformation of the frozen silty clay. If there exists a frozen coarse layer with high water content at a deeper location below the pipeline (e.g., 3–4 m below the bottom of the pipeline), the possible deformation from permafrost thawing may be greater than that of the frozen silty clay at the same ice content. Engineers should consider the difference in the thaw settlement

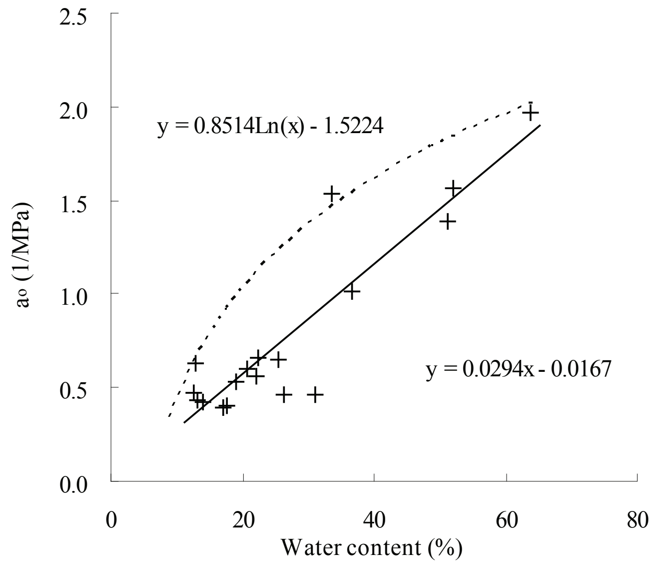

Figure 3. Coefficient of compressibility vs. water content for the fine-grained silty clay.

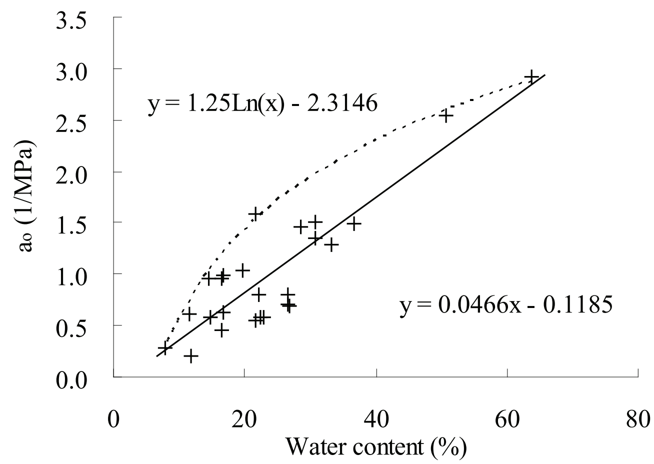

Figure 4. Coefficient of compressibility vs. water content for the coarse-grained soil.

behavior with comprehensive permafrost geological data to optimize the design, so as to choose a reasonable treatment to the permafrost section.

Conclusions

Based on test results, thaw settlement behavior was analyzed for both fine-grained silty clay and coarse-grained soil. Water content appeared to be a dominant factor in the test results. The following suggestions are proposed to provide a guide for the design of the pipeline.

(1) The thaw settlement parameter of the fine-grained silty clay has a high value, which is roughly in agreement with the suggestion in specifications. The thaw settlement parameter of the coarse-grained soil is, however, lower than the value suggested in specifications.

(2) When the water content of the frozen sample is greater than the initial water content of thaw settlement, it was suggested that the thaw settlement parameters of both

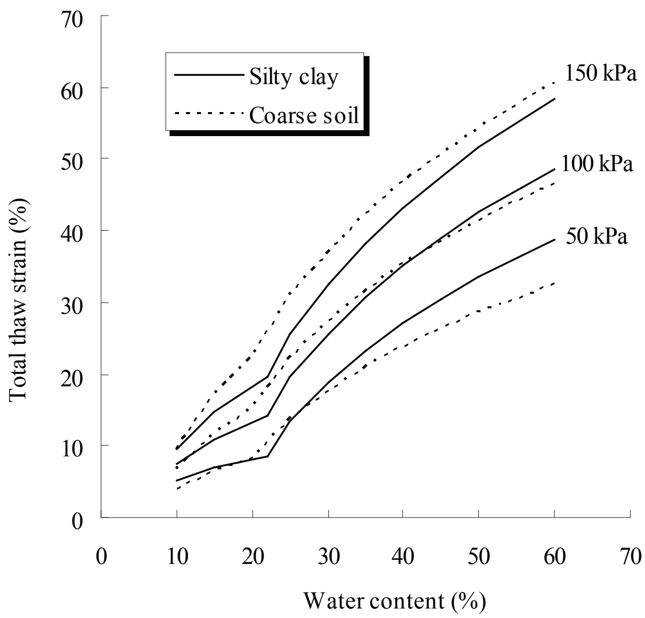

Figure 5. Total strain of the thawed permafrost vs. water content under different pressure.

fine-grained silty clay and coarse-grained soil be predicted using their envelopes of the test results, instead of all data. A logarithmic relationship is proposed to describe the relationship.

(3) The coarse-grained soil has more potential to deform under comparatively high pressures. Its coefficient of compressibility was higher than that of the fine-grained silty clay with increasing water content. Logarithmic envelopes of test results are also useful for predicting the coefficients of compressibility.

Abstract

From 1965–2004, data from all Russian meteorological stations with long-term soil temperature observations at depths 80, 160, and 320 cm were compiled and analyzed. It was found that the prevailing influence on soil temperature variations in the European part of Russia was surface air temperature and in the Asian part of Russia was snow cover depth. By preserving the heat accumulated in the warm season, an observed increase of the winter snow depth in the permafrost zone promotes annual soil temperature increase and therefore may foster the further permafrost degradation associated with on-going regional warming.

Keywords: Eurasia; permafrost; snow depth; soil temperature; warming.

Introduction

According to Izrael et al. (2002), beginning in the mid-1960s, northern Russia experienced climate warming. For the whole of northern Russia, the air temperature rise trend was 0.47ºC/decade. As the sampling stations in Izrael et al. (2006) show, this was accompanied by the soil temperature rise at 80 and 160 cm depths. However, the agreement between air temperature and soil temperature trends has not occurred everywhere. At some stations, soil temperature trends are higher than air temperature trends. The causes of this behavior are to be identified. This work aims at deriving quantitative estimates of the influence of the two major factors of changing climate: air temperature and snow depth, on the soil temperature. The problem is addressed by using data from the network of Russian stations, where soil temperatures have been recorded at depths to 320 cm since 1965.

Temperature rise in the permafrost zone can lead to frozen ground degradation and can change the characteristics of soil toughness. Therefore, the problem of frozen ground degradation is of major practical importance. The Russian permafrost zone contains more than 30% of the developed oil reserves available in Russia; about 60% of natural gas, hard-coal and peat deposits; a significant portion of hydropower resources; deposits of non-ferrous metals, gold and diamond and vast reserves of timber and fresh water. Expensive and vulnerable infrastructure was created here, i.e., petroleum field facilities; main oil and gas pipelines extending thousands of kilometers; mines and pits; and hydroelectric plants. Additionally, settlements and towns, highways and railways, aerodromes, and ports were built in this region (Pavlov et al. 2000). The foundations and base plates of all the structures are supported by pilings frozen in the ground. Melting of frozen ground violates the stability and operational capability of all these engineering facilities (Demchenko et al. 2001).

Analysis and Results

Soil temperature data at depths 80, 160, and 320 cm, as well as air temperature and snow depth data, were analyzed for all Russian meteorological stations for 40 years (for the 1965-2004 period). The monthly data for 150 stations (shown by stars in Fig. 1) were retrieved from the National Roshydromet archive. Thereafter, we conducted multiple correlation analyses searching the factors that control the soil temperature seasonal variations across the Russian Federation.

Correlations, R, between summer soil temperatures at the 160 cm depth and summer air temperatures (mean temperature for June to August) are presented in Figure 1. From the western border of the Russian Federation to 75°E, the Figure shows significant positive R-values (> 0.6). East of 75°E, across West Siberia, southeast Siberia, and at the Far East stations of Sakhalin and Primorie Krai, correlation coefficients (being of the order of 0.4 to 0.5) are still statistically significant at the 0.05 level. The highest positive correlation coefficients (R>0.60) between summer air temperatures and soil temperatures at all depths (with appropriate shifts depending upon the depth, e.g., for 160 cm this shift is around 2 months) are primarily observed outside the permafrost zone. In the vast central part of the permafrost zone, the correlation is close to zero (Fig. 1).

In winter (December to February), the correlations between soil temperatures and air temperatures are weaker and the R-values above 0.6 are absent across the entire nation (Fig. 2). Statistically significant correlation coefficients (0.4 to 0.6) between winter air temperatures and soil temperatures at depths of 80 and 160 cm are observed only over Russia west of the Ural Mountains. Only here in the southernmost part, the impacts of winter air temperature are observed as deep as 320 cm. In winter in the permafrost zone, the impact of long-term surface air temperature changes on soil temperatures is practically unnoticeable at all depths.

The analysis of correlations between winter soil temperatures at different depths and February snow depth shows that significant positive correlation coefficients (0.4 to 0.6) prevail at soil depths of 80 and 160 cm over most of Russia east of the sub-Urals (50°E, with exceptions of the North Siberia Plain, Kamchatka, and southeast Siberia). At the 320 cm soil depth, a significant positive correlation is observed only in small isolated areas in southwest Siberia, Central Yakutia, and Primorie. No significant correlations were found between the February snow depth and winter soil temperatures at all depths over European Russia. The warming influence of snow at each soil depth is recorded over most of Asian Russia, but it becomes weaker as the soil depth increases and is not observed at all in European Russia.

Mean annual soil temperature in different regions is formed in different ways. In European Russia, it is controlled by air temperature changes rather than by snow depth. The warming effect of snow here is practically absent. In Asian Russia, on the contrary, changes in mean annual soil temperature are controlled by snow depth changes rather than by air temperature changes.

The contribution of the mean annual air temperature and the snow depth to the change in mean annual soil temperature was estimated in percent of the total variance of the soil temperature. The analysis of this quantity shows that in European Russia, the main contribution to the total variance is made by the air temperature (23% to 46% of the contribution to the total variance) and the contribution of snow here is minimal (from 0.4% to 8.0%). The impact of snow on the soil temperature in this region is so small that even with negative snow depth trends in northwestern Russia (e.g., in Karelia and Arkhangelsk district; cf. Fig. 3), soil temperature trends are positive and significant.

Tendencies for the increase in mean winter snow depth are observed over most of the Russian territory (mainly in Siberia). But northern regions of European Russia, show a tendency for decreasing snow depth (Bulygina et al. 2007).

Across Asian Russia and in the Urals Region, the values of soil temperature trends are higher than the air temperature trends. Positive soil temperature trends are observed even at the stations with negative air temperature trends (Nizhni Tagil 57.9°N, 60.1°E; Kupino 54.4°N, 77.3°E; Pudino 54.4°N, 79.2°E, and Bokhan 53.2°N, 103.8°E). At the last station (Fig. 4), the contribution of the mean annual air

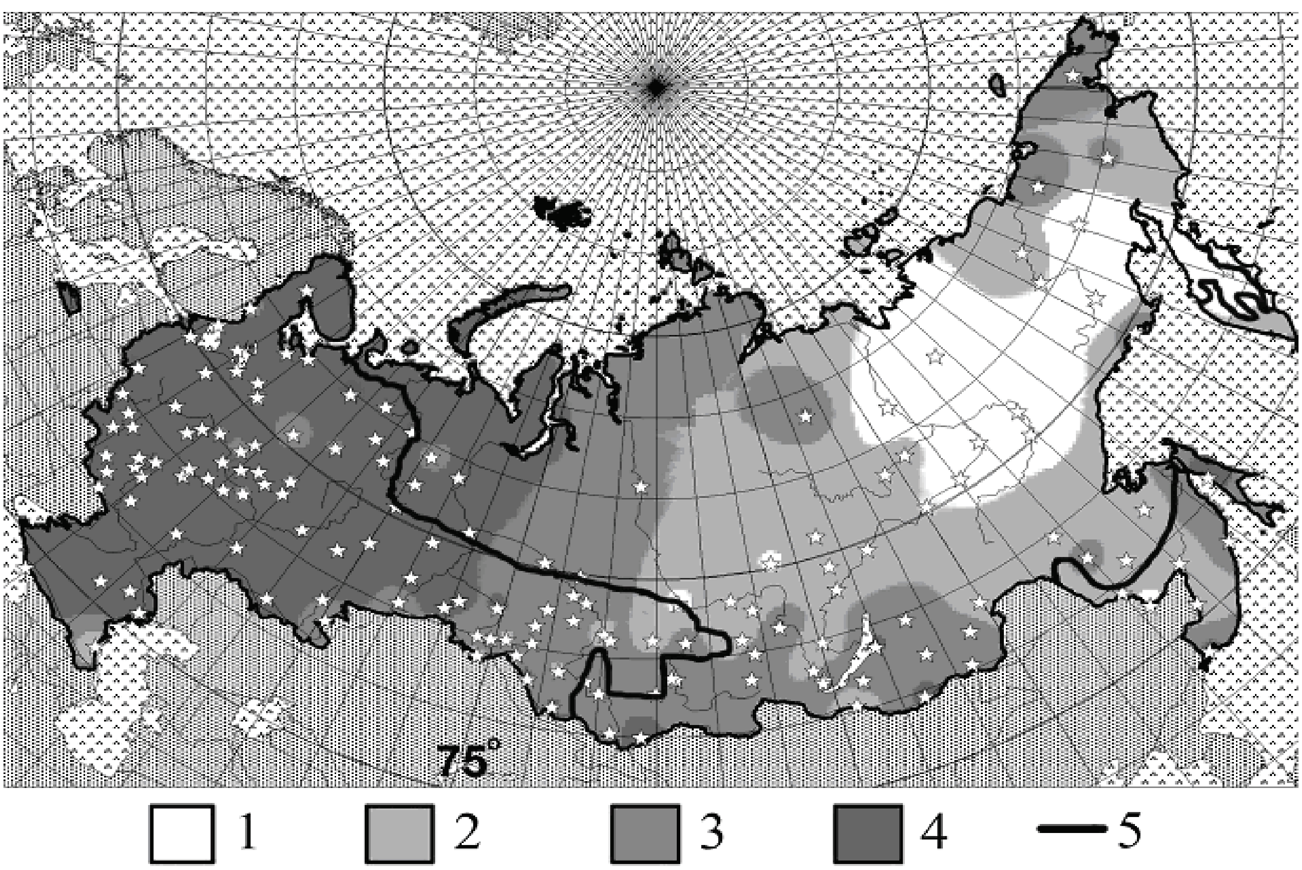

Figure 1. Correlation coefficient (R) between air temperatures and soil temperatures at the 160 cm depth in summer.
1 – 0.1≤k<0.2, 2 – 0.2≤R<0.4, 3 – 0.4≤R<0.6, 4 – 0.6≤R<0.8, 5 – southern border of the permafrost zone.

temperature to the total variance of soil temperatures at 160 cm is only 4.7%, while the contribution of the snow depth is 30%.

A geographical distribution of the contributions of the two factors to the total variance of mean annual soil temperatures at 160 cm is shown as diagrams on the map (Fig. 5). Nearly everywhere in European Russia, the long-term changes in mean annual soil temperature are greatly controlled by air temperature changes (light columns in diagrams, 20% to 50%).

The snow changes here determine no more than 10% of the variance (dark columns in diagrams). In Central Volga, the Urals, and over most of Asian Russia, the long-term changes in mean annual soil temperature are primarily controlled by snow depth changes (10% to 50% of the variance) and air temperature is responsible for less than 10% of soil temperature variability.

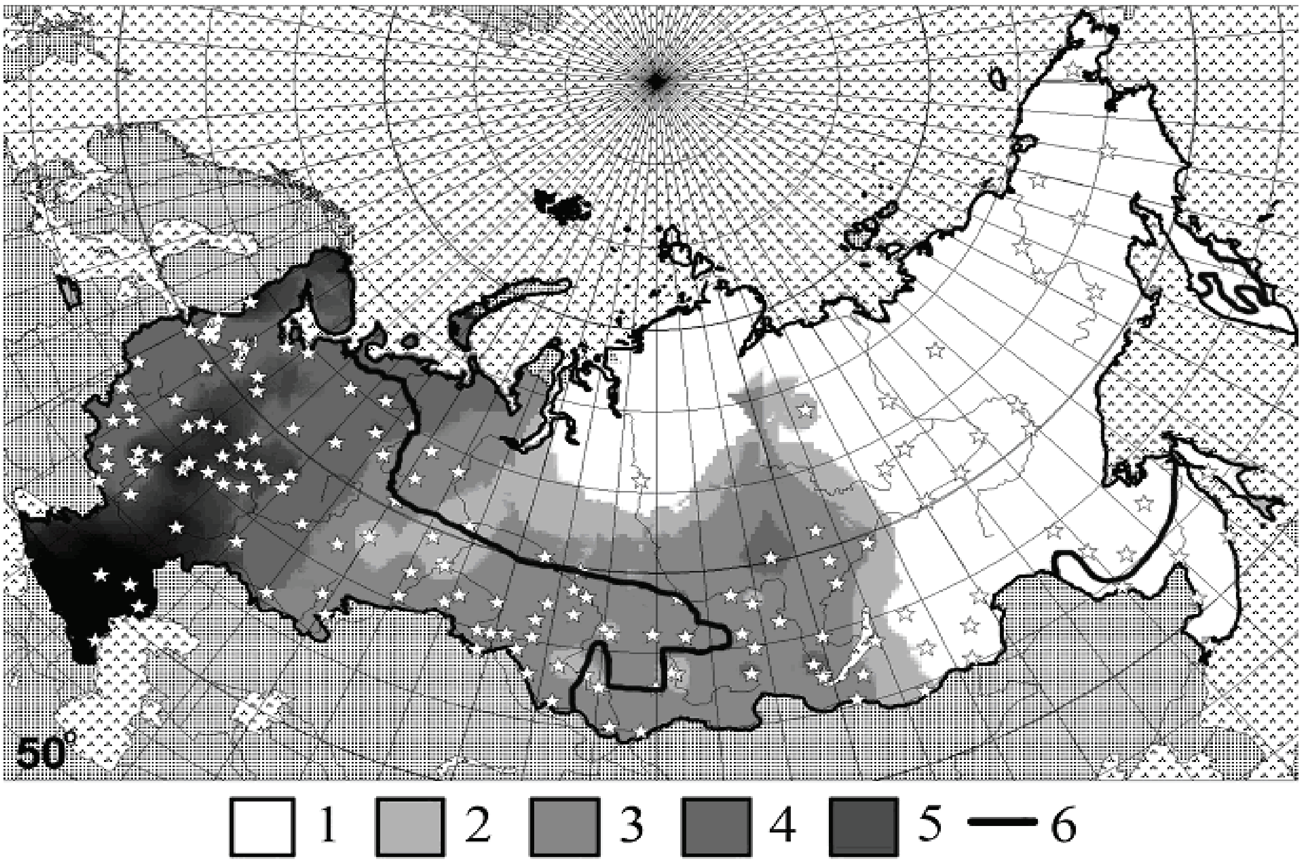

Figure 2. Correlation coefficient (R) between air temperatures and soil temperatures at the 160 cm depth in winter.
1 – $0.1 \le R < 0.2$, 2 – $0.2 \le R < 0.3$, 3 – $0.3 \le R < 0.4$, 4 – $0.4 \le R < 0.5$, 5 – $0.5 \le R < 0.6$, 6 – southern border of permafrost.

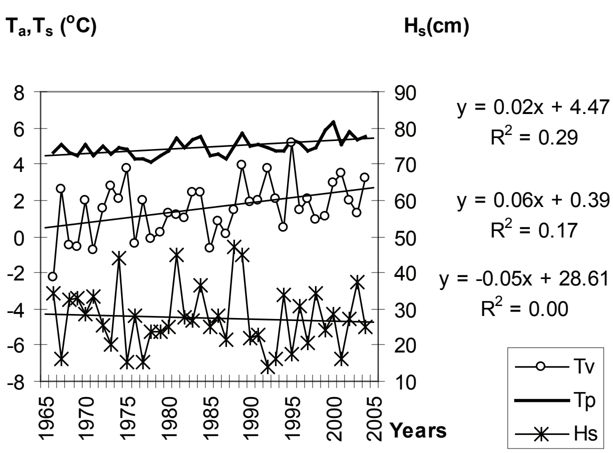

Figure 3. Long-term trends of mean annual air temperatures (T_a), soil temperatures at 160 cm depth (T_p), and snow depth (H_s) at Onega station (63.9°N, 38.1°E, Arkhangelsk district).

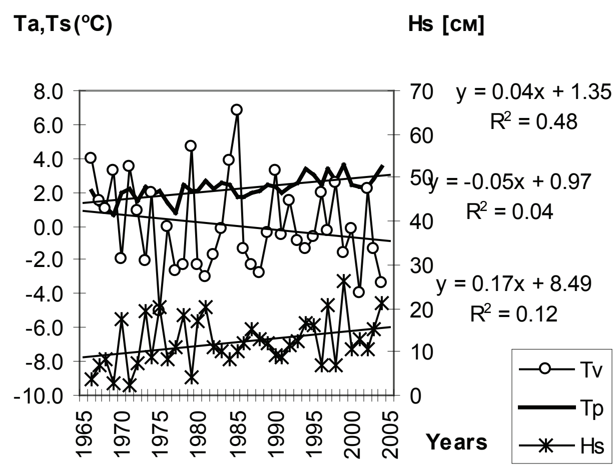

Figure 4. Long-term trends of mean annual air temperatures (T_a), soil temperatures at 160-cm depth (T_p) and snow depth (H_s) at Bokhan station (53°08′N, 103°46′E, elevation 446 m).

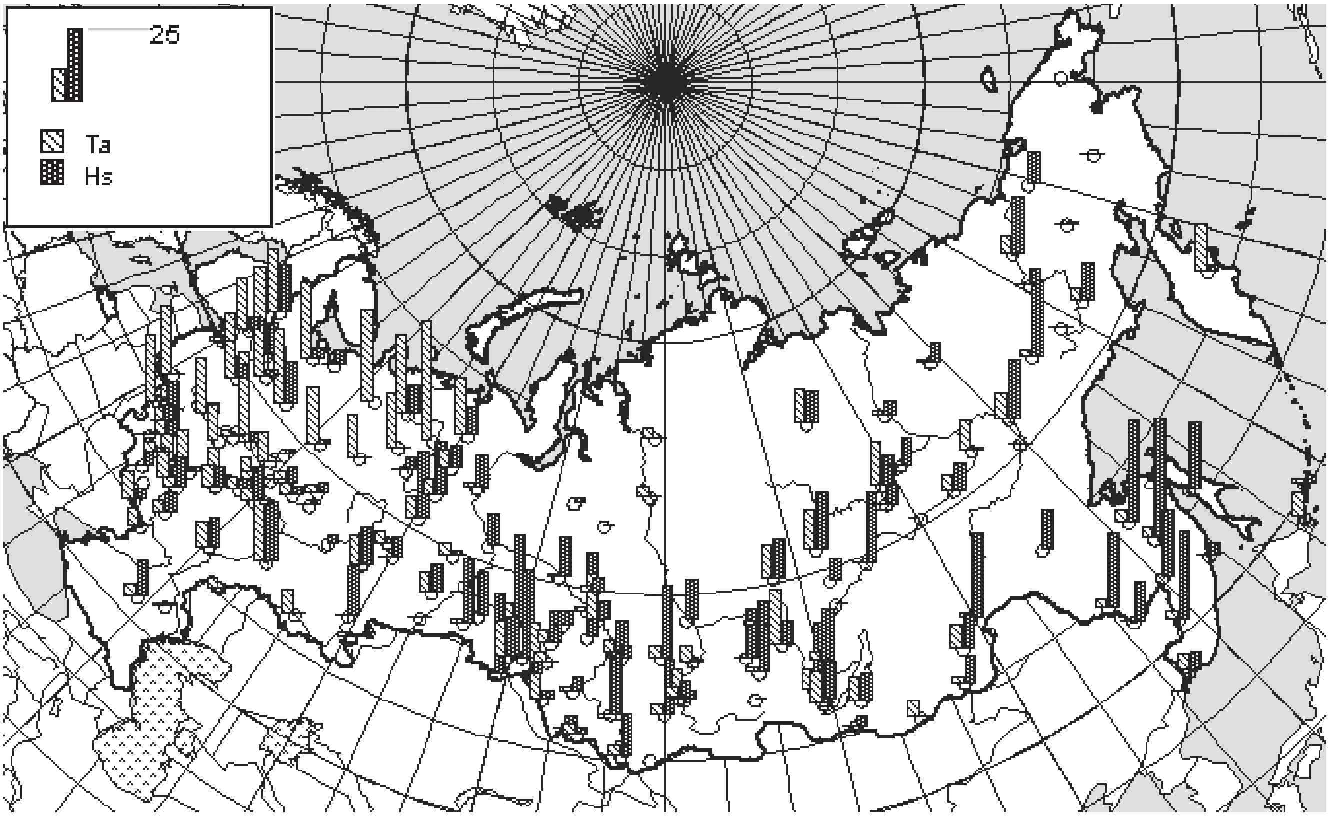

Figure 5. Contribution (in percent of variance) of mean annual air temperature (T_a) and snow depth (H_s) to long-term changes in mean annual soil temperature at 160 cm depth.

At the 320 cm depth, the effect of surface meteorological conditions is very weak and uneven over the Russian territory and is probably controlled by local micrometeorological and soil conditions. The increasing snow accumulation in Siberia results in an additional increase in mean annual soil temperatures and their relatively more rapid increase compared with the lower atmosphere. This fact is of particular importance in the permafrost zone since the increasing snow accumulation here strengthens one of the components likely to contribute to the permafrost degradation.warming.

The impact of long-term changes in air temperatures on soil temperatures in the central regions of the permafrost zone is weak both in summer and in winter. However, in regions with intermittent permafrost, the impact is substantial. The impact of snow depth on soil temperatures is observed throughout the entire permafrost zone of Russia.

Acknowledgments

This research was conducted with the support of the Russian Hydrometeorological Service (Roshydromet) and in the framework of the Northern Eurasia Earth Science Partnership Initiative (NEESPI).

Abstract

The Circumpolar Active Layer Monitoring (CALM) program, established in the early 1990s, was designed to observe temporal and spatial variability of the active layer and near-surface permafrost parameters, and their response to changes and variations in climatic conditions. CALM is the world's primary source of information about the active layer. Auxiliary information includes air temperature, soil moisture, soil temperature at different depths, snow cover, soil composition, and landscape characterization and frost heave and thaw subsidence. Metadata include detailed descriptions and photographs for each site. Several groups of sites have been used to create regional maps of active layer thickness. CALM data are distributed through the program's website (www.udel.edu/Geography/calm) and are also archived in and distributed through the Frozen Ground Data Center at the University of Colorado. This paper provides details about the nature, availability, and uses of data from the CALM network.

Keywords: active layer; data analysis; data archive; permafrost; polar regions; sampling design.

Introduction

The Circumpolar Active Layer Monitoring (CALM) program is a network of sites at which data about active layer thickness (ALT) and dynamics are collected. CALM was established in the 1990s to observe and detect the long-term response of the active layer and near-surface permafrost to changes in climate. CALM is among the international permafrost community's first large-scale efforts to construct a coordinated monitoring program capable of producing data sets suitable for evaluating the effects of climate change. Together with the IPA's Thermal State of Permafrost program, CALM comprises GTN-P, the Global Terrestrial Network for Permafrost. The CALM network's history and organizational structure are reported in Brown et al. (2000) and Nelson et al. (2004).

CALM is currently administered through the University of Delaware (UDel) Department of Geography. Analysis, archiving, and distribution of CALM's long-term observations are integral components of the project. Collected measurements are provided by participants to the CALM office at UDel, where they are subsequently incorporated into several databases. The data are distributed through the program's website, and through data products produced by the Frozen Ground Data Center at the University of Colorado. This paper provides details about the nature, availability, and uses of data from the CALM network. Scientific results are presented regularly at national and international meetings and have been published widely in international scientific journals and symposia proceedings. Several edited volumes focused on the CALM program have been published to date (Brown et al. 2000, Nelson ed. 2004a, 2004b). Several papers focused on CALM appear elsewhere in these proceedings.

Distribution of Sites

The distribution of CALM observational sites in the Northern Hemisphere is shown in Figure 1. The CALM network incorporates sites in arctic, subarctic, antarctic, and mountainous regions. Several sites constitute longitudinal and latitudinal transects across northwestern North America, Europe, and the Nordic region, and northeastern and northwestern Russia. Sites in Europe, China, Mongolia, and Kazakhstan provide high-elevation locations. About 70% of the sites are located in arctic and subarctic lowlands underlain by continuous permafrost. Discontinuous and mountainous permafrost areas contain respectively 20% and 11% of sites. The distribution of sites is not uniform, a circumstance attributable to historical circumstances and logistical constraints. The sites were established in regions of extensive economic activity and/or in areas of long-term climatic, permafrost, and ecosystem research. This logistically driven approach to site selection was adopted to insure regularity and periodicity of measurements. Assessment of the representativeness of the CALM network with respect to climatic and environmental conditions is currently in progress, and initial results were reported by Anisimov et al. (2007).

Monitoring Procedures

Three methods are used to determine the thickness of the active layer: (1) Mechanical probing using a graduated metal rod; (2) temperature measurements; (3) frost/thaw tubes.

The method-specific measurement procedure adopted by the CALM program is described in detail at the CALM web site (www.udel.edu/Geography/calm) and by Brown et

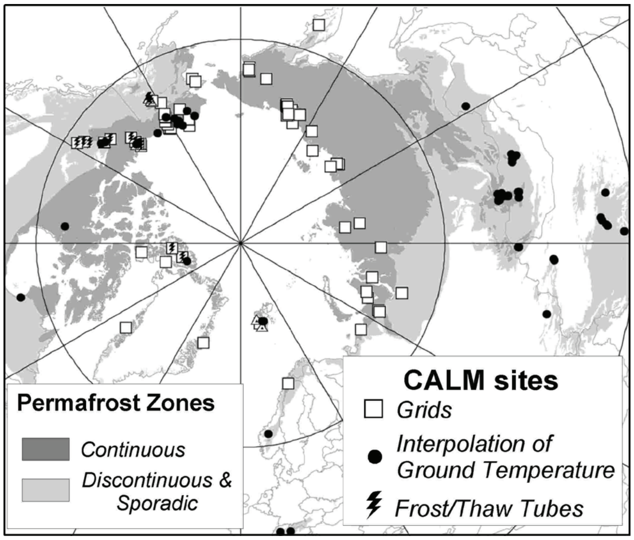

Figure 1. Permafrost distribution and location of CALM sites in the Northern Hemisphere. Sites are grouped according to active layer monitoring methods.

al. (2000). At 86 of the sites the active layer is measured by mechanical probing on regular grids of sampling points ranging from 10×10 m to 1000×1000 m. The time of probing varies from mid-August to the end of September; i.e., when thaw depth is at or near the maximum. More frequent measurements are made at some sites and in some years. The gridded sampling design allows for analysis of intra- and inter-site spatial variability and yields information useful for examining interrelations between physical and biological parameters. Grids are established at undisturbed locations characteristic of dominant environmental conditions. Their size varies depending on site geometry and the level of natural variability of surface and subsurface conditions. In general, 10×10 m to 100×100m size grids are established within relatively homogeneous landscape units. Several sites contain a number of grids representing various landscape units within the area. The 100×100 m to 1000× 1000 m grids usually encompass several characteristic landscapes within the area. CALM adopts a systematic sampling scheme for thaw depth measurements on most grids. The effectiveness of this sampling strategy has been investigated extensively and compared with alternative designs (Nelson et al. 1999). The systematic sampling design involves annual replicate measurement at regularly spaced grid nodes. With a few exceptions, each 10, 100, and 1000 m side grid contains 121 nodes distributed evenly at 1, 10, and 100 m spacing respectively. At some grid nodes thaw depth measurements are not possible due to deep water, roads, or gravel pads. These missing data points are not reported.

At 87 of the sites active layer thickness is determined exclusively by interpretation of ground temperature measurements, obtained by an array of thermistors distributed vertically from the ground surface downward into the permafrost (Romanovsky & Osterkamp 1997, Romanovsky et al. 2003). This method is primarily used in mountain regions and areas with deep (>1.5 m) annual thaw propagation, where spatially oriented measurements by probing are impossible. The depth and spacing of thermistor installation depends on local conditions and the needs of individual research projects.

Liquid- or sand-filled thaw tubes (Nixon & Taylor 1998, Nixon 2000) are employed in 11 Canadian and 3 Alaskan sites. When read periodically, frost tubes provide information about seasonal progression of thaw and maximum seasonal thaw. However, as with temperature measurements, thaw tubes do not provide the information on local variability. Individual thaw tube measurements are highly dependent on location of installation. To address this deficiency, thaw tube measurements are complemented by grid sampling of the active layer.

Data Availability

One of CALM's primary objectives is to develop coherent, quality-controlled datasets of long-term observations on the active layer and upper permafrost, suitable for assessing changes in polar terrestrial ecosystems. At present, the CALM database consists of annual submissions from 168 sites, and includes ALT, soil temperature and moisture (where available), and heave/subsidence data (where available). The majority of available data are distributed through the CALM website maintained by the University of Delaware's Department of Geography. (www.udel.edu/Geography/calm). The web-based summary table contains average ALT at all stations for all years and is linked to metadata and individual data sets. The following subsections provide a brief inventory of available data for specific geographic regions.

Alaska

At 30 out of 41 CALM-designated sites in Alaska periodic active layer observations are conducted on regular grids ranging from 10 m to 1000 m on a side. Geographically, grids are arranged in three north-south transects: (1) Fairbanks to the Beaufort Sea, along the Trans-Alaska Pipeline; (2) Ivotuk to Barrow (Chukchi Sea), and (3) Council and Kougarok, across the Seward Peninsula. These latitudinal transects, positioned from the Bering Sea eastward, encompass areas of steadily increasing continentality from west to east. For 25 of the grids, 10 or more years of consecutive active layer data are available. These include seven sites with 1 km^2 grids (Hinkel & Nelson 2003, Streletskiy et al. 2008), 15 1 ha grids, and three transects with thaw tubes. Two 1 km^2 grids in the Seward Peninsula (Council and Kougarok) and one near Ivotuk have data records dating to 1999. The 1 ha grid at Farmers Loop north of Fairbanks was added to the network in 2005. Pre-1990 data are available for a series of 20 10×10 m Cold Region Research and Engineering Laboratory (CRREL) plots near Barrow (1962–1970, and 1991–2007) and two sites in interior Alaska (Perl Creek, 1969–2007, and Wickersham Dome, 1975–2007).

All grids have data loggers for monitoring air and soil temperatures at various depths. Several sites have installations for continuous monitoring of soil moisture. Detailed spatial characterization of topography and surface and subsurface conditions are available for each spatially heterogeneous 1 km^2 grid. These include DEMs, vegetation, soil, and landform characterization, and organic layer thickness. Annual spatial snow surveys have been conducted at the Barrow 1 km^2 grid, beginning in 1995. In 2000, spatially oriented monitoring of frost heave and thaw subsidence using the Differential Global Positioning System (DGPS) was initiated at three sites representing broad landscape units characteristic of the North Slope of Alaska (Little et al. 2003).

An additional eleven U.S. Geological Survey sites have been established near deep boreholes. At these sites active layer thickness is determined by interpolation of ground temperature measurements. Data from these sites are currently being processed.

Canada

Of the 21 active CALM-designated sites in Canada, 15 are located along the latitudinal transect situated in the Mackenzie River Valley and operated by federal government agencies: Geological Survey of Canada (Nixon et al. 2003) and Agriculture and Agri-Food Canada (Tarnocai 1995, Tarnocai et al. 2004). Several additional long-term, active layer monitoring programs include CALM sites on the Arctic Islands (four sites), and two sites in the Hudson Bay region (Allard et al. 1995, Smith et al. 2001). The spatial active layer observations on grids are conducted at twelve 1 ha and one 1 km^2 grids. The most comprehensive data sets are available for eight 1 ha grids in the Mackenzie River Valley. The data include 10 or more years of active layer observations on grids and thaw tubes, spatial characterization of subsurface conditions (organic layer thickness, organic composition, mineral strata), and several annual snow surveys.

Nordic region

The seven Nordic CALM sites are located in several areas surrounding the North Atlantic: two 1 ha grids in northeast Greenland at Zackenberg; one 1 ha grid in west Greenland on Disko Island (Christiansen 2004); 1 ha grid on the west coast of Svalbard at Kapp Linne (Akerman 1980); four transects constitute two sites at Calypostranda, Svalbard (Repelewska-Pekalowa & Pekalowa 2004); and an alpine-subarctic 1 ha grid in the vicinity of Abisko, northern Sweden. With the exception of Disko and one of the Calypostranda sites, the active layer record for the Nordic region grids is available for 10 or more years. The record for the Abisko site extends back to 1972 and includes thickness of active layer in different landscapes, mean monthly air temperature, and degree days of thawing. The Zackenberg database includes weekly active layer observations for the 1996–2006 thawing periods and snow thickness surveys for selected years.

Russia

Of the 41 CALM sites in Russia, 31 have continuous periodic active layer monitoring. The remaining 10 were either discontinued or are visited only sporadically. All Russian sites have grids ranging from 100 m^2 to 1 km^2. Several sites have supplemental transects that pre-date the establishment of CALM. The Russian CALM network extends from the European tundra of the Pechora and Vorkuta regions to West Siberia and the Lena Delta, eastward to the lower Kolyma River, and to Chukotka and Kamchatka. Most of these sites are within the continuous permafrost zone.

European North: Three 1 ha grids are located in the discontinuous permafrost region of the European tundra: Ayach-Yakha and Talnik near Vorkuta, and Bolvansky in the Pechora lowlands (Mazhitova et al. 2004). Each site has 7 to 11 years of continuous active layer record. The auxiliary data include detailed soil and vegetation characterization, soil temperature, and soil moisture records. Since 1999 periodic, spatially oriented frost heave and ground subsidence measurements using optical leveling are conducted at the Ayach-Yakha site.

West Siberia: Eight active CALM sites are located in West Siberia. The core of the data sets consists of observations from two 1 ha grids at Mare Sale and Vaskiny Dachi in the continuous permafrost zone and 1km^2 Nadym grid in the discontinuous zone (Vasiliev et al. 2008). The active layer observations for Mare Sale are available since 1978 and for Nadym since 1972. The active layer record at the Vaskiny Dachi site dates to 1991. Pre-CALM (1993) observations were performed at the environmentally homogeneous 10 × 10 m plots, and along several transects incorporating the dominant landscape units. Each site has continuous soil temperature records of variable length and detailed spatial landscape, soil, and vegetation characterizations. An additional 1 ha site was established in the continuous permafrost zone in 2005 (Zepalov et al. 2008). During the summer of 2007 four grids were established in the discontinuous permafrost zone in landscapes inadequately represented by the Nadym grid. At present these sites are in the process of being characterized and instrumented.

Central Siberia: In association with the GEWEX Asian Monsoon Experiment (GAME) program in the Siberian Arctic, a 1 km^2 CALM grid was established in 1997 near Tiksi, on the Lena River (Watanabe et al. 2003). The site-specific data base is available in the GAME Siberia website (http://www.hyarc.nagoya-u.ac.jp/game/siberia/index.html). Thaw depth measurements are also available for two 1 ha grids representing different landscapes of the Lena delta since 2004.

Lower Kolyma River: Beginning in 1996, a series of fifteen 1 ha grids spanning a distance of approximately 300 km was established to represent characteristic climatic and environmental conditions in the Kolyma-Indigirka lowlands on the northeast Eurasian tundra (Fyodorov-Davydov et al. 2004). At present, 11 sites are reporting data. Annual active layer and soil temperature observations are carried out at the five most accessible sites situated in close proximity to the North-East Scientific Station in Cherskyi in the transitional zone between taiga and tundra. Logistical problems led to some interruptions in observations at the remaining six sites. All sites have detailed descriptions of surface and subsurface conditions.

Chukotka and Kamchatka Peninsulas: Beginning in 1996, a Mt. Dionisy site was established on the Chukotka Peninsula. A new site was initiated at Lavrentia along the Chukchi Sea coast in 2000 (Zamalodchikov et al. 2004). Both sites consist of 1 ha grids. Annual soil moisture observations and detailed soil characterizations are available for the Lavrentia site. Active layer records are also available for two 1 ha grids on Kamchatka since 2003.

Mongolia

The Mongolian network consists of a series of instrumented boreholes located in the arid land permafrost at the southern fringe of the Siberian permafrost zones. An original network of 12 sites (Sharkuu 2003) was expanded to 37 sites during the last 2–5 years. The majority of the new sites are located in the Hovsgol region. Seventeen boreholes were drilled with depths ranging from 5 to 80 m, and two deep boreholes from the mid-1980s were instrumented for permafrost and active layer monitoring. An additional eight sites were instrumented for shallow ground temperature monitoring (Sharkhuu et. al. 2007). All sites report ground temperature and active layer thickness determined by interpolation of ground temperature profiles obtained in late September and early October.

Mountain permafrost regions

Permafrost occurs in all mountainous regions of the high latitudes and is widespread at higher elevations in mid latitude mountain ranges including the Qinghai-Tibet Plateau. The mountain permafrost is represented in the CALM data base by one site in Norway, one site in Svalbard (Isaksen et al. 2007), two sites in Switzerland (Harris et al. 2001), two sites in Kazakhstan (Marchenko et al. 2007), and six sites on the Qinghai-Tibet Plateau, China (King et al. 2006). All sites consist of boreholes of variable depth. With the exception of Kazakhstan sites, only interpolated active layer values are reported annually.

Southern Hemisphere

The Antarctic Permafrost and Soils (ANTPAS) program (Parsons et al. 2008) incorporates several sites known collectively as CALM-South (CALM-S). Periodic ground temperature monitoring at depths to 2.4 m is conducted at three sites in South Victoria Land, Antarctica and at two others on Livingston Island/South Shetland Islands (Hauck et al. 2007). Data are reported as interpolated maximum annual thaw depth. Detailed site descriptions are available at the ANTPAS website (http://erth.waikato.ac.nz/antpas/). Plans to expand ANTPAS /CALM-S by developing 12 to 15 sites distributed across environmental gradients from the Andes to the subantarctic islands and through the Antarctic Peninsula and Transantarctic Mountains to the McMurdo Dry Valleys are currently under development (Bockheim 2005).

Regional Active Layer Characterization

Several regions with large assemblages of sites and representative of high-latitude climatic/landscape gradients are suitable for spatial data integration. Examples are the North West Siberia region (Yamal-Gydan Peninsulas), the Lower Kolyma River, northcentral Alaska, and the Mackenzie River region (Canada). Each of these regions has been the subject of extensive geocryological research and contains information sufficient to facilitate regional-scale mapping.

At present the CALM database contains two regional (broad-scale) active layer maps compiled from data sampled from multiple sites. The first is a 14-year series of maps (1 km^2 resolution) depicting annual active layer thickness and the probability of the active layer exceeding certain thresholds for the 27,000 km^2 Kuparuk Region in northcentral Alaska (Shiklomanov & Nelson 2002, Anisimov et al. 2002). The second regional compilation is a detailed digital landscape and active layer map of northern West Siberia. The map was compiled in cooperation with the Earth Cryosphere Institute (Russia) and depicts a hierarchy of landscapes units, organic layer thickness, lithology, and the landscape-specific characteristic values of active layer thickness. At present the map is being refined and extended.

Several other regional maps are under construction, including an active layer map for the Kolyma-Indigirka lowlands of Russia, a map of the North Atlantic region, and a map of the Barrow Peninsula on Alaska's North Slope.

Data Use for Models

Active layer observations and auxiliary information from the CALM network provide an extensive circumpolar database which has been used extensively to validate process-based geocryological (e.g., Oelke & Zhang 2003, Shiklomanov et al. 2007) and hydrological (Rawlins et al. 2003) models. Obviously, data obtained from individual observational CALM sites should be used with caution for evaluating model-produced gridded fields, owing to possible discrepancies between the size of observation plots and those of model grid cells. It is well known that active layer thickness and other near-surface permafrost parameters can be highly variable in time and space (e.g., Nelson et al. 1998, Shiklomanov & Nelson 2002). Observational locations may not represent generalized conditions prescribed for the model's grid cells. The use of individual CALM grids or groups of grids representing the diversity of environmental conditions in particular regions can compensate somewhat for such deficiencies. The development/implementation of regional scaling approaches addresses the problem of discordance in resolution between empirical and simulation studies further, and facilitates development of procedures for assimilating geocryological data and modeling results. Shiklomanov et al. (2007) provided an example of a hierarchical approach for evaluating spatial permafrost models. The methodology incorporates empirical data from point locations and observational plots provided through the CALM observational networks, provides regional characterization of permafrost conditions, and can be extended with continental- and circumpolar-scale models.

Conclusions

CALM is the oldest and most comprehensive permafrost-oriented international global-change monitoring program, and has achieved considerable success in this role. Although the CALM network continues to grow in terms of the number of participating sites and the quantity and quality of observations, two outstanding data issues remain to be resolved: (1) Continuation of periodic measurements; this problem relates to difficulties associated with unattended operation of scientific equipment at remote locations and periodic accessibility of sites. For example, approximately one-fourth of Russian sites were discontinued during the last five years due to substantial increases in logistical costs. A large number of sites have suffered from equipment malfunction and vandalism; (2) The methodology of simple sharing of basic data, adopted by CALM in the late 1990s, does not entirely satisfy the growing needs of the increasingly international and interdisciplinary scientific community and general public. Newly developed web-based database and mapping applications provide more advanced, user-friendly vehicles for presenting and sharing geographically referenced information. The first step toward enhancing CALM's archival and dissemination strategies will be to prepare data for the upcoming Circumpolar Active layer Permafrost System (CAPS) Version 3 database compilation developed by the Frozen Ground Data Center and Standing Committee for Data Information and Communication within the IPA (Parsons et al. 2008).

Acknowledgments

The components of the CALM program operating in Alaska, Russia, Mongolia, and Kazakhstan have been supported though the U.S. National Science Foundation's Office of Polar Programs under grants OPP-9732051 to the University of Cincinnati and OPP-0352958 to the University of Delaware. Opinions, findings, conclusions, and recommendations expressed in this paper are those of the authors and other CALM investigators and do not necessarily reflect the views of the National Science Foundation. Transitional (one year) support between USA/NSF grants was provided by the University of Delaware's Center for International Studies. Financial support for CALM activities in other locations has been provided by governmental agencies in the countries of the various CALM investigators. CALM is a collaborative global-change monitoring program and could not exist without good will, generosity, and a spirit of cooperation from scientists from many nations and scientific disciplines.

Abstract

Developing an understanding of permafrost evolution in relation to observed climatic warming requires evaluation of changes in the thermal state of near-surface layers. This paper is based on the results of 25 years of geothermal monitoring at 60 sites. The study is focused on the upper permafrost within the depth of annual temperature variation (10–15 m). The integrated research program involves landscape, microclimatic, thermophysical, and hydrothermal methods. Systematization and mapping generalization of permafrost landscapes have been made with indication of the complexity of geocryological conditions. During the last 30 years, the study area has experienced the highest increasing trend in mean annual air temperature in northern Russia. A database has been compiled that includes parameters needed for geocryological predictions. Proposals for cooperation in implementing IPY projects and establishing a single observational network for geocryological monitoring in cold regions of Russia are presented. Experimental research made it possible to quantitatively evaluate the interannual and perennial variability of the active layer thickness and thermal state of the ground within the depth of annual temperature variations.

Keywords: climate; monitoring; permafrost landscapes; temperature regime.

Introduction

Research on the impact of climate warming on permafrost involves a wide variety of issues, including the thermal evolution of upper permafrost. The ground thermal regime is controlled by energy exchange between the ground and atmosphere and is characterized by spatial and temporal variability. Anthropogenic impacts of varying type and magnitude (clear-cutting, fires, removal of surface vegetation and organic mat, etc.) disturb the natural ground thermal state, trigger adverse cryogenic processes and change the ecology of environmental complexes.

In recent years, the development of research on predicted climate warming in many countries has led to an increasing interest in the response of permafrost to projected warming. It may be said without exaggeration that this problem has become one of the most important issues in geocryological research, both in scientific and practical terms.

Most of the research on this problem has been conducted in northern regions of Russia, Canada, Alaska, and Europe (Pavlov 1994, Varlamov et al. 1990, Burgess & Lawrence 1997, Osterkamp et al. 1994, Harris et al. 2000).

Central Yakutia is a region characterized by complicated geocryological conditions, such as continuous permafrost and the presence of water-bearing taliks and polygonal wedge ice. Continuous monitoring of the thermal regime of the ground, which has been implemented by the authors since 1981, illustrates the dynamics of its thermal state in natural and disturbed landscapes. The research project statement and the results of the first stages of its implementation were set out in the authors' early publications (Skryabin et al. 1998, 2001, Varlamov et al. 2002). This report presents a summary of the results obtained during the entire period of observations.

Objectives and Methods of Research

Investigations are conducted on the west and east sides of the Lena River at the latitude of Yakutsk which are characterized by complicated permafrost conditions. Evaluation of changes in thermal state of near-surface layers of permafrost within the frameworks of climatic warming and man-caused impacts (fires, deforestation, embankment), was effected based on integrated data, acquired from regular observations in Chabyda and Yakutsk stations, sites in Tuymaada Valley, and in the northern section of the prospective Tommot-Yakutsk railroad (Fig. 1).

The basis for this research is the variation in temperatures for shallow soils (upper 10–15 m). The main thermal parameters which can indicate an evolution of near-surface layers of permafrost are: seasonally thawed layer thickness (X) and mean annual temperature at corresponding depth (T_x) and at the depth of zero annual amplitude (T_o). It is known that interannual changes in these parameters depend on peculiarities of climatic features (air and surface temperature, precipitation amount, snow depth and density) and terrain conditions (vegetation and ground cover, soils composition, ground water, etc.). The research area shows X variations from 0.5 to 4 meters, and T_0 variations from 0.5 to -6.0°C, depending on terrain conditions.

Experimental observations of varied duration have been carried out since 1981 at 200 localities covering 6 physiographic regions, 9 landscape types, and more than 100 stows. The research involves a variety of integrated

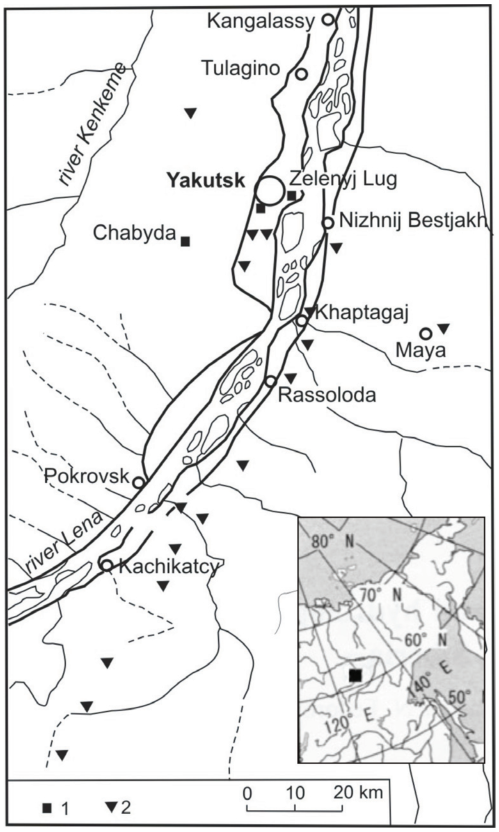

Figure 1. Map of the study area: 1 – stations, 2 – monitoring sites.

techniques and tools used in studying landscape, climate, thermal physics, as well as hydrothermal studies. The project implementation included remote and ground-based sensing of the landscapes, their classification, and mapping summary. The following terrain types were identified in the area covered: flood plain, low-terrace, sand ridge, inter-ridge depression, alas, inter-alas, small valley, upland, and slope.

Long-term records from the nearest weather stations are employed during the study. Snow surveys are carried out in representative permafrost landscapes. The texture and properties of the active layer were determined in test pits. Information on the composition and structure of permafrost soils was obtained from boreholes. Active layer depths are determined by pit measurements, probing with a steel rod, and from soil temperature profiles. To measure temperatures at the snow surface, at the surface and base of the surface vegetation, and in the ground, thermistor and thermocouple sets and cables were used. After installing the cables, the holes were backfilled. Ground temperatures were taken with an accuracy of ± 0.1°C.

Investigations at the Chabyda station included measurements of climatic parameters (air temperature, wind speed, precipitation, evaporation, and snow depth and density) and ground hydrothermal parameters (snow and ground surface temperatures, ground temperature, heat flows, thermal properties of surface covers and ground, and freeze-thaw depths). During the intensive observation period, measurements were made 7 times daily in the warm seasons of 1981 and 1982 and 4 times a day in the cold season of 1982–1983. In the following years, observations were taken once every pentad at 4 standard times and then 1 to 3 times monthly. Since November 1987, measurement frequencies have been reduced at the Chabyda, Yakutsk, and Tyumaada stations, and measurements are now taken on the 15th day of each month. On the east side of the Lena River, observations are made once or twice in the warm and cold seasons. The total number of monitoring locations on the east side of the Lena River is 60.

Results

Central Yakutia is among the areas in Russia that have experienced the highest increasing trends in mean annual air temperature over the last 30 years (up to 0.07°C/yr). Warming of the climate, which was slight in the 1960–1970s became significant in the 1980s. The last decade (1998–2007) has been the warmest in the instrumental record for the region. At Yakutsk, mean annual air temperature increased at a rate of 0.06°C/yr between 1982 and 2007. Mean annual air temperatures were below the normal of -10°C (USSR Hydrometeorological Service 1989) only in four of the last 25 years. All other years were consistently warmer (Fig. 2a).

The rise of the mean annual air temperature is primarily associated with the increasing number of anomalously warm winters which in turn is due to changes in atmospheric circulation. In the period 1982–2007, there were 19 winters with a freezing index higher than the long-term mean. The increase of summer air temperatures was less significant.

In this study, anomalous climatic seasons are defined as those with the average values of climate elements ($\Sigma(-T_{air})$, $\Sigma(+T_{air})$ and h_c^{max}) beyond the average standard deviation σ. If the value is within σ, but it is larger than ½ σ, the season is referred to as warm or cold, and low-snow or snowy. By average winter air temperature, there were 6 normal, 2 warm, 16 anomalously warm winters, and only 1 anomalously cold winter during the observation period. By snow depth, there were 11 normal, 5 anomalously snowy, 4 snowy, 3 low-snow, and 2 anomalously snowy winters.

Variations in X, T_x, and T_o have been studied over 25 years in the Chabyda station, west of the Lena River, where experimental sites were set on the bottom of a small valley (3a, 8a, and borehole 1), gentle slope (5), interfluve (7b), bottom of a drainage depression (8), watershed area (9), moderate north-facing slope (10), and moderate south-facing slope (11).

Active layer depth depends on weather conditions, vegetation, surface cover, soil type, and soil moisture. Interannual variability of active layer thickness is thought to be primarily controlled by the air thawing index and summer precipitation. However, investigations in northern Russia have found no clear correlation between the long-term variations in thaw depth and the air thawing index (Pavlov et al. 2004). Ground conditions, especially soil moisture variations, appear to have significant effects on thaw depth. Data from the Chabyda station indicate that the most

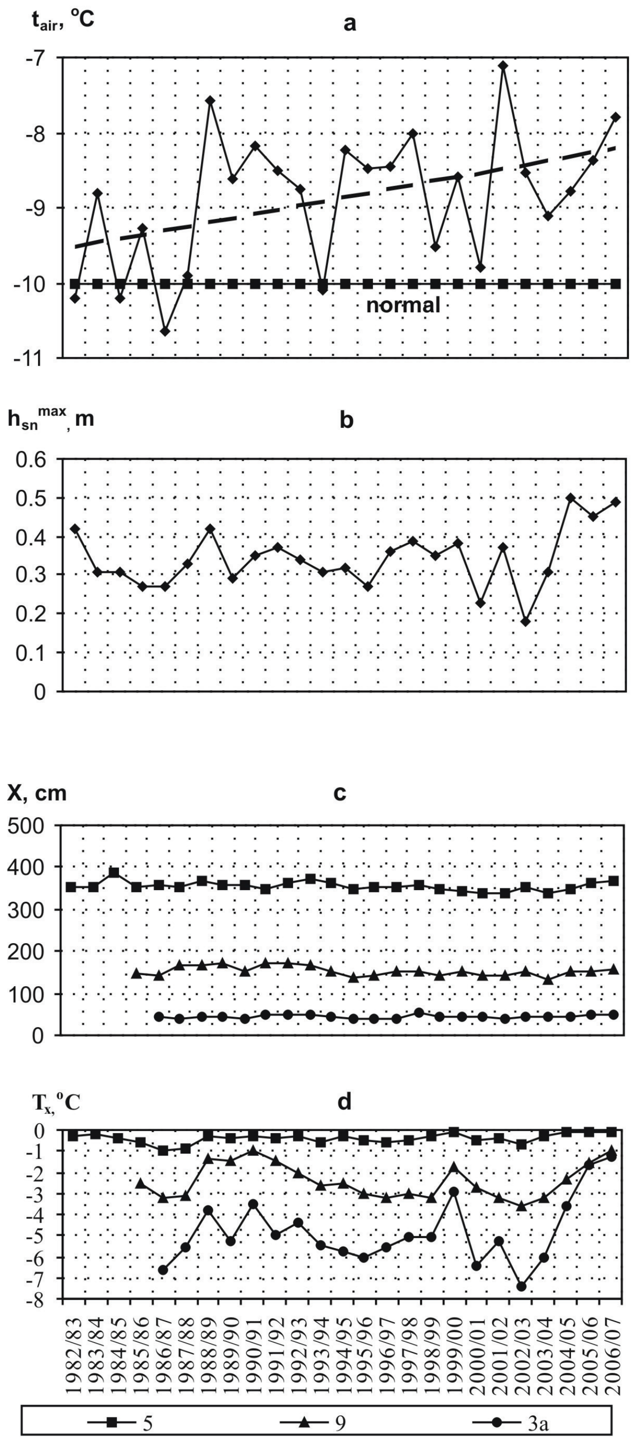

Figure 2. Long-term variations of mean annual air temperature at Yakutsk (a), maximum snow cover depth (b), active layer thickness (c), and mean annual ground temperature (d) in the small valley (3a – bottom of stream valley) and slope (5 – gentle slope, 9 – watershed area) terrain types at the Chabyda station.

significant interannual variations in X (up to 73 cm) occur in small valleys with organic soils. Slope sites on sandy soils show thaw depth variations of 30 to 58 cm. No statistically significant increasing trend in thaw depth has been observed for any of the sites. To the contrary, three sites (5, 6b, and 9) in the slope terrain type show a decreasing trend. The three longest series are given in Figure 2c to illustrate the interannual variations in active layer depth.

Table 1. Variations in mean annual ground temperature (T_x) and its trends in 1986-2007 at the Chabyda station.

Experimen. sites	Soil texture	Mean °C	Max °C	Min °C	Trend T_x, °C/10 yr
Slope terrain type

8	Sand	-3.7	-1.3	-5.5	0.45
8a	Peat, sand	-3.6	-0.1	-6.5	0.65

Depending on terrain and soil conditions, ground temperature is controlled by the same factors as is X. The interannual variation of ground temperature is predominantly related to winter weather factors, such as the air freezing index and snow cover. Table 1 illustrates the complete set of variations in T_x for the warmest and coldest terrain types.

Ground temperature is a better indicator of the long-term changes in the thermal state of near-surface permafrost compared to active layer thickness. The temperature variation was largest in the small-valley areas, as was the thaw depth fluctuation (Fig. 2d). This variation was mainly due to the effect of two winter factors: snow cover conditions and air freezing index. In the continental climate of central Yakutia the first factor appears to be more important. The lowest mean annual permafrost surface temperatures were observed in the winter of 2002–2003 which had an anomalously thin snow cover (see Fig. 2d). In subsequent snowy years (2004–2007) which had the largest snow depths in the last 25 years (0.45 to 0.50 m), the ground temperatures were warmest. Variation in T_x due to anomalous winter conditions can be as high as 1.2–3.5°C. One warm, low-snow winter will cool ground temperatures more than a cold, snowy winter. The effect of one anomalously cold winter will be stronger than that of a few successive anomalously warm winters. However, statistically significant trends in mean annual ground temperature have been observed only for four sites. A positive trend in T_x of 0.2°C per decade was found at site 5, and a negative trend of 0.1°C per decade at site 9. At a depth of 10 m, warming of 0.2°C per decade occurred at site 7b and cooling of 0.1°C per decade at site 9 and 0.1°C per decade at site 11.

On the east side of the Lena River, monitoring of the ground temperature regime has been conducted in 8 terrain types during the last 20 years. The observations have identified the landscapes that are most sensitive to changes of climatic factors. The terrain units have been classified into three sensitivity categories, high, moderate and low, in the following order: small valley → inter-alas, inter-ridge depression, floodplain, slope → low terrace, sand ridge, alas, interfluve. Respective ranges of interannual T_o variations for these categories are 1.0–2.3°C; 0.2–1.2°C and 0.1–0.9°C.

Observational data from 1987 to 2006 show that the trend of mean annual temperatures at the depth of zero annual amplitude varies from negative to positive in different terrain types (Table 2). Negative trends are detected in low terrace, sand ridge, and inter-ridge depression terrain types (up to -0.02°C/yr), while positive trends occur in floodplain and small valley terrain (0.02–0.04°C/yr). Monitoring observations suggest that there is no uniform pattern in t_o variation, and lowering of ground temperature in some landscape units indicates their stability. In the Yakutsk area, snow depth, especially in the early winter, had been decreasing over 20 years until 2004, with a corresponding decrease in its warming effect. This factor, although not alone, has probably been decisive for the ground temperature evolution in the last 20 years. However, during the last three winters of 2005–2007, which had anomalously deep snow and warm air temperatures, there was a notable increase in ground temperature. For northern Alaska, Romanovsky et al. (2003) report increasing trends in air temperature and active layer thickness over the period of 1987 to 2001. Mean annual ground temperatures at several sites increased by 1–2°C over the 15-year period.

Experimental investigations were carried out in order to quantitatively evaluate the anthropogenic impact (ground cover disturbance and stripping, deforestation, fires, etc.) on the thermal regime of the ground in 40 stows within five terrain types.

At an alas site, snow and dwarf-birch/sedge tussock covers were removed in March 1989. This disturbance increased the active layer thickness by 0.4 m and the ground temperature at 10 m depth by 0.4°C (Br. 68 and 186 compared to the undisturbed site. Seven years later, the depth of seasonal thaw was 0.5 m deeper, and T_x was 2.7°C warmer than at the undisturbed site. At an inter-ridge depression site, a moss-lichen layer was stripped in July 1990. The mean annual ground temperature increased by 0.8°C in the second year and by 1.8°C in the third year after disturbance. The depth of seasonal thaw increased by 0.5 by the end of the first summer and by about 1 m, or 2.8 times, by the end of the second summer (Br. 205). At inter-alas sites supporting larch stands, the removal of a *Vaccinium vitis-idea*/moss cover resulted in an increase in upper permafrost temperature of 1 to 0.2°C. Thaw depths increased by less than 0.5 m (Br. 1601). Similar observations conducted from 1984 to 2000 along the Norman Wells oil pipeline in northern Canada indicate that thaw depths increased most rapidly in the first 7 years after disturbance and continued to increase slowly thereafter, reaching depths of 3 to 5 m in fine-grained and organic units and 5 to 7 m in coarse mineral soils (Burgess & Smith, 2003).

Table 2. Variations in mean annual ground temperature (T_0) and its trends in 1987–2006 in landscapes at the right-bank area of the Lena River.

Terrain type	Soil texture	Mean, °C	Max °C	Min °C	Trend T_0, °C/10 yr
Floodplain	Sand, sandy silt	-1.6	-0.8	-2.3	0.2
Low-terrace	Sand, sandy silt	-1.2	-0.1	-2.4	-0.2
Slope	Sand, sandy silt	-1.4	-0.3	-2.4	~0.0
Small valley	Peat, sandy silt	-5.2	-3.6	-6.9	0.4
Sand ridge	Sand	-0.9	0.7	-2.5	0.0…-0.2
Inter-ridge depression	Peat, sand	-2.4	-0.6	-4.1	-0.1…-0.2
Inter-alas	Sandy silt, Clayey silt	-1.4	-0.7	-2.2	~0.0
Alas	Peat, clayey silt	-0.4	-0.1	-0.8	~0.0

In sand-ridge terrain, clear-cutting of pine stands increased thaw depths by 1.8 m and ground temperatures by 1.0°C. In inter-alas terrain, clear-cutting of larch trees resulted in 1°C warming of ground temperatures after 3 years (Br. 12/93).

Removal of pine trees and lichen cover in warm soils (T_o= -0.1…-0.3°C) of well-drained sand ridges resulted in a dry talik (Br. 1324). Clearing of a pine/lichen/ *Arctostaphylos* stand in low-terrace terrain type caused an increase in T_o by 0.3°C and in X by 1 m (Br. 177).

At a sand-ridge site in pine forest burned by a fire in 1987, ground temperatures increased by 0.7–1.5°C during the first two years. From the fourth year after the fire, ground temperatures on the burn began to stabilize with vegetation regrowth. (Br. 13). In low-terrace terrain, the larch stand burned by a fire in 1986 was removed (Br. 166). A considerable increase in T_o, by 0.3–0.5°C, occurred in the first 5 years after the fire. The recovery of vegetation in 6-8 years stabilized the ground thermal state. In an inter-ridge depression, selective tree cutting, surface cover disturbance in 1988, and fire in 1993 (Br. 30) increased T_o by 0.3–1.0°C over 9 years. Gradual cutting of a burned larch stand in inter-alas terrain type resulted in a 1–1.5°C increase in T_o and a 0.7 m increase in thaw depth during 15 years (Br. 56). Selective tree cutting with surface cover disturbance after a 1986 fire in inter-alas terrain (Br. 209) resulted in warming of T_o in the first years. Vegetation recovery lowered ground temperatures (Fig. 3). The T_o difference over the 18-year period was 1.3°C.

Maximum impact on the thermal state of ground results from ground cover stripping and post-fire deforestation in inter-alas type terrain. In inter-alas where wedge ice occurs close to surface, a more intensive thermokarst activity is indicated. The dynamics of the ground thermal state at sites of anthropogenic activity demonstrate dependence on types of impact, their duration, and stages of revegetation during post-anthropogenic period. On the whole, the ground thermal

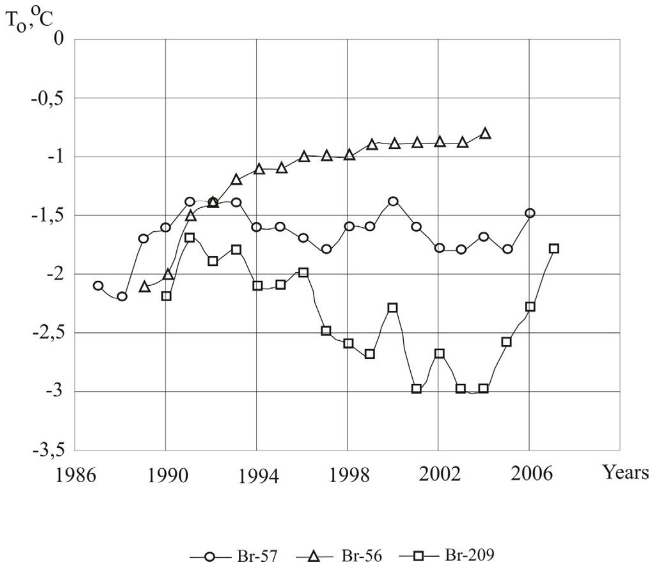

Figure 3. Variations of mean annual ground temperature in the inter-alas terrain unit: larch forest site (Br-57), site of gradual tree removal (Br-56) and burned site with recovering vegetation (Br-209).

state recovery after man-caused damage in sand ridge terrain type is mainly reversible, while in inter-alas type it is either reversible or not.

The database of facts, accumulated during a long period of time is comprised of the following: climatic features, natural and anthropogenic landscapes, content and structure of permafrost, ground cover temperature, temperature, water content ratio, and thermophysical characteristics of ground, seasonal thawing, temperature of water, and bottom sediments in lakes.

Further enhancement of the geothermal monitoring network utilizing automatic loggers is thought to have a great potential. This essential project's feasibility depends on joint Russian and international investigations, pooling human and material resources.

Conclusions

1. Change trends were identified for climate, active layer thickness, and temperatures of natural and anthropogenic landscapes.

2. Small valley and inter-alas terrain types are the most sensitive to man-triggered damage and climatic changes.

3. Long-term dynamics of the ground thermal state illustrate relatively high resistance to climate warming, due to a tendency towards a thinner snow cover during the first half of winter season and, as a result, a lower warming effect.

4. A database was created containing information on landscapes, frozen soils, climate parameters, and ground thermal state.

The results of this study are used in the design and construction of the northern section of the Tommot-Yakutsk railroad. Information obtained is also used in numerical modeling of ground temperature variations and in the Yakutian Permafrost GIS Project.

Micromorphological Analyses of Main Genetic Permafrost Types in West Siberia

E.A. Slagoda
Earth's Cryosphere Institute, RAS, Russia
A.N. Kurchatova
Tyumen State Oil & Gas University, Russia

Abstract

The formation of the geomorphological structure on the northern West Siberian plain and the main genetic types of sediments were caused by Arctic Sea regressions during the Pleistocene-Holocene period. Postcryogenic features in the upper part of all terraces testify of climatic cooling in the Latest Pleistocene. During this stage, syngenetic freezing on sites of accumulation and epigenetic freezing of the earlier melted deposits had occurred. Syngenetic sediments are characterized by the postcryogenic voids associated with sedimentary lamination and complex morphology. Walls of voids are coated by clayish particles and iron hydroxides, and filled by oriented mineral grains. The research of epigenetic sediments has shown the deformed sublayers in the form of tongues and displacements of ground blocks. Micromorphological analyses for correlation of cryogenic events in the upper part of Cenozoic sediments sections should be based on the regional database of microtexture of different genetic permafrost types in West Siberia.

Keywords: micromorphological analyses; postcryogenic microtexture; syngenetic and epigenetic permafrost.

Introduction

The present two-layer permafrost on the northern West-Siberian Plain formed during the Late Pleistocene-Holocene. After Arctic Sea regressions, the marine clayish sediments drained and froze as epigenetic permafrost. They were partially transformed to an active layer in subaerial conditions and deeply thawed during the periods of climate warming or sea transgressions (Dubikov 2002). It is possible to distinguish the sequence of cryogenic events using micromorphological features of syngenetic and epigenetic sediments. Results of micromorphological analyses of the main genetic types of permafrost are presented in the report. Samples were taken from sediment sections of exposures and borehole cores (up to 30 m depth) located at the main geomorphological levels within the territory between Nadym and Pur Rivers and on Yamal Peninsula (Fig. 1). Fifty thin soil sections were studied in all.

Study Region

The terrain of the Nadym-Pur watershed is a plain gently inclined to the north and divided by several geomorphological levels consisting of marine and lacustrine-alluvial facies (Baulin et al. 1996, Dubikov 2002).

A flat, slightly wavy plain is located at an elevation of 65–90 m above see level and consists of the loamy Middle Pleistocene Salekhard Suite made of marine and glacial-marine genesis (m,gmQ_{II}^{2-4}). Sediments are characterized by non-clear lamination, lumpy structure, regular distribution, and inclusion of coarse-sized mineral grains, gravels, pebbles as well as sublayers and lenses of sand (Fig. 2, I). Frozen grounds have layered cryostructure. The thickness of ice layers changes from 0.2–4 cm. Thick layered kinds of cryostructure up to 5–6 cm thick have been observed at 4–10 m below the surface and deeper. Total water content in

these horizons changes from 30–50%. A massive cryogenic structure with ice-cement is typical for frozen grounds of the drained sites (total water content is 15–25%). On the marsh sites of the flat plain, the Salekhard Suite is overlain by the Holocene palsas.

A flat plain located at an elevation of 55–65 m above sea level (up to 70 m in the southern part) surrounds as a rather narrow strip the highest terrain, and consists of regressive marine series of the Late Pleistocene Kazantsevsky Suite (Q_{III}^{1}). The bottom of the sediment section is presented by light gray homogeneous loams accumulated under shallow sea conditions. Towards the top, they are replaced by sandy loams and silts of lacustrine-alluvial genesis (*lal*), and sometimes form an alternation with layered alluvial sands that are characterized by the presence of thin sublayers and lenses of allochthonous peat and plant detritus. Kazantsevsky sediments have a thickness 15–20 m and are covered by a indurate silty-loamy layer. Frozen loam has layered and reticulate-layered cryogenic structures. Sands have basically a massive cryostructure. Thin-layered cryostructures are widespread (Fig. 2, II). The thickness of ice layers is 0.2–0.7 cm with distance between them of 2–4 cm. Total water content changes from 25–35%, sometimes increasing up to 40%.

3. The third geomorphological level of the West Siberian Plain is located at an elevation of 35–55 m and formed during the Latest Pleistocene ($Q_{III}^{2\text{-}4}$), the Kargian-Sartanian stage of the regional stratigraphy. On the north of the territory, the marine terrace consists of estuary and delta sediments (Fig. 2. IV). On the southern part of the plain, the sediments are presented by an alternation of sands, sandy-loams and loams of the lacustrine-alluvial genesis with a total thickness 10–20 m (Fig. 2, III). Usually, light–grey, slanting layered sands have been observed at the bottom of the section. Small lenses of slightly decomposed fibrous allochthonous peat are distinguished in sands. The layered cryostructure is typical for loam and massive structure for sands. Horizontal and wavy ice layers occurred at the distance 2–3 cm from each other. Their thickness is 0.1–0.2 cm. Total water content is 20–25%.

Permafrost thickness changes south to north from 220–430 km and has a two-layer structure. The thickness of the upper sediment complex is 30–50 m; the second layer was revealed at the depth 70–75 m. The frozen layers are divided by a horizon of thawed and often water-saturated sediments with thickness up to 10–15 m and more. Average annual ground temperature varies from 0.0 to -3.0°C (Baulin et al. 1996).

Complex post-sedimentary deformation structures, extending to depths of 3–4 m below the surface have been observed in many localities within lacustrine-alluvial terraces. The deformations include ice wedge casts, involuted beddings, and sediment-filled kettle-like depressions.

The other working area is located on the territory of the gas-condensate field Kharasavey (West Yamal Peninsula) in a continuous permafrost area with an average annual ground temperature of -4 to -6°C (Vasilchuk et al. 2006).

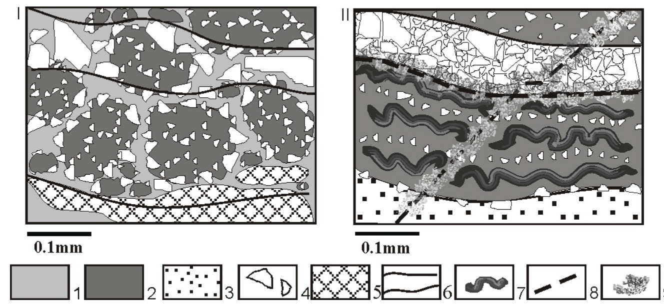

Figure 3. Microstructural scheme of the syngenetic (I) and epigenetic (II) sediments. I – the voids divided the complex aggregates, rock fragments and grains form circular pattern. II – shallow involutions, closed postcryogenic fissures coated by iron.
1 – voids; 2 – fine material; 3 – silt; 4 – debris; 5 – plant remnants; 6 – sediment lamination; 7 – involution; 8 – closed postcryogenic fissures; 9 – ferruginate zone

The thickness of the upper part of cryolithozone within the high terraces is 140–170 m; the lower part is presented by a cryotic saline ground up to the depth of 300 m. Within the gas field, the permafrost thickness and the bottom boundary of cryotic ground are distorted by the thermal influence of gas cupola and a high salinity of marine sediments.

The formation of the terraces on Yamal Peninsula was also associated with Late Pleistocene regressions of the Arctic Sea. The discrete fragments of the first marine terrace ($mQ_{III\text{-}IV}$), located at an elevation of 8–12 m above see level, are extended along the shoreline. The highest third terrace ($mQ_{III}^{2\text{-}3}$) is located at an elevation of 25–35 m a.s.l. and has been observed only in the northeastern part of the territory (Fig. 2, V). The second marine terrace ($mQ_{III}^{3\text{-}4}$), located at an elevation of 12–25 m, consists of loam and clay of the shallow sea with inclusions of a large amount of plant remnants, carbonized organic fragments, and layered sands of lagoon-littoral genesis. Epigenetic permafrost is characterized by massive, massive-agglomerate, and layered cryostructure. The thickness of horizontal, vertical, and broken layers is 0.5–1.5 cm.

Method

As was established and tested on the permafrost objects in the different Arctic regions, the sediments remain postcryogenic textures corresponding to distribution and form of melted-ice inclusions (Slagoda 2005, Konischev et al. 2006, Kurchatova & Slagoda 2006).

Subaerial facies of syngenetic sediments are characterized by microscale fissures which resulted from repeated thermal contraction-expansion in an active layer (Fig. 3, I):

1. mineral grains and debris which have cracked in situ;
2. sediment fragments and blocks which have moved concerning the former texture orientation;
3. complex aggregates of the fine material and debris, and associated with sediment lamination;
4. voids and postcryogenic textures corresponding to aggregates.

Change of structural-textural features of the epigenetic sediments is observed locally near the contact zone of the ice lenses and is characterized by Figure 3, II:

1. ferruginate borders and concentration or dispersion of the fine material observed along the contact zone of the postcryogenic voids, and
2. block-moving of sediment fragments, microfaults of layers without the deep structural unconformity.

The study of macro- and microscale features of sediment structure in the borehole sections was used to determine a type of freezing with complex of facies-genetic analysis.

Results

Salekhard Suite (m, $gmQ_{II}^{2\text{-}4}$) was revealed by boreholes only within Nadym-Pur terrain. Sediments are presented by non-sorted sandy loams with gravel inclusions of 1–2 cm size. Toward the top of the terraces, loams are overlain by small- and fine-grained sands usually with inclined alternation. In the loam layers the microtexture is presented by non-homogeneous material with rare coarse-sized grains included in the silty-clayish fabric. Sandy fraction consists mainly of rounded to subangular quartz grains. Some coarse grains are covered by a clayish coating. Finer material has a chaotic texture. There are fragments of mussels.

Sediments of the *Kazantsevsky Suite* (*la, pmQ_{III}^{1}*) of the third and second terraces are distinguished by finer material of the marine facies to compare with the lacustrine-alluvial ones. However, the common feature of them is a layered structure of sediment and an increase in the sandy fraction towards the top of the section right up to the formation of sandy layers within the lacustrine-alluvial facies.

Silty loam lying at the bottom of lacustrine-alluvial terraces is characterized by banded fabric. Coarse-sized particles often form lenses and sublayers. Particles are mainly presented by rounded quartz grains with hydromica coating. Sediments include a large amount of plant remnants of different decomposition and also fragments of marine fauna. Silts in the middle part of the terrace section have a clear layered structure presented by alternation of mineral sublayers and organic matter. Silts have a reticulate-blocky network cryostructure, and mineral layers have a massive postcryogenic microtexture. In several layers, there are traces of thawing and repeated freezing of sediments. They are presented by deformation of the lamination, tongue-like features of the overlying deposits along the melted ice veins, ferruginate spots, and layers enriched by iron.

The finer material of the second marine terrace on Yamal Peninsula is characterized by a reticulated postcryogenic microtexture that changes into lens-layered ones due to an increase in the quantity of coarse-sized grains. The distinctive feature of Kazantsevsky sediments is a large amount of undestroyed green hydromica particles and clayish rounded debris. There are also sublayers of ferrous diffusion that did not associate with the lamination of clayish plasma. The amount of carbonized organic debris and big plant remnants with good cellular structure (moss?) increases in the loamy-sandy horizon. Similar to lacustrine deposits the

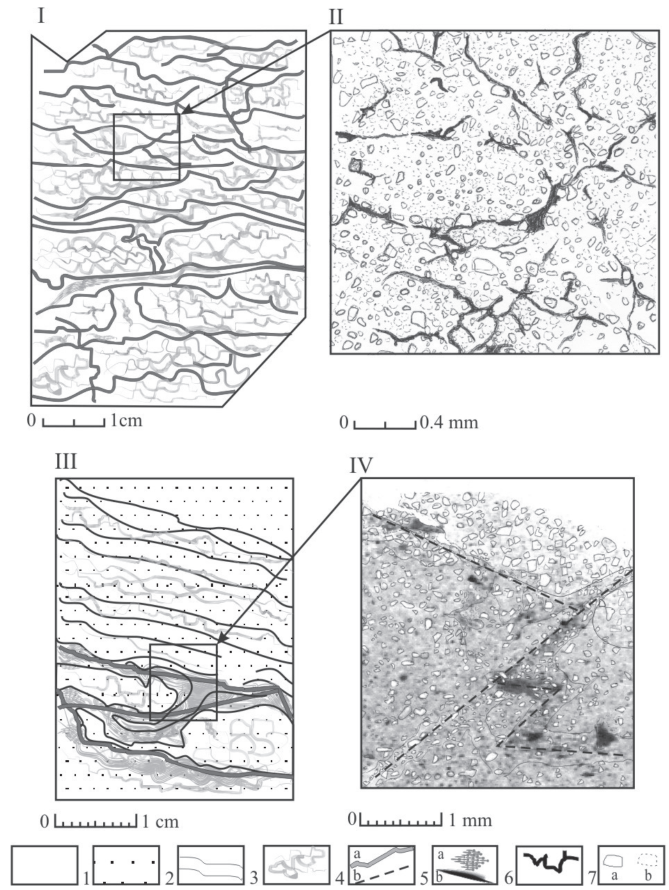

Figure 4. Scheme of macrostructure (I, III) and microstructure (II–IV); I–II – syngenetic sediments of the 3rd terrace, 42 m a.s.l; III–IV – epigenetic sediments of the 2nd terrace, 4 m a.s.l. *1 – silt; 2 – silty-sand; 3 – sediment lamination; 4 – unclear clotted pattern of the fine material underlined by ferruginate; 4 – postcryogenic fissures: a) closed, b) opened; 5 – ferruginate: a) monolith, b) thin soil section; 6 – voids; 8 – debris and coarse-size particles (a) and microaggregates (b).*

shallow-water estuary deposits of the second marine terrace are characterized by layers with sedimentary deformation (involutions).

Karginian-Sartanian sediments (*la, $pmQ_{III}^{2\text{-}4}$*) of the research area are presented by sandy to sandy-loam composition with inclusions of allochthonous peat. Sands of marine and lacustrine-alluvial facies consist of quartz grains with sublayers and lens of the plant detritus. Micromorphological analyses of the shallow-water deposits in the upper part of the third lake-alluvial terrace have shown horizons with clear evidence of syngenetic permafrost. Fine material is characterized by conglomeric fabric with discrete fragments and rounded grains, a circular pattern of coarse-sized grains (orbiculic fabric), lens-type, and layered and reticulate postcryogenic microtexture formed by processes of ground freezing and thawing in a wet active layer.

Sediments in the upper part of the second marine terrace are presented by loam with ferrous spots and a large amount of plant remnants. The micromorphology is characterized by a conglomeric fabric of the complex discrete rounded units consisting of clayish particles and mineral grains. Plant remnants mark sedimentary lamination. An increase in the amount of green hydromica has been observed in the sandy-loamy and loamy layers. Hydromica particles are presented by fresh grains and also by chemically decomposed ones. Plates are split and became colorless around. Iron hydroxides that are the indicators of subaerial oxidation occur in sediments of the upper part of the terraces. Horizons with postcryogenic microtexture of the repeated freezing in the form of downward-penetrating sediment tongues and deformed wedges enriched by finer material along cracks and by oriented mineral grains filling the voids have been observed there.

Conclusions

All marine and lacustrine-alluvial terraces within the research area are overlain by regressive formation with cryogenic and postcryogenic features that testify of climatic cooling in the Late Pleistocene. During this stage the syngenetic freezing on sites of accumulation and epigenetic refreezing of the earlier melted deposits had occurred.

Research of continental and shallow-water marine sediments in northern West Siberia has shown that equally, with direct indicators of syngenetic and epigenetic freezing, the distinct soil micromorphology is formed (Fig. 4):

- Syngenetic permafrost of the different genesis is characterized by postcryogenic voids associated with sedimentary lamination and cryogenic fabric, complex discrete fragments of fine material enclosed by a circular to ellipsoidal pattern of the mineral grains, and coarse-size particles. The walls of the postcryogenic voids are coated by clayish particles and iron hydroxides; the voids are filled by oriented mineral grains.
- Micromorphological analyses of epigenetic permafrost have revealed postcryogenic microtexture in the form of involutions, deformations of sedimentary lamination associated with broken vertical and reticulate-blocky cryostructure.

Permafrost micromorpology can be used for reconstruction of the cryological history of northern West Siberia. The method allows the distinguishing of syngenetic and epigenetic sediments in the section, and therefore, the determination of subaerial conditions of syngenetic stratum accumulation and subaqueous conditions of the cryogenic transformation of the marine facies of epigenetic permafrost.

Results of the micromorphological research for correlation of cryogenic events in sections of upper Cenozoic sediments should be based on the regional database of microtexture of the different genetic permafrost types in West Siberia.

Ground Temperature and Thaw Settlement in Frozen Peatlands Along the Norman Wells Pipeline Corridor, NWT Canada: 22 Years of Monitoring

Sharon L. Smith, Margo M. Burgess, and Daniel W. Riseborough
Geological Survey of Canada, Natural Resources Canada, Ottawa, Canada

Abstract

A monitoring program along the Norman Wells pipeline corridor has generated 22 years of observations of ground temperature and thaw settlement in frozen peatlands south of Fort Simpson NWT. Thawing beneath the right-of-way (ROW) and associated thaw settlement in response to vegetation clearing, surface disturbance, pipeline construction and operation is still continuing. Where alteration of the ground thermal regime was greater, significant settlement (>2 m) and collapse of peat across the ROW has been observed especially near the edge of a peat plateau. Complete degradation of thin permafrost has been observed in undisturbed terrain adjacent to the ROW which may be a result of the natural evolution of peatlands and recent warming. Thaw depths off-ROW have increased by up to 0.9 m following fires that burned extensive areas of peatlands in 2004.

Keywords: active layer; peatland; permafrost; thaw settlement; thermal regime.

Introduction

Permafrost in the southern portion of the discontinuous zone in western Canada is largely confined to organic terrain. Much of this permafrost likely formed during the Little Ice Age (e.g., Halsey et al. 1995) and has been preserved under subsequent warmer climatic conditions by a thick layer of insulating peat. These frozen peatlands may be particularly sensitive to small changes in the ground thermal regime that may result from construction and operation of infrastructure, forest fires, or climate change. Thawing of ice-rich organic terrain may have implications for infrastructure integrity, hydrological processes, and ecosystems, and it may result in alterations to carbon sources and sinks (ACIA 2005).

The Norman Wells oil pipeline (in operation since 1985), 869 km in length, crosses the discontinuous permafrost zone (Fig. 1) of the Mackenzie Valley, Northwest Territories and northern Alberta. Organic and morainic terrain units dominate the southern portion of the route. Since the mid-1980s the Canadian government and the pipeline company, Enbridge Pipelines (NW) Inc., have collaborated in a permafrost, terrain, and geotechnical research and monitoring program which includes a network of long-term instrumented sites located along the pipeline corridor in organic terrain south of Fort Simpson NWT. This network has generated over 20 years of data on the ground thermal regime and ground movements and provides the opportunity to investigate the response of frozen peatlands to both environmental disturbance and climate change and variability.

This paper focuses on environmental changes at 5 frozen peatland sites, associated with pipeline construction and operation and with natural changes such as fire and climate change and variability. An updated documentation is presented (updates Burgess & Tarnocai 1997) of the evolution of the ground thermal regime both beneath the pipeline right-of-way (ROW) and the adjacent undisturbed terrain over a 22-year period. Changes in thaw depth and settlement of the ground surface are also documented.

Background

Peatlands in the corridor

Peatlands are organic wetlands that have 40 cm or more of peat. They cover over 60% of the terrain along the pipeline corridor south of Fort Simpson (Burgess & Lawrence 2000). The two major classes in the Mackenzie valley are bog and fen, and each has distinctive vegetation assemblages, morphologies, water regimes, and thermal conditions (Aylsworth & Kettles 2000).

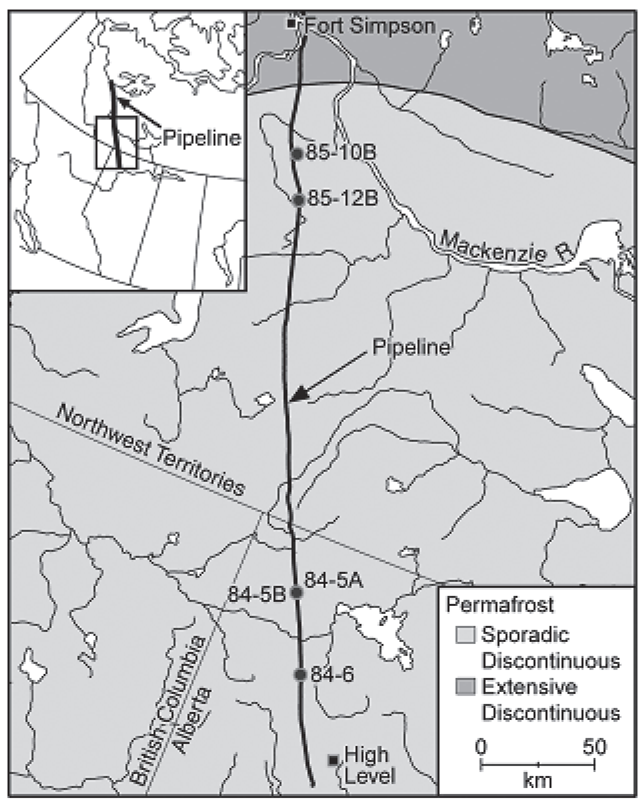

Figure 1. Location of the Norman Wells pipeline and permafrost distribution in the Mackenzie Valley.

Bogs are flat or very gently inclined plains either raised about 1 m above surrounding fens or peat filling slight depressions. Along the pipeline route, the common bog types include peat plateaus, palsa bogs, and collapse scar bogs. Fens and collapse scar bogs are generally unfrozen, while all other bog types are associated with permafrost.

Dominant peat materials of bogs are undecomposed *Sphagnum* and moderately decomposed woody moss peat underlain, in places by moderately- to well-decomposed sedge peat. Heath shrubs are also common. Trees, if present, tend to be low and stunted, forming open canopy forests. Fens are flat to very gently inclined plains which tend to be featureless although some have a reticulate network of low ridges. Dominant peat materials in fens are shallow to deep well- to moderately-decomposed sedge or woody sedge peat. Fens may or may not be vegetated with trees or shrubs (Burgess & Tarnocai 1997).

Bogs commonly developed from fens which in turn formed as organic materials accumulated in lakes or poorly drained depressions. Collapse scars in degrading peat plateaus may develop into fens (Aylsworth & Kettles 2000).

Climate

The Norman Wells pipeline corridor experiences a cold and relatively dry continental climate. Mean annual air temperature, based on 1971–2000 climate normals, is -3.2°C at Fort Simpson and -1.3°C at High Level. Normal annual precipitation is 369 mm at Fort Simpson and 394 mm at High Level with 40–45% falling as snow.

There has been a general increase in air temperature since the mid 1980s (Fig. 2) with the largest changes tending to occur during the winter. A number years with extreme temperatures (>1 standard deviation from normal) have also occurred over the last three decades including extreme warm and dry summers (for example in 1994, 1995, and 2004) that were also associated with forest fires.

Pipeline construction and operation

Pre-construction activities consisted of clearing a ROW up to 25 m wide during the winter mainly between January and March 1983 with the remainder completed by early 1984. Construction occurred over two winters (1983–84 or 1984–85) and involved blading and scraping of the peat surface to provide a stable work platform along the ditchline and travel side of the ROW. A trench about 1 m wide and 1 to 1.2 m deep was excavated for pipe installation. Excavated material (native spoil) was generally mounded over the trench following pipe installation. In peatlands, the native spoil was often blocky frozen peat that was not easily compacted. Although revegetation for erosion control occurred through seeding and fertilizing mineral soils, no revegetation was conducted where peat was greater than 1 to 1.2 m thick (present below the trench bottom).

Oil is chilled as it enters the line at Norman Wells, approximating the temperature of the surrounding permafrost. Although the pipeline operates as an ambient line, the oil warms by 1.5 to 3°C as it passes through the pump station compressors and the temperature remains elevated for more than 20 km downstream. Mean annual pipe temperatures in the southern section of the route have been above 2°C since the second year of operation. A pump station is located just south of Fort Simpson at KP 585, and downstream mean annual pipe temperatures have reached values greater than 6°C (Burgess 1992). During operation, winter pipe temperatures have generally never been below 0°C in the southern peatlands.

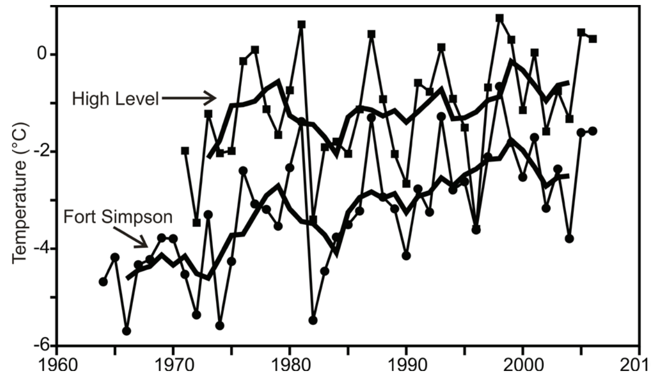

Figure 2. Mean annual air temperature record for the Environment Canada weather station at Fort Simpson, NWT (61°45′N 121°14′W) and High Level Alberta (58°37′N 117°09′W). The 5- year running mean is also shown.

Study sites and instrumentation

A description of the 5 peatland study sites is presented in Table 1. Generally 4 boreholes 5 to 20 m deep were drilled in 1984 or 1985 at each site. Three of these were located on the cleared right-of-way (on-ROW) at varying distances from the pipe and a fourth was located in the adjacent undisturbed terrain (off-ROW), 10–15 m from the edge of the ROW. Temperature cables placed in PVC casing, in each borehole, measure ground temperatures. The accuracy of the temperature sensors is ±0.1K, while the measurement system allows for a resolution of ±0.01K. Details on the site establishment and initial instrumentation are provided in Pilon et al. (1989). Manual measurements of ground temperature were made at monthly to quarterly intervals until 1996. Since 1996, dataloggers have been used at some sites and at least one complete site visit has occurred each fall close to the time of maximum active layer development. Thaw depths based on the maximum annual depth of the 0°C isotherm were determined by interpolation of the ground temperature profile between sensors. At some off-ROW sites a ground temperature sensor has been placed at 2–5 cm depth.

Thaw settlement across the ROW has been determined through level surveys initiated at site establishment and repeated at intervals of 2 to 5 years. The accuracy of these surveys ranges from less than 1 cm for compacted soil surfaces to about 15 cm for softer wet and compressible soils (Burgess & Lawrence 1997).

Observations and Discussion

Initial observations at undisturbed off-ROW sites (Fig. 3) indicate that mean annual ground temperatures in frozen peatlands are close to 0°C (above -0.3°C). Temperature gradients are small or near isothermal within the permafrost although steeper gradients are found below small bodies of permafrost surrounded by unfrozen terrain (e.g., 85-12B, KP608). Permafrost thickness (Table 1) varies from a few metres to greater than 10 m. Thaw depths were initially less than 1 m. The ground thermal regime responds to changes at the ground surface, such as clearing of vegetation related to ROW preparation and pipeline construction. Climate change and variability and natural factors such as fire may also lead to alterations in the ground thermal regime. These factors are discussed below.

Effects related to pipeline construction and operation

Changes in the ground temperature on and off the ROW over the monitoring period observed at a peat plateau near Fort Simpson and one in northern Alberta are shown in Figure 3. Initial observations off-ROW indicate that ground temperatures were colder and permafrost was thicker (10–11 m) at 84-5B (KP783) than at 85-12B (4–7 m). The warmer conditions at 85-12B are due to its lower elevation and also its proximity to the unfrozen fen as the monitoring site is located near the edge of the 2 m high peat plateau.

Over time, temperatures beneath the ROW increased above those in the surrounding undisturbed terrain in response to clearing of the vegetation and other disturbance to the ground thermal regime. This warming of the ground has led to increases in thaw depth (Table 1). At 85-5B, the increase in thaw depth beneath the ROW was about 3 m. At 85-12B, where the disturbance to the ground thermal regime has been greater, the thin permafrost completely degraded beneath the ROW.

The greater amount of warming and thawing beneath the ROW at 85-12B is due to both natural effects and those

Table 1. Characteristics of study sites discussed in this paper (updated from Burgess and Tarnocai 1997). ON and OFF refer to on-ROW and off-ROW, KP refers to kilometre post. The range in thaw depths observed at the site is given. Where the thaw depth is given as less than or greater than a given value, this indicates the depth of thaw is above the shallowest sensor or below the deepest sensor.

Site	KP	Elev m asl	Location	Peat Thickness (m)		Initial Permafrost Base (m)		Initial Thaw Depth (cm)		2006 Thaw depth (cm)

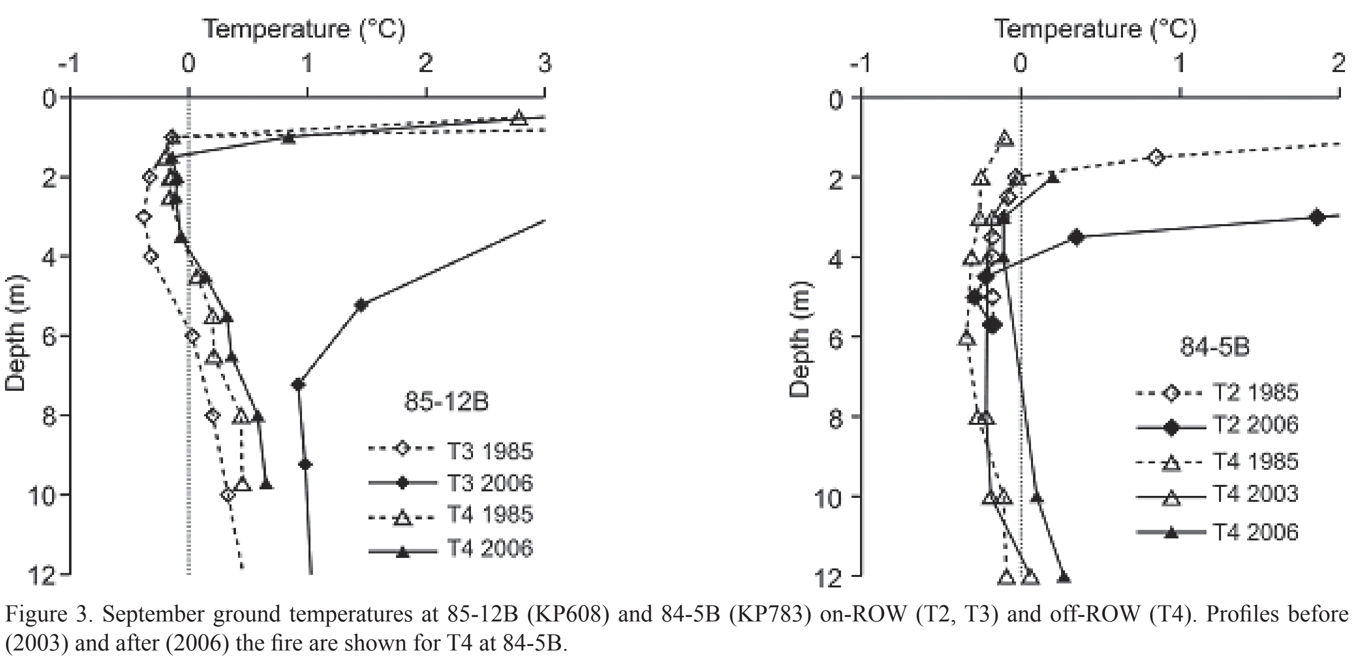

Figure 3. September ground temperatures at 85-12B (KP608) and 84-5B (KP783) on-ROW (T2, T3) and off-ROW (T4). Profiles before (2003) and after (2006) the fire are shown for T4 at 84-5B.

related to environmental disturbance. Since the site is near the collapsing edge of the peat plateau, effects related to the natural evolution of peatlands such as thermal and hydrological erosion will be important (Burgess & Tarnocai 1997). Disturbance due to blading was greater than at 84-5B. In addition, the site is located about 25 km downstream from the pump station, and the ground will be subject to warmer pipe temperatures than at 84-5B which is located much farther south. At 85-10B (KP588), located just a few kilometres south of the pump station, degradation of thin permafrost has also occurred.

Thawing of ice-rich soil can result in thaw settlement. Peat is particularly ice-rich and thaw strains of 30% or more have been determined for the pipeline sites in organic terrain (Burgess & Smith 2003). Surface settlement data obtained through periodic level surveys are presented for three sites in Figure 4. They show the ground surface movements that have occurred across the ROW between 1985 and 2006 (except for 84-6, KP819, where the most recent survey was 2001). At all sites settlement that has occurred on-ROW exceeds that occurring off-ROW due to the greater disturbance and increases in thaw depth that have occurred beneath the ROW.

During the first few years following clearing and construction, the greatest settlement generally occurred near the ditchline. This is partially due to the trenching and settlement of native backfill in the trench. Additional thawing and settlement occurred around the warm pipeline and as the thaw bulb grew, collapse of peat into the trench occurred (Burgess & Tarnocai 1997). Farther from the pipe, settlement was generally less and is mostly associated with thawing of the ground in response to clearance of vegetation. Over time, rates of settlement generally decreased as the thaw progression slowed. However, thaw settlement is still continuing on the ROW 22 years after the initial clearing. The amount of settlement on the ROW has been up to 2 m at the ditchline and up to 0.5 m toward the edge of the ROW.

The greater amount of disturbance related to ROW preparation, trench excavation and warm pipe temperatures has led to greater subsidence and collapse of peat at 85-12B than at 84-5B and 84-6. The higher ice content of the underlying material and higher associated thaw strains at 85-12B are also factors. Proximity to the edge of the peat plateau and the thermal and hydrological erosion along the subsided ditchline at 85-12B has resulted in accelerated collapse of peat into the ditch (Burgess & Tarnocai 1997) and considerable ponding on-ROW which contributed to further thermal disturbance beneath the ROW. Collapse of peat has continued and the area of ponding has enlarged over the 22-year period. By 2006 the area of collapse was found to extend to the edge of the ROW (Fig. 4a), and the trench had widened from an original width of about 1 m to about 16 m. In fact, this area of collapse has extended to the temperature cable (T3) that is near the edge of the cleared ROW and complete degradation of permafrost has occurred (Fig. 3). Although ponding has made it difficult to determine the total amount of settlement that has occurred in the trench area at 85-12B, it is at least 2 m. Toward the ROW edge (right side

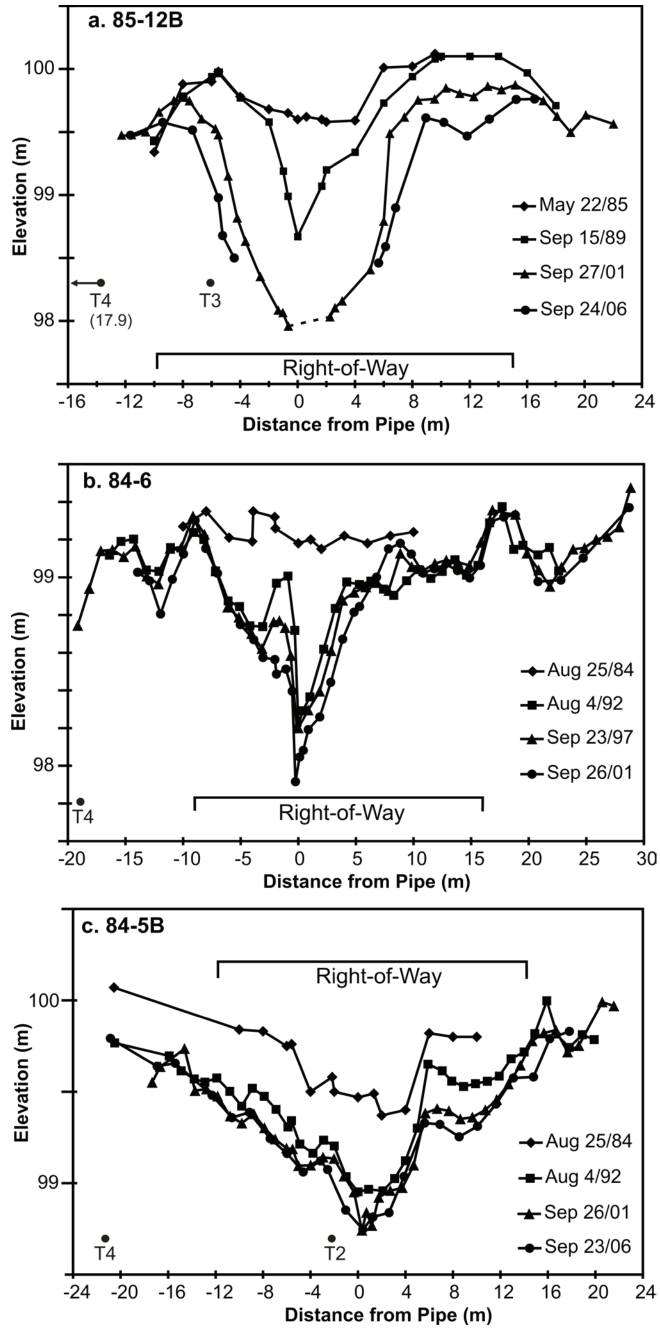

Figure 4. Ground surface elevation (relative to local datum) for peat plateau sites located at (a) KP608, (b) KP819 and (c) KP783.

Fig. 4a) up to 0.6 m of settlement has been observed.

Settlement and collapse of peat is observed to a lesser extent at 84-5B and 84-6. At the most southerly site (84-6), settlement of up to 1.3 m occurred in the trench area between 1984 and 2001. Collapse of peat is also observed and this has occurred over a distance of up to 10 m from the pipe and has extended to the edge of the ROW on one side (Fig. 4b). Farther from the trench, settlement ranges from 0.2 to 0.3 m (right side Fig. 4b). Proximity of this site to the edge of a collapse scar bog is probably also a factor in addition to the disturbance related to the trench excavation, ROW clearing and warming around the pipe.

At 84-5B where permafrost was initially colder and thicker and where effects related to the pipe temperature are less than that at 85-12B, settlement and collapse of peat has been less. Total settlement between 1984 and 2006 within the trench has been about 1m (Fig. 4c) with less collapse, which is limited to about 4 to 5 m from the pipe. Toward the edge of the ROW, settlement up to 0.5 m is observed.

Other effects

The record of ground temperatures at the off-ROW sites provides an indication of the baseline conditions and also the potential effect of climate warming on frozen peatlands. Increases in shallow permafrost temperatures at all off-ROW sites along the pipeline route have been observed over the monitoring period (Smith et al. 2005). The rate of change, however, has varied with smaller changes, or no obvious trend (<0.01°C per year) where permafrost temperatures are close to 0°C, likely due to the latent heat required to thaw the ice-rich soil. In the ice-rich organic terrain south of Fort Simpson, particularly sites with thicker permafrost, the change in ground temperatures at off-ROW sites has been small, but thaw depth has increased at some sites (Table 1). Part of this increase in thaw depth (especially in the first few years following site establishment) is likely due to surface disturbance related to borehole drilling. The general increase in thaw depth, however, is consistent with the increasing air temperature over the monitoring period (Fig. 2) and also the increase in thaw depth observed at other active layer monitoring sites in the Mackenzie Valley in the 1990s (Nixon et al. 2003).

Where permafrost was initially thin, complete degradation of permafrost off-ROW has been observed. At 85-10B, located near the edge of a degrading peatland near Fort Simpson, very warm permafrost less than 3 m thick was present in 1985 (Fig. 5). Ground temperatures then increased, with most warming occurring in the 1990s. The rate of warming was initially slow due to the energy required for phase change. By 2001, ground temperatures were greater than 1°C and permafrost was no longer present (Fig. 5). This warming (and subsequent degradation of permafrost) may be partly due to proximity of the site to the edge of the frozen peatland. Perennially frozen peatlands go through a natural cycle of early (when permafrost development begins), mature (stable), and overmature stages (Burgess & Tarnocai 1997). Thermal degradation results in thawing of ground ice and collapse of peatland surfaces during the later stage. The progression to the latter stages of the natural cycle may therefore be a factor in permafrost degradation at 85-10B.

The loss of permafrost at 85-10B may also be related to extreme warming during the summer of 1998 followed by warm winters over the next three years. Less cooling of the ground during the winter following a period of high heat input may have limited the cooling and freezing of the active layer and resulted in a general warming of the ground (Fig. 5). Both long-term trends in climate and shorter-term variations may be important, therefore, in the maintenance of these marginally frozen peatlands.

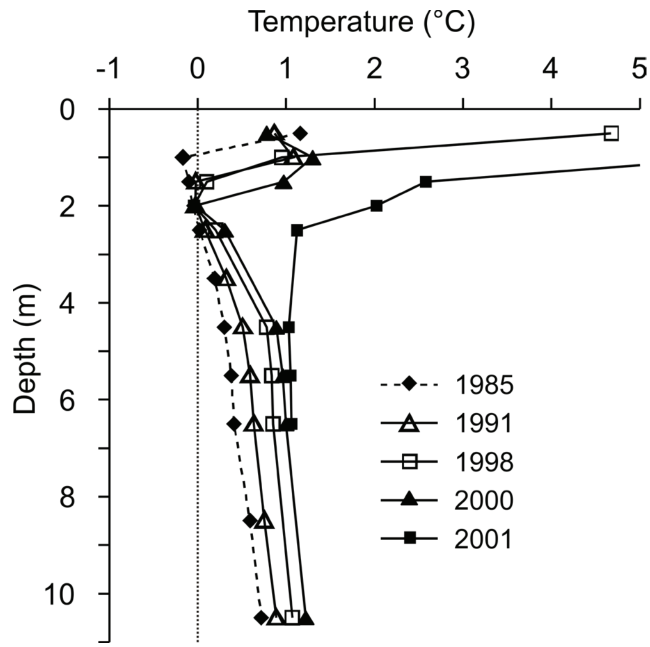

Figure 5. September ground temperature profiles off-ROW at 85-10B (KP588).

Other natural factors are also important in the evolution of the ground thermal regime. Wild fires may have an important influence on permafrost conditions. Burning of vegetation and the organic layer reduces the buffer layer and the surface albedo leading to overall increases in ground surface temperature, which over time propagate to the ground below (e.g., Viereck 1982). In summer 2004 for example, extensive areas of the southern portion of the pipeline corridor were burned. While the ROW acted as a firebreak and was generally not affected by the fire, areas adjacent to the ROW were burned including sites 84-5A and 84-5B. Figure 3 shows the increase in ground temperature and thaw depth (see also Table 1) that occurred in the two years following the fire. Thaw depths increased about 0.5 – 0.9 m over the 2 years following the fire. Analysis of data obtained from the temperature sensor placed at 2 to 5 cm depth at 84-5B indicates that mean annual near-surface ground temperature was about 1°C higher following the fire (2004–2006) than during the 3 years prior to the fire. The level survey data for 84-5B (Fig. 4c) indicates that some settlement did occur off-ROW between 2001 and 2006, but this appears to be limited to within a few metres of the edge of the ROW. Some of this settlement may be related to the burning and subsequent thawing of ground ice. However, a few more years of monitoring will be required to fully assess the impact of the fire in terms of thawing of the frozen peatland and related settlement and collapse of the peat.

These examples of permafrost degradation off-ROW associated with natural causes or climate warming show that during some periods, there may be larger changes in permafrost conditions off-ROW than on-ROW. In addition, some of the changes to permafrost off-ROW may eventually impact the ROW as surface settlement and collapse of peat progresses to the ROW edge in response to thawing.

Summary

Observations from the monitoring program in the Norman Wells pipeline corridor have provided information on the long-term evolution of the thermal regime and ground movements associated with thawing of peatlands in response to environmental disturbance related to pipeline construction and operation and natural factors. Ongoing warming at peatland sites has been observed, with the greater amount of warming occurring beneath the ROW and near the pipe. This warming and thawing of permafrost has led to settlement, particularly within the trench area. At sites where permafrost was initially warm and thin, and also adjacent to the edge of the peat plateau, disturbance to the thermal regime related to both a warm pipe and vegetation clearing has resulted in settlement of up to 2 m. Collapse of peat into the trench is also observed at these sites, in one case extending to the edge of the ROW. The possibility of permafrost thaw, settlement, and collapse of peat extending into the area adjacent to the ROW is also illustrated by these results and indicates that impacts related to infrastructure development may not be confined to the cleared ROW.

Other factors such as climate change and variability and the natural evolution of peatlands are also important. The complete degradation of thin permafrost off-ROW is observed to occur at sites near the edge of the peat plateau (and adjacent to unfrozen terrain). Warmer climate conditions over the last decade have also likely been a factor in thawing of thin permafrost. Forest fires have also resulted in changes to the ground thermal regime, especially in the off-ROW areas, resulting in permafrost thaw and settlement. The effect of fire indicates that changes off- ROW may over time affect ROW conditions should settlement and collapse of peat continue to occur.

The results generated from the monitoring program provide information to improve our understanding of the response of frozen peatlands to environmental disturbance and for planning and design of future infrastructure in similar environments.

Acknowledgments

This project has been supported over the years by: the federal departments of Natural Resources Canada and Indian and Northern Affairs Canada, federal programs of PERD (Panel on Energy Research and Development), NOGAP (Northern Oil and Gas Action Plan) and Northern Energy Development Memorandum to Cabinet, and Enbridge Pipeline (NW) Inc. Numerous colleagues have contributed to data collection and analysis over the life of the monitoring program.

Systematization of Underground Ice

V.I. Solomatin, N.G. Belova
Moscow State University, Department of Geography, Moscow, Russia

Abstract

This paper examines the history and problems of classification of underground ice. A new approach to genetic classification of ground ice in the permafrost area, taking into account cryolithological, geological, and geographical aspects, is suggested. The general picture of the role of different ice types in permafrost regions is shown.

Keywords: genesis; ice structure; recrystallization; systematization of underground ice; underground ice.

Introduction

Ice with its specific properties has a special place and plays a special role in cold areas of the Earth. These properties reveal themselves in global and micro processes and in events in formation of the Earth's cryosphere.

The basic principles of general systematization of natural ice have been substantiated by Dobrowolsky (1923), Veinberg (1940), Shumskii (1955, 1959) and others. Later, as new facts and theoretical ideas were accumulated, the problem of systematization and structural-genetic conceptions were elaborated (Grave 1951, Pihlainen & Johnston 1963, Katasonov 1965, Popov 1967, Vtiurina & Vtiurin 1970, Mackay 1972, Solomatin 1986, Murton 1999, French 2007 and others).

Ground ice classifications proposed by different authors were based on origin, type, and age of ice formation, relationship between ice formation and formation of the deposit containing ice, source and properties of the water used for ice crystallization, a morphology of ice body, an origin of host deposits, and other characteristics. The classification by Mackay (1972) takes into account the source of water and processes of its movement.

Shumskii (1964) considers ice as a variety of rock. It is necessary to recognize that ice is an unusual rock, the place of which in classifications of rock is hard to describe.

In this paper, the history and problems related to classification of ground ice are examined, and a new approach to genetic classification of ground ice in the permafrost, which takes into account cryolithological, geological, and geographical features, is suggested.

Classification of Ground Ice by Shumskii

The first step in systematization of ground ice is a recognition of its place among the other objects similar in nature and in methodology of study. We already mentioned above that ground ice obviously belongs to rocks, but not what place it occupies among rocks and what class of rocks to which it can be referred. It is clear that ground ice is widespread in absolutely certain geographical space—in the permafrost zone. It is a light mineral and rock, and due to this feature, it lies mainly in the uppermost layers of the lithosphere, at depths of first tens of meters (rarely hundreds) from the surface. Formation of ground ice depends on environmental (facial) and thermal conditions. As with other rocks, ice occupies its own inherent place in the lithosphere, forms unique geological bodies due to specific mechanisms and factors of ice formation, and is characterized by individual features of structure.

Shumskii (1955, 1959, 1964), on the basis of his own studies and analysis of works by Dobrowolski (1923), Veinberg (1940), Tolstikhin (1936) and other founders of glaciology, came to the conclusion that the crystal structure of ice and its formation from a liquid phase during crystallization provides the basis for attributing it to magmatic rock. Also, some types of ice (e.g., glacier ice) have similarities with metamorphic rocks, affected by deep recrystallization and metamorphic transformation of their primary structure. At the same time, the direct analogy of natural ice with magmatic or metamorphic rocks is not completely correct, even though some types of ice are formed by crystallization of the liquid phase and others undergo deep forms of dynamic metamorphism. Ice differs sufficiently from all other rocks in its physical properties and, first of all, in density and thermal properties. Understanding the tentative character of his classification, Shumskii after Veinberg suggested the definition of ice, which is formed from a liquid phase, as *congelation ice*. Shumskii considered glacier ice as metamorphic rock, while snow cover he attributed to sedimentary rocks. The scheme of natural ice classification (including ground ice) suggested by Shumskii, appears to be the least contradictory in the general system of rocks, considering the unique nature of ice-formation processes. Usage of concepts of magmatic and metamorphic rock formation in glaciology establishes important principles and methods of structural-petrographic study, helps to comprehend physical and genetic processes of natural ice formation, and at the same time, allows the use of direct terminological analogies.

Subdivisions of Underground Ice

Applying Shumskii's approach, we can distinguish the following types of ground ice (Table 1):

1. Congelation ice – the analogue of magmatic rocks, the structure of which is determined mainly by processes of crystallization of a liquid phase, with subsequent structural

Table 1. The schematic classification of underground ice.

Group of ice rock	Ice rocks		Physical processes and conditions of formation	Structure
Deposit like ice (buried ice)	All types of primarily surface ice in permafrost		Burial of primarily surface ice in permafrost	The reduced structures of corresponding surface formed ice
Metamorfic ice	Wedge ice	Syngenetic	Dynamic metamorphism of congelation ice of yearly ice veins in thermal crack	Laminated schistose structures
		Epigenetic		
	Regelation-segregation (regelation-migration) ice		Regelation and migration of ice in weakened zones of dislocated frozen soil	Catablastic structures
Congelation ice	Segregated ice		Migration and crystallization of a interfacial water	Hypidiomorphic-granular, less often allotriomorphic-granular structure fabric
	Ice-cement		Crystallization of the free and interfacial water *in situ*	Anisomerous allotriomorphic-granular
	Injection ice		Slow crystallization of free pressurized water in closed and partly closed volumes of a freezing ground	Massive coarse-grained ice fabric of slow not orthotropic crystallization
	Cave ice	Thermokarst-cave ice	Volumetric crystallization of free water in cavities of a ground	Laminated prismatic-granular structures of orthotropic growth
		Incrusted ice	Layer-by-layer crystallization of free water	Laminated fine-grained ice fabric
		Sublimation (hoar) ice	Ice crystal growth from water vapor on cave wall	Conglomerate of crystals
	Crack ice		Crystallization of water in cracks of rock	Prismatic-granular structures of orthotropic growth with axial junction of ice crystal proceeding growth from opposite crack wall

transformations insignificant. Ice of cracks and injective and thermokarst-cave ice can be attributed to this type.

2. Metamorphic ice – first of all wedge ice, the development of which is not limited by formation of elementary vein structure, but includes also the determining role of the subsequent dynamic metamorphism.

3. Buried ice – which remains a still poorly-studied group of underground ice. It is possible to consider this ice as an analogue of sediment.

Of course there are some terminological uncertainties in this interpretation, but not more than in other cases of terminology of ice formation as a geological body. The petrography of buried ice is the result of its formation on the surface and slight changes in ice structure during sediment accumulation. On the other hand, a development of syngenetic wedge ice is also in very close connection with the accumulation of containing deposits. Therefore, the syngenetic ice wedges of Pleistocene sediments, which widely occur in northern Siberia and are up to 30 m tall, should be placed in the classification system between metamorphic (as all ice wedges) and sedimentary ice rocks. The term *sedimentary ice*, however, is used usually for products of snow accumulation (Shumskii 1955, 1964). Therefore, in this classification, we offer the term *deposit like ice* for buried ice and partly for any syngenetic ice.

Modification of Ice Structure with Time

The classification scheme (Table 1) reflects existing uncertainty and terminological inconsistency, which is impossible to avoid if we consider ice (including ground ice) as a type of rock. Shumskii (1955) uses widely the concept of natural ice metamorphism. Thermodynamic conditions, even in the most severe areas of the Earth during parts of the year, are close to a point of phase change of water which determines the unstable condition of ice and its transformation by recrystallization and change in its initial structure.

Ice is always subjected to transformations of any scale due to internal or external stock of free energy. This transformation reveals itself in recrystallization and in different scale changes of primary structures. Especially deep changes of primary ice structure occur during and after dynamic metamorphism, associated with movements of ice masses by external forces. Shumskii (1955) showed that thermometamorphism of ice reaches sufficient results only at temperatures close to a melting point of ice and for ice crystals of smallest size. Rogov (1981) compared size of ice grains in ice veins of ice wedges of Pleistocene and Holocene age and found that size of crystals of Pleistocene ice wedges are greater than in Holocene ice wedges, which shows that the size of ice crystals has increased with time. However, dynamic metamorphism has a more significant influence. The degree of dynamic metamorphism is determined by the origin of ice. For example it has an obvious effect in ice wedges but not in segregation ice, even in layers close to soil surface where tension is maximal.

Every rock undergoes the certain processes of diagenesis, but that does not mean that a structure of the natural ice, which is subjected to deep transformations, has completely lost its primary features with the origin of rock having become unrecognizable. On the contrary, ice as well as other metamorphic rocks, retains features of primary structure, even after intensive metamorphism. For example the sea origin of gneisses is out of doubt, despite intensive thermo and dynamic metamorphic processes through which the rock has passed after sedimentation. So we may say that ice recrystallization is a part of its petrogenesis, and in a certain sense, is an attribute and distinctive feature of its origin. Despite recrystallization, ice masses of different origin, which have formed at the same time and experienced since then identical thermodynamic conditions, preserve features of structure developed during their formation.

Spatial Patterns of Underground Ice-Formation

Because formation of ground ice is determined by thermodynamic conditions of adjacent rocks, patterns and genetic types of ice rocks vary with change in these conditions. In other words, the origin of ice is a function of physiographic conditions and depth of ice-forming horizon. Natural geographical changes and depth of frozen ground in earlier-described sediments should be reflected in permafrost structure (Solomatin 1982, 1996). However, patterns of ground ice predetermined by zonal factors are also affected by azonal lithogenic factors. This should be taken into consideration while studying the formation of ice at spatial boundaries of areas with different genetic types of ground ice.

Conclusions

Underground ice is a special natural mineral and rock. It is the main product and factor of permafrost forming, and is distinct as frozen ground from all other rocks.

The authors try to develop a classification of underground ice, which could help in understanding the general mechanism and spatiotemporal distribution and development of ice-rich permafrost. The classification offered in this paper takes into account the existing ideas, and also is based on initial structural features of different types of underground ice. The general picture of the role of different ice types in permafrost regions has been shown.

Abstract

The Beaufort Shelf offshore the Mackenzie Delta is characterized by shallow nearshore slopes that result in extensive regions where seasonal bottom-fast ice (BFI) can develop with attendant ground freezing and aggradation of permafrost. Ground temperatures in four 10-m deep boreholes were measured for 2 years along an ~18 km transect from a distributary channel across a nearshore shoal. Maximum BFI thickness in March was 1.05 m with the coldest ground temperatures occurring where BFI was thinnest. Field observations constrained a two-dimensional geothermal model for the study area. The observations and model show the sensitivity of permafrost and ice bonding to subtle changes in bathymetry and to the residency period of BFI. The permafrost table rises beneath shallow water where annual residency of BFI is the greatest, and a subsurface talik develops beneath deeper water where residency is minimal.

Keywords: bathymetry; bottom-fast ice; ground temperature; ice-bonding; nearshore; permafrost.

Introduction

The Mackenzie Delta, located in the western Canadian Arctic (Fig. 1), is under intensive exploration for natural gas, and a proposed gas pipeline may pave the way for production of known reserves in the nearshore off the delta front. Environmentally-sound development of hydrocarbon resources in this region will require an understanding of the processes that govern coastal stability, nearshore morphology, and sediment properties in the extensive, very shallow coastal zone. In water depths <2m during the winter months, sea ice forms and thickens until it contacts the seabed (i.e., becomes "bottom-fast"). Once the ice is bottom-fast, heat is rapidly removed from sediments by conduction via the strong temperature gradient induced by the very cold air temperatures at the ice surface. This facilitates the formation of seasonal frost, and creates conditions conducive to permafrost aggradation into sediments which were formerly unfrozen. This paper reports on recent ground temperatures measured beneath zones of BFI, and on efforts to develop a thermal model for the shallow seabed along a borehole transect.

Study area

Our study transect lies at the northwest edge of the Holocene ("modern") Mackenzie Delta (Fig. 1). The shoreline of the Holocene delta is characterized by lobe-shaped vegetated islands separated by funnel-shaped bays (Hill et al. 2001). The erosional nature of the delta front, drowned morphology, and other features indicate that the Mackenzie Delta is undergoing transgression resulting in limited water depths for sediment accumulation (Hill et al. 2001). However, bar accretion still occurs within large embayments and at the mouths of most distributary channels. In general, the nearshore, seaward of the Holocene delta, is very shallow. Water depths are less than 2 m (relative to chart datum) at distances in excess of 15 km from the shore. Mean tides are 0.3 m and large tides range up to 0.5 m, whereas winds may raise water levels up to 2.4 m (Hill et al. 2001) or lower them by up to 1 m (Henry 1975).

The Mackenzie River is the largest of North American rivers supplying water and sediment to the Arctic Ocean. The abundant supply of freshwater is maintained throughout the year as a surface plume in the summer and as an under-ice freshwater "lake" during the winter (MacDonald & Carmack 1991). Thus the "sea" ice that forms in the winter is primarily formed from Mackenzie River water. Similarly, nearshore sediments deposited beneath the plume have been found to exhibit low pore water salinities (unpublished data).

The Holocene delta is underlain by permafrost to depths of 40–90 m (Judge et al. 1987). Offshore the Holocene delta, the depth to the top of permafrost is variable or absent (e.g., Judge et al. 1987, Pullan et al. 1987). Several drilling transects undertaken in the region have illustrated the nature of the onshore-offshore transition for a range of coastal morphological conditions (Dallimore et al. 1988). As described by Dyke (1991), the thermal state of sediment in the nearshore region depends on the period of time during which the sea ice is bottom-fast. In bottom-fast ice (BFI) zones, permafrost can be aggrading (in shallower water where ice becomes bottom-fast early in the winter) or degrading (where water depths are greater and ice does not become bottom-fast or does so later in the winter). Subtle changes in water depth may play an important role in determining whether or not BFI is present, and therefore can make a significant difference in the thermal state of the nearshore

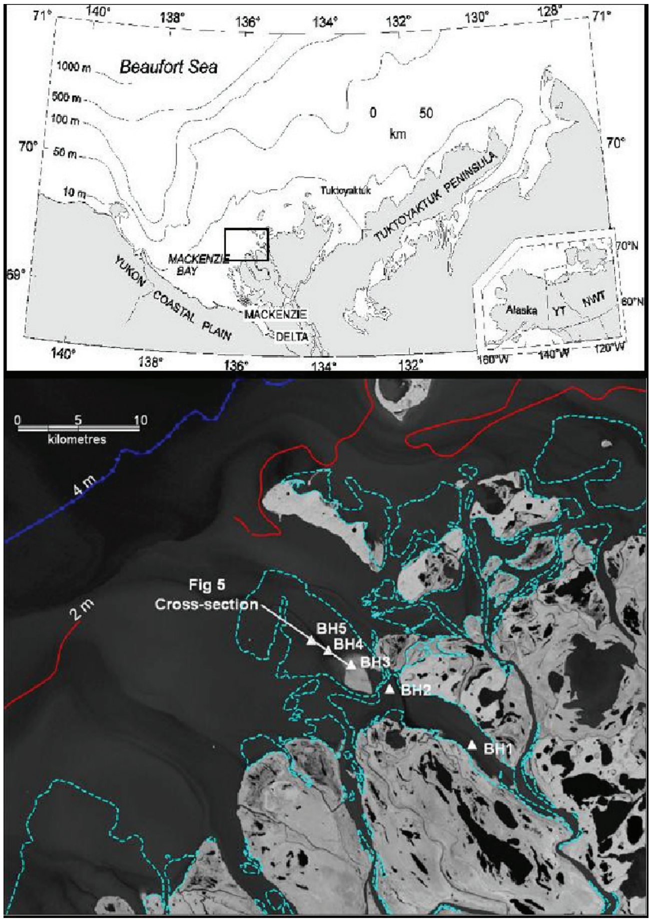

Figure 1 General and detailed location of the study area and boreholes. The Landsat image (lower, composite of summer scenes in 2000-2003) depicts the 2 and 4 m bathymetric contours, the distribution of bottomfast ice (in light blue; as mapped using synthetic aperture radar – Solomon et al. 2005), and the borehole locations (triangles). The 2 m contour is discontinuous due to a lack of data.

sediments since that will determine to what extent (if any) the seabed is coupled through BFI to very cold winter air temperatures (Dyke 1991).

Once the sea ice has become bottom-fast, the active layer above permafrost (or the zone of seasonal freezing) begins to refreeze (e.g., Osterkamp et al. 1989, Dyke 1991, Wolfe et al. 1998). This zone is also characterized by large horizontal spatial variability in temperature and seasonally reversing vertical temperature (Hunter 1988).

Methods

Ground temperature

Ground temperatures were measured in four boreholes drilled to 10 m using a seismic shothole rig. A fifth borehole was drilled in deeper water but not instrumented because of hole problems. Boreholes were located along a transect extending from a partially infilled distributary channel across a large nearshore shoal (Fig. 1). Borehole locations with varying thicknesses of BFI were chosen (Table 1). The boreholes were cased with 2” PVC pipe coupled to 4” pipe for the upper metre. The larger diameter pipe was required to house the 8-channel RBR™ data logger. One borehole (BH3) was completely filled with silicone oil while the remaining boreholes were filled to 7 m (from the bottom). The temperature cable consisted of eight YSI™ thermistors spaced at varying intervals (0.5 m, 0.5 m, 0.5 m, 1 m, 2 m, 2.5 m, 2.5 m) with the uppermost thermistor located approximately 0.5–1.0 m below the riverbed or seabed surface from which all depths are measured; we use the term “seabed” for all boreholes.. An independent temperature logging unit (Vemco™ Minilog) was mounted inside the casing at the seabed surface. Seabed surface temperatures were logged every 3 hours and subseabed temperatures were logged every 8 hours. The YSI thermistors have an accuracy of ±0.1°C and the measurement system can resolve changes in temperature of 0.1°C (S. Smith, pers. com. 2007). The Vemco™ surface temperature loggers are specified to have a resolution of ±0.3°C and an accuracy of ±0.5°C.

Table 1. Borehole characteristics and thermal parameters derived from ground temperature data (2005–06).

			"Depth"	"MAGT$_0$"	"MaxT$_0$"	"MinT$_0$"	"MAGT$_{AL}$"
	Mean BFI thickness 2005-07	Base of ice-bonding (driller)	upper sensor depth	mean annual seabed temperature	maximum annual seabed temperature	minimum annual seabed temperature	mean annual ground temperature at AL depth
	(m)		(m)	(°C)	(°C)	(°C)	(°C)
BH1	0.3	frozen	0.67	0.52	14.83	-17.83	-2.34
BH2	1.0	~5 m	0.60	2.03	14.35	-9.94	-0.28

Borehole positions were surveyed using a geodetic quality global positioning system. The positions were then used to relocate the borehole sites during the recovery of the data loggers.

Finite element geothermal model

Ground thermal modeling was undertaken to investigate the spatial variations in ground thermal conditions that attend BFI, such as the initiation of seasonal seabed freezing and the possibility of the growth of permafrost. The modeling was performed using the software TEMP/W™ (Geo-Slope International Ltd. 2004). This two-dimensional finite-element program combines the physics of heat transfer and phase change in porous media and realistic geologic and temporal boundary conditions to model transient thermal conditions. The model has been verified extensively against analytic solutions and is used widely by the permafrost community.

Boundary conditions, both spatial and temporal, are critical to match observations and for model predictions. The seabed temperatures along the modeled transect throughout the 2005–06 year are crucial “forcing functions” for the numerical model. They were estimated from two sources: (1) the temperature time series from a logger placed at the seabed inside each borehole collar (referred to as BC$_{measured}$), and (2)

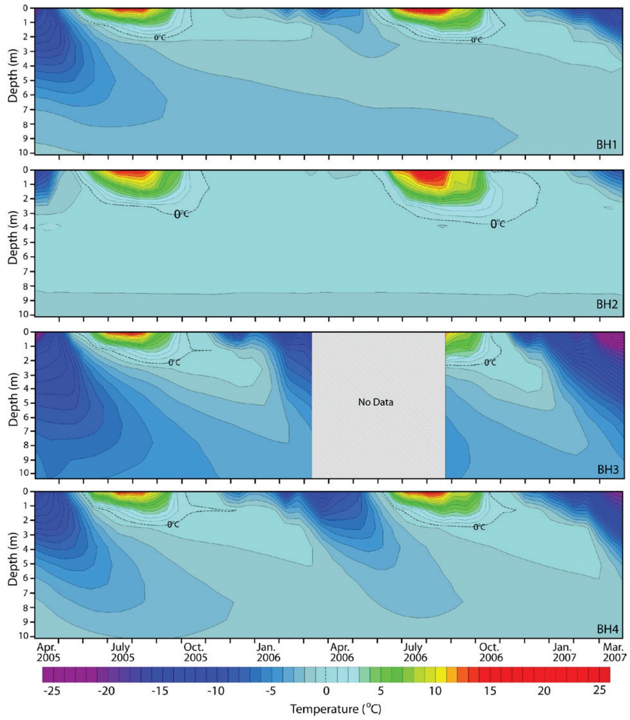

Figure 2 Two years of ground temperature variations for the 4 boreholes are illustrated as depth versus time plots. BH2 (thickest BFI) exhibits the warmest temperatures; BH3 (sub-aerial shoal), the coldest. Part of the data from BH3 is missing due to a malfunctioning data logger.

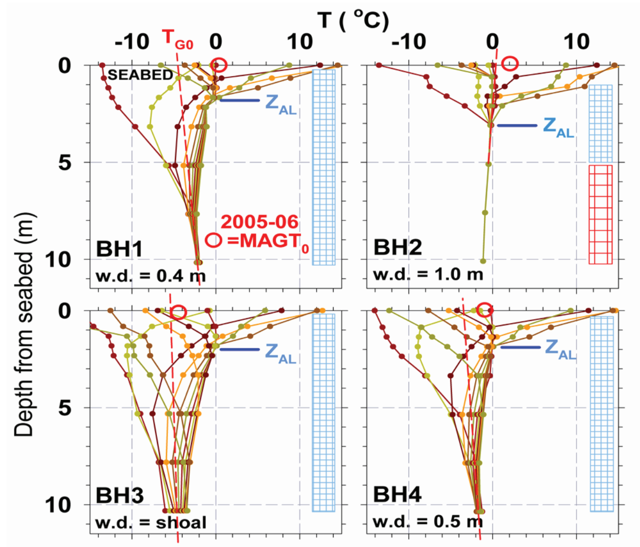

Figure 3 Monthly temperature envelopes for year Mar. 2005 – Mar. 2006 showing diverse character of borehole thermal conditions. Z_{AL}, $MAGT_0$ and T_{G0} are indicated (Table 2). Depth 0 m is at seabed. Hachured, state during drilling: blue = frozen, red=thawed.

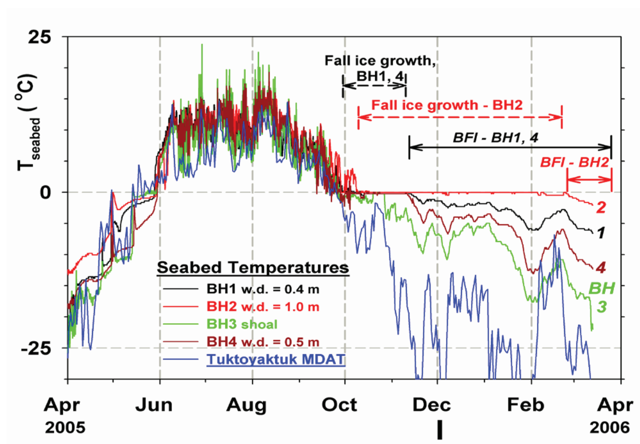

Figure 4 Tuktoyaktuk mean daily air temperatures and seabed temperatures measured at the borehole collars. Onset of fall sea ice freezing (floating), and onset of BFI (grounded) are shown. w.d. = water depth.

a temperature time series developed from Tuktoyaktuk air temperatures, ice thickness growth rates (Menard & Duguay 2006), and near-shore distributary water temperatures (Dyke, pers. com. 2006; $BC_{estimated}$). The first, $BC_{measured}$, is a borehole-specific measurement of temperatures over the periods during which water or BFI covers the seabed along our borehole transect. $BC_{estimated}$ is a regional estimate of seabed conditions based on independent, external data. The latter were used to interpolate conditions between boreholes.

Results

Ground temperatures

The annual ground temperature cycle over the two years of record (2005–2007) is illustrated by Figure 2. Annual ground temperature envelopes ("trumpet curves") calculated from the 2005–06 data were used to calculate a range of parameters pertinent to geothermal interpretations (Table 1, after definitions in Brown & Kupsch 1974).

The general trends in temperature show cooling of the ground in the winter and warming in the spring and summer with illustrated inter-annualinterannual variability. All of the boreholes terminate above the depth of zero annual amplitude and therefore experience changes in ground temperatures that relate to fluctuations in air temperature. The most obvious difference between the four temperature records is the warm and nearly isothermal ground temperatures below 3 m at BH2 (beneath ~1m of BFI) in contrast to colder temperatures at the other three boreholes.

Figure 3 shows plots of mean monthly ground temperatures for 2005–2006 versus depth ("trumpet curves") below the seabed. Permafrost (annual temperatures <0°C, (Brown & Kupsch 1974) underlies an active layer (Z_{AL}) of ~2 m at three of the boreholes (~3 m at BH2, Table 1). Ground temperatures that are below freezing combined with observations made during drilling (March 2005) indicate that the sediments below Z_{AL} in BH1, 3, and 4 are partially or fully frozen throughout the year. Mean annual seabed temperatures ($MAGT_0$) range from ~-4°C on the intertidal shoal (BH3), to >0°C at BH1 and BH2 within the river distributary, and to <0°C offshore at BH4 (Table 1, Fig. 2).

The seabed along the transect experiences a wide range in temperatures, from 14.8°C to -26°C throughout the year,

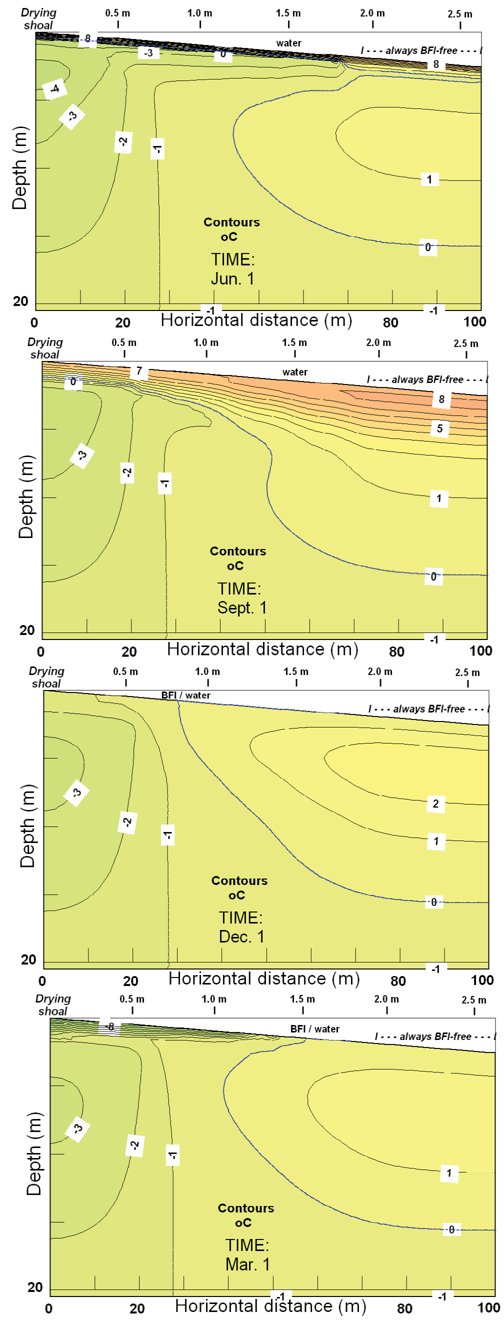

Figure 5 Temperature contours at times indicated for the hypothetical model (using $BC_{measured}$) of linearly increasing water depth (upper scale). The interpreted maximum offshore extent of the seasonal boundary between BFI and a water-covered seabed is shown.

with the greatest annual variation occurring at BH3 where BFI is thinnest (Fig. 4). The rate of change at the seabed is most rapid in the spring coincident with river breakup. As river discharge increases in late May, water overflows onto the surface of bottom-fast ice and under the ice and causes warming of the sea bed. During the open water of summer, the river and seawater are the dominant control on the seabed and riverbed temperatures. During fall and winter, seabed or riverbed cooling occurs more slowly and differs more markedly between boreholes than spring warming. Water cools first to the freezing point, where it remains for several weeks as ice forms. In shallow water, ice becomes bottom-fast relatively early in the winter, allowing low air temperature to penetrate the ice column and freeze the seabed (BH1 and BH4). In deeper water, ice does not become bottom-fast, and therefore, the seabed remains within a narrow range around the freezing point throughout the winter. At intermediate water depths, the onset of BFI is delayed resulting in a shorter duration of BFI than in the shallow water case with proportionally less freezing of the seabed. In the case of BH2, bottom-fast ice conditions were not achieved until mid- February during the winter of 2005–06 (Fig. 4). The late winter ice contact is reflected in the near-isothermal temperatures below 3 m in depth at BH2. Subsequently, freezeback of the active layer also occurs in late winter which results in minimal heat exchange at depth. The following year BFI conditions at BH2 occurred two months earlier (late December), resulting in more rapid freezeback of the active layer and colder shallow ground temperatures (Fig. 2). BH1 and BH4 were bottom-fast early in both the 2005–06 and 2006–07 freeze-up seasons (mid-October to mid-November; Fig. 4). In general, temperatures at the base of BFI correlate with air temperatures but are attenuated to about -2°C to -10°C (Fig. 4).

Numerical modeling

Figure 5 shows the thermal impact of BFI for a modeled scenario in which water depth increases linearly from a shoal to depths beyond maximum seasonal ice thickness. Using a seabed temperature boundary condition based on Figure 4 ($BC_{measured}$) as forcing function, we model the thermal impact on subsurface temperatures throughout the year. An unfrozen seabed is pervasive in summer, with seabed cooling in the fall and nearshore BFI forming in November (compare to Fig. 4). Note how the BFI/seawater boundary moves gradually further offshore during the winter, reaching its maximum extent in late April when sea ice thickness is maximum. In the process, seasonal freezing of the seabed due to BFI develops to ~2 m nearshore and becomes less deep further offshore at the maximum extent of BFI. In May, the spring freshet of warm water floods the ice and detaches it from the seabed, initiating summer open water conditions and thaw of the seasonally-frozen seabed. The effect of BFI is to support offshore permafrost, as indicated by the 0°C isotherms in Figure 5, at shallower sub-seabed depths than in open water areas.

Four zones may be identified in Figure 5: (1) the shoal that is intertidal and over-washed irregularly to create thin BFI, and where frozen sediments occur from the ground surface to >10 m during winter (cf. BH3, Fig. 3), (2) water depths <1/2 of the maximum ice thickness of BFI, where residency of BFI is the longest, and beneath which the permafrost table lies (in this example) at 1 to ~5 m (cf. BH1 and BH4), (3) a transitional zone landward of the BFI-water margin where water depth is somewhat less than the maximum seasonal ice thickness, and (4) water depths > maximum ice thickness where BFI never occurs and beneath which the permafrost table lies deeper (here ~15 m). Note that for a water depth of ~1 m (Zone 3), the model predicts seabed temperatures to be nearly isothermal around -1°C from ~4 to 10 m depth, with a seasonal variation from -8 to +8°C in the upper 4 m. Temperatures at BH2 (Fig. 3) also exhibit an isothermal section <-1°C below 3 m, with a seasonal variation from -14 to +14°C in the upper 3 m.

Discussion

The borehole data presented in this study illustrate the interannual variability in ground temperatures and permafrost conditions within the shallow nearshore environment (Fig. 2) resulting from subtle changes in water depth (Fig. 3). Permafrost *sensu strictu* (<0°C) exists at all boreholes; however, differences in the extent of ice-bonding were found to occur. Drilling data indicates that the sites located beneath the shallowest water (BH1, BH3, and BH4) host ice-bonded permafrost to the maximum drilled depth (10 m), while a deeper water site (BH2) with temperatures marginally below 0°C hosts unfrozen to marginally ice-bonded sediment at depth. Seabed temperatures were found to track variations in air temperature closely with some thermal offset (Fig. 4).

Unique, continuously recorded temperature data collected throughout the fall and winter seasons reveal differences between rates of cooling and warming that are indicative of the processes occurring at those times of year (Fig. 4). Rapid warming at all of the water depths in spring is a response to overflow of warm river water originating at southern latitudes onto the ice surface and eventually melting or floating BFI off the seabed. The relatively slower cooling in the fall is a consequence of ice thickening and the gradual increase in the seaward extent of the zone of bottom-fast ice.

While the borehole temperatures quantify the impact of BFI on the seabed, other unmeasured parameters (sediment type and water content, thermal properties, sediment scour and deposition, snow cover, tidal range, storm surges, etc.) complicate the detailed interpretation of ground temperatures. Numerical modeling of a simplified case provided additional insight into the impact of BFI versus water depth. As described above, the two-dimensional model of a linear increase of water depth in the offshore direction clearly demonstrates the spatial variability of the subsurface thermal and permafrost regime across the complete range of water depths as opposed to the discrete measurements at the boreholes (Fig. 5). Clearly, the impact of residence times of BFI and summer water temperatures on the seabed are primarily a function of water depth. The “end members” are the shoal (thin intertidal BFI) and water deeper than maximum seasonal ice thickness (no BFI and perpetually submarine).

Other investigators have observed similar phenomena. For instance, previous work in the Prudhoe Bay area (e.g., Osterkamp et al. 1989 Osterkamp & Harrison 1982) examined the properties of nearshore permafrost in a narrow bottom-fast ice zone exposed to saline marine waters. They found that development of brines through salt exclusion had a significant effect on the properties of shallow materials. However, as observed in our study, they also noted the presence of an active layer where water depth or ice thickness is about 1.2–1.3 m. Temperature measurements in sediment beneath BFI were made to depths of 2 to 22m in the spring (late May–early June) and fall (November) over the course of one year. These discrete measurements have some similarities to those shown here but lack sufficient temporal detail for in-depth comparisons. The Prudhoe Bay site also differs from our study area in that Prudhoe Bay is far from any major rivers and is in an area of active coastal erosion, where thick onshore permafrost is being transformed into subsea permafrost by erosion and subsequent submergence. In contrast, the Mackenzie Delta study site is likely recording the initiation and evolution of permafrost in an aggradational setting of a freshwater-dominated delta-front of a major river.

A geotechnical investigation undertaken approximately 50 km northeast of the present study site (Hunter & Pullan 1986, Kurfurst & Dallimore 1991) examined ground temperatures across a wide sand flat adjacent to and north of the Mackenzie Delta. A series of 10 temperature cables were installed out to 800 m from the tundra shoreline and were all within the zone of bottom-fast ice. Temperatures recorded in September 1985 and April 1986 show very similar patterns to our data presented above, with a wide range of temperatures at the surface where BFI thickness was relatively thin and a much narrower range where ice was thicker (similar to BH2). Most of their boreholes were drilled to 30 m depth and all were ice-bonded throughout with little annual fluctuation below 12–16 m. Their study differed from ours in that the sand flats are interpreted to overlie older and likely previously frozen material. We believe that our sites are characterized by deposition over unfrozen seabed (based on unpublished drilling results obtained in March 2007).

Conclusions

1. Observations and model results show the importance of the duration of BFI in controlling the temperature regime at the seabed surface.
2. There is a strong seasonality to the influence of BFI with rapid and nearly simultaneous removal of BFI at all four boreholes in spring, and slower, more depth-dependent onset of BFI conditions in the fall.
3. Small changes in water depth causing ongoing natural deposition and erosion or resulting from human intervention (e.g., dredging or trenching) are likely to have dramatic effects on subsea ground temperatures and therefore ice-bonding and permafrost.

Abstract

Some new forms of buried ice and firn were recovered in the section of the Late Pleistocene deposits by drilling in several near-watershed sites (220–250 m a.s.l.) on the Lena-Amga Rivers Plain (Russia, Central Yakutia). The recovered section consists of three separate horizons of ice and firn formations occurring between 2.5, 5.0, 12.0, 17.0, 33.6, and 39.0 m from the ground surface. The ice and firn horizons are divided by strata of epigenetically frozen sandy silts and silts.

Keywords: Central Yakutia; cryolithology; ground ice.

Introduction

During several cryostratigraphical expeditions to Central Yakutia undertaken by the authors in recent years, two boreholes were drilled in autumn 2004 and spring 2005 to the depths of 50 m on the near-watershed areas (220–250 m a.s.l.) of the Lena-Amga Rivers interfluve. The boreholes located, correspondently, 82 km (62°08'N, 131°18'E) and 94 km (62°04'N, 131°33'E) east of Yakutsk (Fig. 1) recovered strata of wedge ice and horizontally layered ice and buried firn divided by silt and sandy silt horizons.

The investigated area is located on the high Lena-Amga plain (200–300 m a.s.l.) which is restricted to the group of plains separating the Central Siberian Plateau and Prilenskoe Plateau. It is situated within the continuous permafrost zone with ground temperatures at the depth of zero annual variations as low as -3°C to -6°C (Ivanov 1984).

In winter the Siberian anticyclone extends over the whole region resulting in falling of winter temperatures down to -50°C–60°C. The mean annual air temperature in Yakutsk is -10.3°C; mean annual precipitation amounts to 250–300

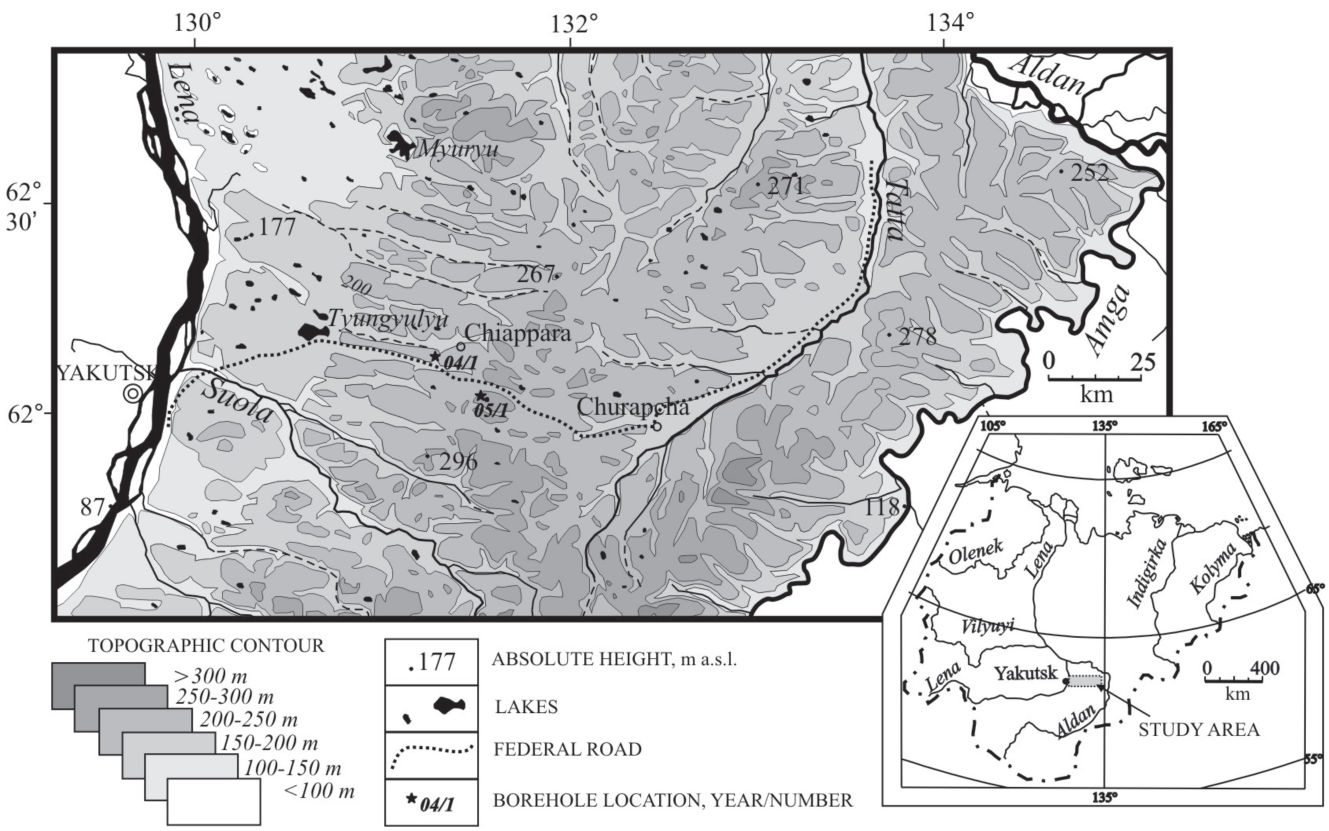

Figure 1. A map view of the study area with the borehole locations within the Lena-Amga Rivers Plain (Central Yakutia).

mm, and the height of snowpack varies between 5–30 cm (Fundamentals 1998). The permafrost thickness may be as much as about 300 m (Ivanov 1984). The upper 150 m of the geological section is loose Quaternary deposits.

According to previous investigations (Solov'ev 1959, Structure 1979, Katasonov 1975, Péwé and Journaux 1983, Ivanov 1984, Spektor & Spektor 2004), a unified stratum of ice complex containing ice wedges and structure ice is widespread on the areal surface. By different accounts the depths of ice complex with syncryogenic ice wedges vary between 10–30 m (Fundamentals 1998) to 50–60 m (Ivanov 1984).

In the course of studies made in 2004–2005, we observed new, not earlier noted, horizontally layered "sedimentary" types of ice, as well as poorly metamorphized buried firn and delineated a rhythmical texture of the upper permafrost section. Probably, similar formations were indicated by P.A. Solov'ev (1959) on the watershed of the Tatta and Amga Rivers (Central Yakutia), which he referred to the category of segregation ice. Later, the same ice forms encountered by P.A. Solov'ev were classified as buried icings (Shpolyanskaya & Streletskaya 2004).

Observation

A most complete and deep section including various forms of buried ice was observed in the borehole drilled in 2004, 82 km east of Yakutsk. The drilling was conducted, successively, by core barrels with reamer bits 147 mm, 127 mm, 108 mm, 89 mm, and 76 mm in diameter. Using air blowing, the core recovery from coring tubes was easy, and the preservation of thin cryostructures inside the core was good. The crushed ground portions up to 20 cm in thickness, caught during tripping process between well-preserved cores, were in a melted state and clearly differed from the rest of the core.

The studied section comprises three irregular intervals of ice and firn formations: upper (2.5–5.0 m from the ground surface), middle (12.0–17.0 m), and lower (33.6–39.0 m) divided by horizons of epigenetically frozen silts and sandy silts. The description of this section is given below. The second borehole drilled in 2005, 94 km east of Yakutsk, recovered buried firn and ice at a depth of 2.8–8.2 from the surface. By its stratigraphic position and cryolithological peculiarities, this horizon can be correlated to the interval 33.6–39.0 m of the 2004 borehole.

The upper ice horizon (2.5–5.0 m) is represented by ice wedge ice. The cored ice wedge had width of not less than 30 cm, and thickness of not less than 2.5 m. The wedge ice is semitransparent and yellowish. It exhibits a vertically layered structure with bands containing different amounts of mineral and organic matter and gas bubbles. The widths of the vertical bands are 1–2 cm.

The middle ice horizon (12.0–17.0 m) is represented by thin, horizontally layered, fine-crystalline and, rarer, coarse-crystalline ice (Fig. 2A). The formation of this type of ice is associated with recrystallization of snow.

The ice has a complex multi-ordered layering. It consists of several packs of layers including: 1_{M*}) packs of clean micro-layered firn, 3–5 cm in thickness, 2_M) packs of thin-layered mineralized firn, 1–2 cm in thickness, and 3_M) packs

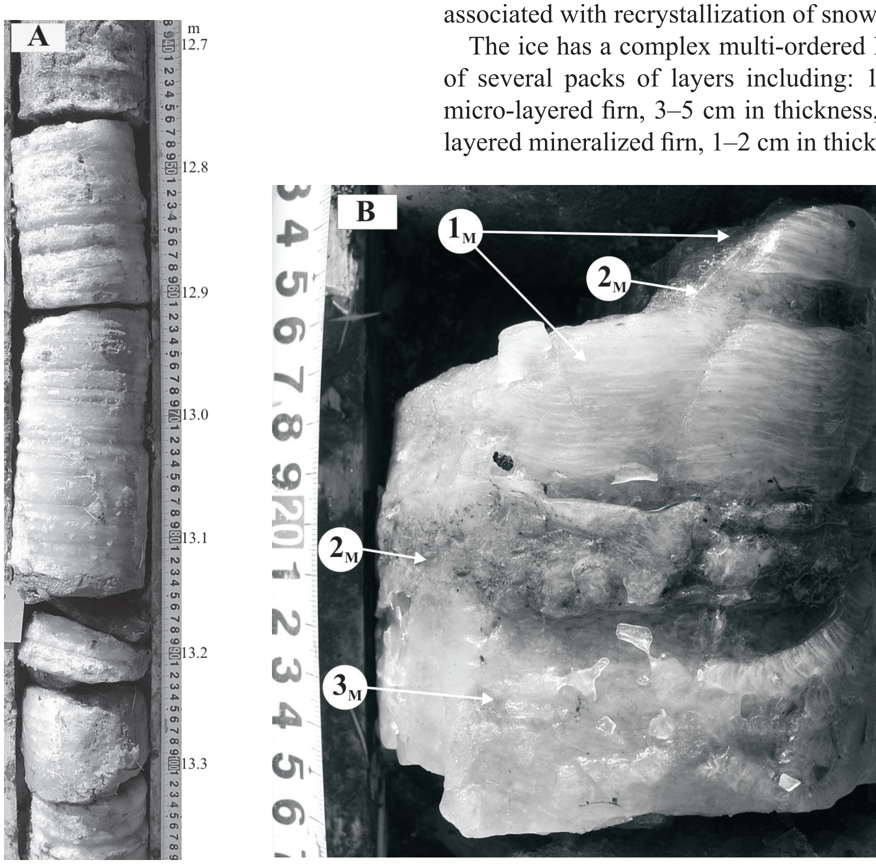

Figure 2. A – The ice core from the middle horizon represented by the horizontally-layered ice (firn) in the interval 12.7–13.4 m from the day surface. B – The multi-ordered layering of ice in the interval of 13.75–13.85 m from the day surface. Index explanation is given in the text.

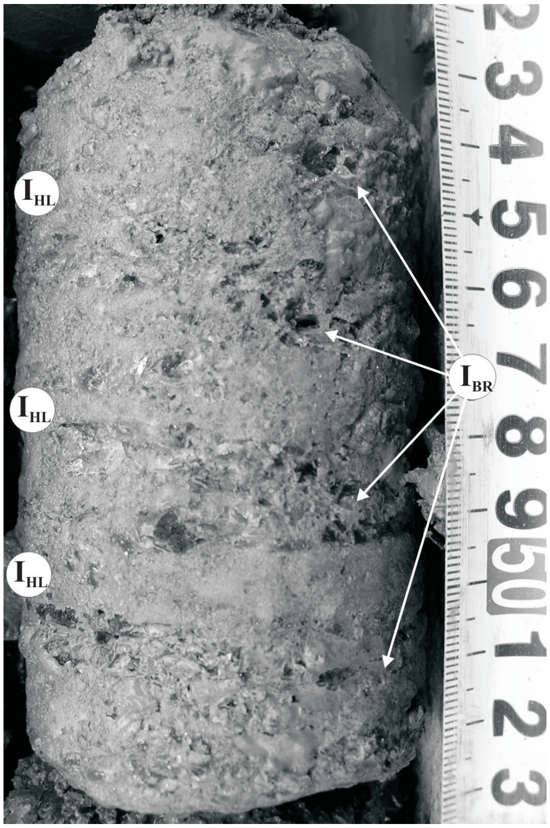

Figure 3. The alternation of ice breccia (I_{BR}) and horizontally-layered ice (I_{HL}) from the lower ice horizon in the interval of 34.02–34.13 m from the day surface.

of brecciated and coarse-crystalline firn, 1–4 cm in thickness ($*_M$ – index of layers, see Fig. 2B).

Separate interlayers of the brecciated and coarse-crystalline firn are 1–3 cm. They consist of partially-melted and rounded crystals of ice of round- or right-angled form up to 5 mm in diameter. Also, sectors with vertically orientated ice crystals, as well as hollows 1 cm in height and several cm in width are marked here.

The lower ice horizon(33.6–39.0 m) consists of big layers with different cryostructures. The upper part of the interval is divided into the layers of 1) horizontally-layered milky fine-crystalline ice (33.60–33.75 m), and 2) the alternation of ice breccia (Fig. 3, index I_{BR}) and horizontally-layered ice (33.75–34.50 m) (Fig. 3, index I_{HL}).

The ice breccia, mineralized in more or less extent, consists of pieces of fine-crystalline ice from the first to 15 mm in size. The pieces are acute-angled, rarer elongated and partly melted. The breccia cement represents milky, semitransparent, coarse-crystalline ice containing mineral particles. The cryostructure of the breccia interlayers is likely massive-agglomerate. The thickness of separate interlayers is 1–3 cm, up to 5 cm in the upper part.

The alteration of horizontally layered mineralized ice bodies and icy silts (ice-ground) is developed down the section (33.5–35.5 m). The layers are often lens-shaped, having first cm in thickness.

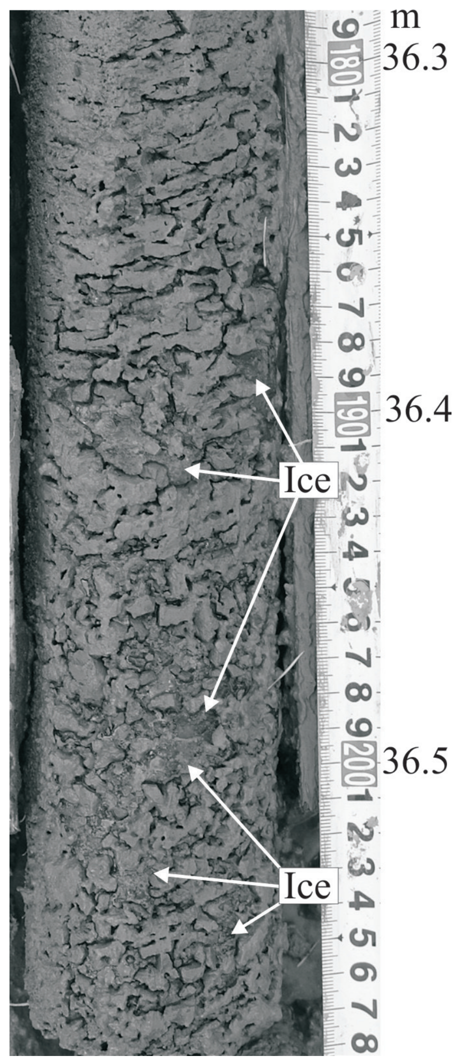

Figure 4. Ice-ground in the interval 36.30–36.58 m from the day surface. Ice, partially melted from the surface, forms the lens-braided structure in the enclosing bluish-grey silts.

Ice-ground with lens-braided cryostructure predominates in the lower part of the interval (35.5–39.0 m) (Fig. 4). This type of ice likely formed due to syncryogenic freezing of unconsolidated silty sediments from a downward direction (Fundamentals 1996).

The uppermost ice horizon is overlain by a stratum of homogeneous yellowish silts, which is developed under a thin soil cover to the depth of 2.5 m. The intervals of 5.0–12.0 m and 17.0–33.6 m are represented by strata of epigenetically frozen silts and sandy silts. A coarse, latticed cryostructure with a predominance of vertical lens ice is characteristic for them. Ice lenses are thicker (up to 3 cm), more frequent, and longer in the layers bedding directly above the ice horizons. The density and thickness of ice lenses decline upward along the section, which becomes almost iceless in the upper parts of these strata. A thin horizontal lens cryostructure appears at the upper contacts with the overlying ice horizons.

Conclusions

In our opinion, the horizontally layered ice strata of the middle and lower ice horizons had formed on the ground surface and present, probably, buried snow fields in contrast to "buried icings." This is supported by their high position on the Lena-Tatta Rivers watershed. The modern icings of the region are, as a rule, restricted to valley bottoms or watershed slopes foot. Besides, these formations are not remnants of modern perennial snowbanks because they are buried under thick (more than 10 m) ground strata. The overlying strata have spore and pollen complexes characteristic of the Late Pleistocene deposits of the region. The presence of various buried firn, ice, and ice-ground formations in the upper portion of the Lena-Amga Rivers plain loose cover points to a more complex, than it was supposed earlier, history of the cryolithozone evolution in the study area.

Recent Advances in Permafrost Geotechnics

S.M. Springman
Institute for Geotechnical Engineering, ETH Zurich, Switzerland

L.U. Arenson
BGC Engineering Inc., Vancouver, Canada

Abstract

Tribute is paid to progress in Permafrost Science and Engineering, from a geotechnical point of view, since the Millennium. Advances and concerns will be presented, embellished with thoughts about geotechnical aspects of the Ultimate and Serviceability Limit State requirements for cold regions infrastructure "Soil Structure Interaction," to be able to answer the challenges posed by climate change on a warming planet. Improvements and new developments have been described, briefly, for laboratory testing, physical and coupled numerical modeling. However, recent research progress in geotechnical aspects has not always permeated into practice, and a fundamental need remains to develop, calibrate and validate fully coupled thermo-hydro-mechanical models. This short review paper does not claim to cover all research and developments and will attempt to summarise topical findings in cold regions geotechnics.

Keywords: field Investigation; laboratory testing; modeling, permafrost engineering; review.

Introduction

This paper was commissioned to focus on geotechnical advances in Permafrost Science and Engineering, which can not be decoupled from the effects of global climate change. This has dominated recent work, as researchers seek ways of identifying the hazards to infrastructure in cold regions (ACIA 2005, IPCC 2007, U.S.A. RCPTF 2003), to establish distinct uncertainties through a risk based consideration of sensitivity and consequences and thereby mitigate the risk of permafrost degradation (e.g., Hayley & Horne 2006).

Reliable climate modeling on a regional scale for 30 to 100 years in the future is essential, as geotechnical engineering should also play an important role in integrated strategies. Designers of new infrastructure or rehabilitation measures wish to guarantee that both Ultimate (failure: ULS) and Serviceability (deformation: SLS) Limit States will be achieved throughout the life cycle of their project. Allowable deformations will be dependent upon the structure concerned. Allowable movements are more restrictive for a machinery hall than for a "flexible" pipeline that can sustain greater average and differential settlements.

Hayley & Horne (2006) condemn broad generalisations, which they comment are misleading. The same is true with geotechnical aspects. Each project must be treated on its own merits, to the level of detail required. Some progress has been made on long term solutions to practical issues relating to "Soil-Structure-Environment Interaction." This paper argues that significant fundamental work still remains to be done on geotechnical issues, and outlines contributions required over the next quadrennial. Examples are cited from mainly northern hemisphere polar and mountain permafrost: from America, Canada, Russia, China and Europe.

The authors recognise early literature on topics discussed herein, and have elected to concentrate on recent progress. References of earlier works are in the publications cited.

The Influence of Climate Modeling

When designing structures, engineers are challenged with forecasting future trends in soil properties over the entire expected lifetime. Since the deformation behaviour and strength of foundations in frozen soils depend on soil temperature (e.g., Arenson et al. 2007a), some predictions are required of combinations of permafrost temperatures, active layer thicknesses, freeze thaw cycles or frost penetration. Ultimately, all these parameters, of which further technical detail can be found elsewhere in this conference volume, depend on the climate and hence geotechnical engineers have to understand the strengths and limitations of climate models. Climate trends predicted by such models not only influence the design method, but also form the basis for site investigations and/or monitoring that has to be performed.

In addition to air temperatures, precipitation strongly influences the ground temperatures, and this has increased in toto over the past century, at a rate of about 1% per decade (ACIA 2005, Instanes 2006). Trends in precipitation are hard to assess because precise measurement is difficult in the cold arctic environment. Snow cover extent around the periphery of the Arctic also appears to have decreased.

The latest IPCC report (IPCC 2007) summarises past permafrost and snow conditions, with temperature increasing at the top of the permafrost layer in the Arctic by $\leq 3°C$ since the 1980s. The permafrost base has been thawing at a rate ranging up to 0.04 m/yr in Alaska since 1992 and 0.02 m/yr on the Tibetan Plateau since the 1960s. Permafrost degradation is also causing changes in land surface characteristics and drainage systems. Furthermore, snow cover has decreased in most regions, especially in spring and summer. Where snow cover or snowpack decreased, temperature often dominated; where snow increased, precipitation almost always dominated, reflecting the feedback between snow and temperature. Decline in snow cover area in the mountains of western North America and in the Swiss Alps has been greatest at lower elevations.

Even with physical evidence of ground property changes, predicting the future is challenging. Global climate models (GCMs) do not represent permafrost dynamics and potential critical feedbacks on climate. Nicolsky et al. (2007) and Alexeev et al. (2007) evaluate the land surface scheme Community Land Model (CLM3), against observations, and identify potential modifications to improve fidelity of permafrost and soil temperature simulations. Soil thickness should be > 30 m, to compute annual temperature dynamics cycle for cold permafrost. Decadal-to-century time scales require significantly deeper soil layers, e.g., > 100 m.

Vegetation changes and thermal disturbances in lowland permafrost environments due to forest fire activities, lead to increased active layer depth through reduction of the insulating quality of the surface and potentially greater likelihood of instabilities (Anisimov & Reneva 2006, Dyke 2004). This further complicates prediction of future ground temperature trends and hence the effect on frozen soil properties (Yoshikawa et al. 2003).

Site Investigation and Monitoring

The basis of any geotechnical input is an effective mixture of site investigation and monitoring of response to environmental conditions, especially of deformations in conjunction with thermal details. More progress has been made in the latter area than the former recently, although there remains significant potential for in situ tests in fine grained permafrost, in more advanced forms, or as combinations of pressuremeter, cone penetration (e.g., Buteau et al. 2005, with seismic measurement LeBlanc et al. 2004, 2006) or dilatometer testing in order to determine selected soil parameters such as shear strength, small and large strain stiffness for subsequent modeling. Obtaining basic classification data from disturbed samples, without mineralogical or strength testing, is currently the industry standard (e.g., Couture et al. 2000), with thermal properties estimated empirically from earlier consulting reports.

Sometimes, insitu permeability tests may be helpful if drainage conditions in degrading permafrost are relevant. Using probes to determine associated thermal properties is also advantageous (Overduin et al. 2006). However, thermal disturbances due to drilling, or through variations in thermal contact resistance between sensor and soil, make insitu determination of these properties challenging.

Samples must be extracted with minimal disturbance in terms of melting of the frozen phase and rearrangement of soil grains, and protected during transport for storage and subsequent testing in the laboratory for obtaining accurate soil parameters for constitutive modeling (e.g., Arenson & Springman 2005b). While this does not necessarily pose significant difficulties in polar permafrost, inevitably, this is further complicated by altitude and the blocky nature of the soils encountered when dealing with mountain permafrost. Despite additional expense during drilling, further studies are required on natural soil samples under permafrost conditions to investigate responses under selected stress-strain paths, suitable for a slowly warming environment from below to above zero °C (see laboratory testing).

Geophysical approaches are now common for spatial determination of frozen/unfrozen zones (Hauck et al. 2007, Kneisel & Kääb 2007, Maurer & Hauck 2007, Wu et al. 2005, Musil et al. 2002). Tomographic inversion techniques are adopted to reveal ground structure and for monitoring thaw in the seasonal active layer (Hauck et al. 2003, Ribolini & Fabre 2007). The challenge is to determine geotechnical parameters. This is possible through seismic approaches, although the small strain stiffness obtained can not represent stiffness over the entire strain range to failure and particularly less so in a creeping soil. Consequently, adopting geophysical approaches to determine a ground model and associated parameters is not the sole solution.

In parallel with site investigations, it is essential to plan monitoring experiments to deliver optimal data for design decisions, considering geotechnical aspects in conjunction with predictions of the conditions pertaining over the lifecycle. Monitoring should be used for design of a structure and as a part of ongoing observation that regulates future maintenace requirements. A conservative prognosis should be made of lifetime deformations, including surface deformation fields (e.g., Kääb et al. 2007, Kääb et al. 2005) as well as the deformation fields and structure (e.g., Arenson et al. 2003, Hausmann et al. 2007). GTN-P, CALM, PERMOS 2000-4 provide data of standard temperature measurements with depth, and will not be discussed here.

Inclinometers are effective only when they are able to move with the surrounding soil and when a measuring probe is able to pass through the deflecting tubing (Arenson et al. 2003). Shearing of the tube may occur eventually in slopes demonstrating considerable creep. Recent advances have been made by using TDR cables in a rock glacier to locate a concentrated creep zone, but the data are inconclusive, and the magnitude of strains can not be measured. Novel techniques for fibre optic strain measurements in boreholes, are becoming available and might be valuable in the future.

Laboratory Testing

Some recent papers report the mechanical properties of alpine permafrost both in a natural state (undisturbed) or reconstituted from soil particles extracted by “undisturbed” sampling in boreholes (Vonder Mühll et al. 2003, Arenson et al. 2004, Arenson & Springman 2005a). Issues remain about selecting an appropriate laboratory test to represent stress history and path, as well as to allow for sample heterogeneity and size effects. Interface tests have also been carried out on ice filled joints and between active layer and underlying permafrost (Günzel 2008, Rist 2007, Arnold et al. 2005). Additionally, thermal properties are required to be able to carry out integrated “thermo-hydraulic-mechanical” (THM) modeling, although their determination is well established and will not be discussed further in this paper.

Triaxial testing

Triaxial constant strain rate and constant stress tests have been performed on artificially frozen soil specimens as well as samples won from, for example, rock glaciers (Arenson et al. 2004, Arenson & Springman 2005a). Mainly two types of tests were carried out: constant strain rate (CSR) and constant stress, creep (CSC) tests, to study the effect of the volumetric ice-solid-air fractions, temperature, strain rate and also confining stress on the mobilised shear strength.

Peak shear strengths of artificial samples increased with lower volumetric ice content and faster strain rates. Loading conditions influenced modes of deformation and eventual mechanical failure. The existence of significant percentages of air within the frozen matrix changed mobilised stiffness, strength and volumetric response from ongoing dilatancy, interlocking particles, higher stiffness and strength, in conjunction with increasing volume and rubblisation (see Yasufuku et al. 2003, Da Re et al. 2003 for artificial samples with no air) to lower stiffnesses and strength, with ductile contraction (Arenson & Springman 2005a).

Hydrate bearing soils are important because they contain natural gas (energy resource), and function as a source or sink for atmospheric methane, which may influence global warming (Brouchkov & Fukuda 2002). They are suspected to be a potential factor in the initiation and propagation of submarine slope failures (Anuruddhika & Grozic 2007, Nixon & Grozic 2007). Determining geotechnical properties of such "gassy" deposits may prove to be much more important in future. Tomographic imaging techniques (e.g., Calmels & Allard 2004 determined gas content) offer potential for integration into geotechnical laboratory studies on frozen soils. Other recent advances focus on improved methods of examining cylindrical sample response through the entire stress strain range in triaxial compression, under confining pressures as great as 20 MPa, by including small strain measurement (Da Re et al. 2003) or with radial laser measurements (e.g., Messerklinger & Springman 2007).

Interface testing

Arnold et al. (2005) conducted direct shear tests on active layer material from a 38° rock glacier slope (Pontresina-Schafberg), in support of Rist (2007). Significant dilation under low normal stresses was obtained for elongated rough particles excavated within the active zone, mobilising maximum angles of friction > 60°, and confirming that the active layer was stable for insitu conditions. Replacing the bottom half of the shear box with smooth clean ice reduced the interface friction to just over 30°. It is unlikely that such a smooth surface will form during annual freezing and thawing processes at the base of the active layer. Reliable interface friction values will lie between these two limits.

Rist (2007) created an inclinable sled model filled with active layer material to slide on a permafrost surface to investigate the shear resistance and hence to determine an interface friction angle. Grain size and volumetric water content of an artificial active layer and the degree of ice saturation of the permafrost were varied, with the latter proving to be the most important influencing factor. Soil grains embedded in an ice matrix at the permafrost surface increased the mobilised friction angle by 8° compared to a dry permafrost block, without ice. This implies a probable long term decrease of the active layer slope stability in alpine permafrost terrain under warming conditions.

Günzel (2008) carried out direct shear tests on analogue models of ice filled rock joints to determine the temperature dependent strength. She confirmed earlier findings by Davies et al. (2003) that the strength is lowest for temperatures fractionally below 0°C.

Physical Modeling

Physical modeling offers good opportunities to expose mechanisms of deformation and failure in frozen soil and in interaction with structures. Harris et al. (2003) summarise scaled, centrifuge modeling experiments in fine sandy silt, designed to simulate multi cycle thaw-related gelifluction. They concluded, from considerations of scaling laws, that flow was elastoplastic in nature with a "flow" law based on the "Cam Clay" constitutive model for soils, in which frictional shear strength is dependent on effective stress. Response was not time dependent and viscosity controlled.

Stability of model ice filled jointed rocks has been studied in a geotechnical centrifuge by Davies et al. (2003). Warming rock joints through permafrost degradation can lead to increased instabilities and rock fall events in high mountain permafrost areas. This trend was also noted by Gruber et al. (2004) and Gruber & Haeberli, (2007), who studied Alpine rock walls, and Schwab et al. (2003) for rock avalanches in West Central British Columbia, Canada.

A further series of centrifuge tests (Günzel & Davies 2006) was performed with an ice filled joint within a model rock slope, reinforced by rock bolts, and allowed to thaw. The slope was instrumented with thermocouples, displacement transducers and load cells for observation of stress development and movement during the experiment.

The combination of centrifuge experiments and direct shear tests confirmed that warming of ice inside a joint critical to the stability of a slope could lead to slope failure, even if the slope had an initial safety margin of over 200%, when the joint was filled with "cold" ice or was dry. Reinforcing a slope with pre-stressed bolts should be effective, although the bolts would need to be tested regularly in practice in case of loss of tension during joint closure. The findings from these experiments may offer a valuable means of mitigating the consequences of slope failure in high mountain areas, if the thickness of permafrost ice inside a joint can be assessed and measurements of temperature, displacement, and bolt tension are carried out regularly. Validation of these results with instrumented field tests would be most valuable.

Coupled Modeling

Constitutive and numerical modeling

Existing geotechnical models have become increasingly complex as demands to represent specific aspects of soil response become essential when designing to ULS and SLS. Mohr Coulomb approaches based on one value of cohesion and angle of friction are too simplified to account for the effects of temperature, strain magnitude and rate, relative density and opposing effects of dilatancy and crushing.

Various forms of elastoplasticity offer a modeling basis for coupled thermo-hydro-mechanical (THM) response of soils and rocks. Significant improvements are due to long term investment from the unsaturated soil community (e.g., Sánchez et al. 2002, Khalili et al. 2000). Hydromechanical (HM) aspects are well reproduced by critical state concepts of plasticity. Models for surface cracking at low stresses have also been presented in the literature.

Thermal aspects have mainly been related to temperatures > 0°C, e.g., for radioactive waste disposal. Phase change around 0°C is not covered, although applications such as ground freezing offer interesting perspectives. The representation of thawing and freezing under variable groundwater flow regimes is well modelled (e.g., Pimentel et al. 2007). However links to volume change, ice lensing and the related mechanical behaviour are not yet established.

Recent creep modeling (e.g., Haeberli et al. 2006, Arenson & Springman 2005a) is able to represent time dependent deformations, however, imposing a valid failure criterion remains somewhat empirical. Since large strains have a significant influence on the mobilised strength of frozen geomaterials, establishing insitu strain states is necessary when analysing stability of frozen slopes.

While TH modeling has advanced from one up to three dimensions (Liu et al. 2006), more advanced approaches, (e.g., Zhang et al. 2007a, who couple water flow and heat transfer in soil with water phase change) may still only be available in 1D to date. This can be problematical when the prototype "structure" investigated is multidimensional.

Despite new findings from laboratory and field investigations, no novel constitutive relationships have been presented in recent years for frozen soils. Often only one or two dimensional solutions are adopted, when reality is three dimensional. It is no surprise then that limited progress has been made in developing new numerical models. To the authors' knowledge, none exist for practical engineers to couple thermo-hydro-mechanical processes fully. Mostly, only two elements are modelled and used as an input in the third. Future research efforts should therefore focus on such coupling. Realistic risk assessments in permafrost environments due to changing climatic conditions can benefit significantly from simulation of transient conditions under varying boundary conditions that continuously alter thermal, hydrological and mechanical soil properties. It is important to remember that a true risk analysis incorporates the variability in the predictions, which is extremely challenging for cold region climates.

Challenges for continuum analysis methods lie in the inability to model penetration installation effects or to deal with tension cracking and discontinuities. Future advances are expected in discrete element modeling, in conjunction with validation from physical modeling or field monitoring.

GIS-based modeling

GIS technologies are increasingly powerful and have recently been used for risk assessments or as visualisation tools (Giardino et al. 2004, Heggem et al. 2006, Kneisel et al. 2007, Romanovsky et al. 2006). However, they are only as powerful as the constitutive relationships and the risk determination behind the GIS model when they are used for more than visualisation or database purposes. Insufficient information on the complex interaction between the atmosphere and the ground currently limits the area of applications, which would be a helpful instrument for stakeholders and decision makers.

Phenomena

Frost heave

Frost heave presents severe challenges to owners of infrastructure threatened by temperature and groundwater dependent volume change. Segregation potential or the discrete ice lens theory are still used in practice to estimate frost heave. However, ongoing developments in the laboratory are generating opportunities to achieve greater certainty about soil parameters derived (e.g., Konrad 2005).

Côté & Konrad (2007) demonstrate the use of a heat balance model at the freezing front to compute the frost depth and the frost heave as a routine tool for moderately cold regions pavement designs based on the concept of segregation potential. Studies on the influence of fines on the frost susceptibility of base-course crushed aggregates showed that for a given kaolinite fraction, the segregation potential increases linearly with fines content, until the fines create a matrix in which the coarser particles are embedded (Konrad & Lemieux 2005). Uthus et al. (2006) present frost heave data showing sensitivity, with significantly different heave rates for almost equally graded materials. The occurrence of temperature induced vapour flow in a non-frost-susceptible granular material of pavement base layer was studied by Guthrie et al. (2006). Their laboratory tests demonstrated increased water contents, which may lead to frost heave and thaw weakening behaviour typical of that associated with water ingress through capillary action.

Based on freezing tests on small physical clay models tested under 1g as well as in a centrifuge, Han & Goodings (2006) confirm that low permeability clays experience closed freezing conditions that limit the frost heave.

Improvements in measuring techniques led to detailed observations of ice lens formation and driving mechanisms behind frost heave. Water migrated through the frozen fringe from the unfrozen soil towards the warmest ice lens, while colder ice lenses continued to grow without access to the unfrozen zone, because water was sucked from soil beds between ice lenses (Arenson et al. 2006, 2007b).

Application to road pavements has confirmed again from case histories that frost heave contributes to thermal cracking and unstable permafrost (Dunn & Gross 2006, Mills et al. 2006, Doré et al. 2006). The number of freeze thaw cycles combined with precipitation, particularly on low volume roads in seasonal frost areas, plays a role in the vulnerability of this type of lifeline (Kestler 2003).

Impurities within frozen soils may change thermo-mechanical behaviour completely. Hydrocarbons affect soil properties, such as the unfrozen water content (Siciliano et al. 2007), or the permeability of the permafrost and how contaminants spread (Fourie et al. 2007). They change not only contaminant transport but also the frost heave behaviour of a soil, because chemicals may alter the availability of unfrozen water to migrate towards the freezing front. Laboratory investigations and theoretical considerations have demonstrated the relevance of pore water chemistry on frost heave potential and ice formation (e.g., Beier et al. 2007, Vidstrand 2007, Arenson & Sego 2006b, Arenson et al. 2006, Torrance & Schellekens 2006).

Slope stability

Local physiographic landforms will experience different modes of failure in slopes, despite the same temperature change signatures. Thickening of the active layer and subsequent detachment failures, formation of taliks, debris flows, bi-modal flows, retrogressive slumps, deep seated rotational slides are some of the failure modes reported recently by authors in China, Canada and Russia (Chenji et al. 2006, Wei et al. 2006, Lyle et al. 2004, Dyke 2004, Mazhitova et al. 2004). The presence and exposure of massive ice that released moisture into the slope was found to be critical during permafrost degradation.

Wei et al. (2006) also investigated thaw induced gelifluction in cut slopes along the Qinghai Tibet railway. Thaw slump and retrogressive debris flows developed after only one year, causing unexpected damage to the lifelines. Local erosion due to floods, waves or sea ice (e.g., at lake margins or undercutting coastal tundra blocks; Forbes 2004) or the influence of clay and mineralogy should also be accounted for. Dyke (2004) discussed the loss of both thickness and cohesive strength in an ice bonded surface layer that cracked in tension, due to thaw settlement initiating bending in the ice slab.

Such events are episodic and of a spatially discontinuous nature. Future global climatic conditions will influence site-level slope stability and require transcendence of multiple levels of uncertainty and complexity (Huscroft et al. 2004).

As in any unfrozen geotechnical system, pore water is also the critical element in frozen soil mechanics. An understanding of the pore water pressure response in thawing permafrost is key to ensuring the slopes along linear structures such as roads, railways and pipelines, remain stable. Analysis of over 20 years of pore water pressure data from the Norman Wells pipeline suggests that the sites monitored encountered lower excess pore water pressures than expected and that many slopes experienced long-term drainage as the permafrost degraded (Oswell et al. 2007). Likewise, pore pressure changes induced by sea level rise in coastal regions will cause reduced effective stresses and hence lower stiffness and strength.

But also in other permafrost environments, large slope failures, mainly active layer detachments (e.g., Lewkowicz 2007), are observed that may jeopardise engineered structures. In addition, thermal regime changes can cause slope instability to develop so that mitigation measures must be implemented (e.g., Niu et al. 2005). Field studies on solifluction processes, currently ongoing in Svalbard, highlight the correlation between thaw consolidation, reduced effective stress and pore pressures in the active layer (Harris et al. 2007). These data confirm earlier field measurements by Kinnard & Lewkowicz (2005).

Simple decoupled analyses can be carried out using a combination of conduction and convective heat flow caused by water flow in the active layer. Limit equilibrium slope stability analyses can then be used to examine the effect of degrading permafrost and different water regimes on a traditional global factor of safety. However, neither these nor coupled finite element analyses can represent large strain problems close to the ULS and caution is required in the analysis of the results. Back analysis and verification with field mesurements are crucial in the interpretation of such numerical simulations.

Natural convection

Some progress has been made in numerical TH modeling of natural convection in granular soils in cold regions to demonstrate the cooling generated in embankments or heaps of coarse stones (e.g., Cheng et al. 2007, Lebeau & Konrad 2007, Sun et al. 2007, Arenson & Sego 2006). Ventilation properties (He et al. 2007), wind direction (Zhang et al. 2006, Pham et al. 2008) and embankment surface permeability, geometry of slopes, layers and revetments (Klassen et al. 2007, Sun et al. 2007, 2005, Lai et al. 2004) influence the convection potential, and conditions should be optimised to promote cell formation.

Winter convection effects benefit from embankment surface air permeability, and largely eliminate the 0°C horizon within the subsoil, even after a few summer seasons, apart from at the embankment toe. Davies et al. (2003) have already pointed out that temperatures even marginally below 0°C can still be critical. So, geotechnical implications are that stiffness and strength are raised through reduction of the underlying thaw bulb. Settlements and possibility of failure decrease and the embankment system will be more sustainable, with reduced maintenance costs over the lifetime of the structure. However, load transfer inside embankments brings greater loads onto the toes through arching (e.g., Ellis & Springman 2001), coinciding with zones marginally softened by partial thawing. This must be allowed for in predictions of relative settlement (SLS).

Sun et al. (2005) recognise that reality differs from numerical assumptions made, although many simulations are supported by laboratory and field investigations (e.g., Zhang et al. 2006, 2007a, b, Yu et al. 2006, Goering 2003). Indeed, there is some danger in performing numerical experiments without due consideration of geotechnical effects such as abrasion and long term, often cyclic, mechanical and clastic effects in dense, coarse grained fill (e.g., McDowell 2003). For example, compaction is essential during construction to densify the fill and minimise subsequent settlement. This will cause dilatancy on shearing as well as abrasion and crushing of the coarse stone layers and possible cyclic shakedown (settlements) in long term (Festag 2002). This will lead to fouling, whereby smaller particles will trickle down through the voids creating anisotropy, particularly in respect of water and air permeability in the fill, and will block development of the convection cells over the lifetime of the structure. In addition, layers of low air permeability that form during construction change the formation of convective cells, hence the cooling effect of the embankment/pile. Even though innovative solutions might be derived from numerical modeling with adjacent layers of coarse and fine grained material, the fundamental basics of soil mechanics must not be forgotten, such as maintaining filter relationships to prevent internal erosion.

Soil Structure Interaction – SLS & ULS

Soil Structure Interaction (SSI) represents the inter-dependent reaction between ground and structure, in which both ULS and SLS must be assured. Foundations for typical infrastructure, including linear structures such as pipelines, road pavements, railway beds, communication cables, electrical power lines, or more two dimensional loading problems typical in oil tanks, buildings, airports, embankments, dams, mines, encapsulated landfill sites, are all susceptible to thaw and creep settlement (SLS) and reduced bearing capacity (ULS), under warming planetary conditions, as well as mobility of groundwater (and any related soluble or immiscible contaminants) (e.g., Mills et al. 2006, Mazhitova et al. 2004, Hayley et al. 2004, Cole 2002, Couture et al. 2000). Furthermore, relative or interactive seasonal effects (such as thermal cracking and frost heave, Tighe et al. 2006, frost heave and upheaval of pipelines buried in cold regions, Kanie et al. 2006, Palmer & Williams 2003, or creep of pylons founded on creeping permafrost, Phillips et al. 2007) may threaten the integrity of structures and exacerbate damage.

Mazhitova et al. (2004) call for long term investments in adequate infrastructure in Russia, with consideration of lifetime effects, for oil and gas pipelines, given the potential for serious environmental disasters. Adaptability must also be well thought out, so that design can be enhanced for most vulnerable infrastructure, as geotechnical risk is minimised within an integrated risk approach that considers the entire lifecycle (e.g., Auld et al. 2006).

Solutions that promote improved SSI performance can be described as either active or passive by ensuring the ground remains frozen (e.g., assisted by thermosyphons or thermopiles) or by avoiding, changing or modifying the SSI conditions. Innovative thermosyphon technology that will be operational to 100 m depth, was investigated within a large scale field experiment by Noël & Hockley (2004) and offers tremendous opportunities for future active measures. Managing the effects of thaw in a controlled fashion, or by adding berms to prevent thaw softening developing under the toe of embankments by natural convective air flow are other examples. Numerical modeling confirmed that thermal insulation (e.g., using expanded polystyrene at different embedment depths combined with construction in the cold season, Wang & Dou 2007) can contribute to active measures, although the long term performance at SLS must be guaranteed as well.

Innovative long term solutions are required:

- to place constraints on perennially frozen ground by maintaining a frozen state (Bjella 2006), or
- for structural measures by developing devices to permit superstructures to be realigned on foundations to fulfill SLS requirements (Phillips et al. 2007), or by adopting stabilising measures such as rock bolts and anchors.

Conclusions

Contemporary advances in frozen soil mechanics and geotechnical engineering in cold regions have been described for application to natural permafrost and infrastructure built on or within permafrost. Recent work on field studies, laboratory investigations, physical modeling and coupled simulations are reviewed, in connection with warming planetary conditions, under which permafrost has been recognised as an indicator for climate change. Some phenomena related to frost heave during cyclic freezing and thawing, slope and active layer stability, and convection cooling in coarse granular fill, are discussed within this framework as well.

Urgent need has been identified for ongoing basic geo-technical research in permafrost engineering and science. Investment must be made in site investigations for high risk projects, supported by effective monitoring regimes and advanced laboratory testing to determine key parameters. Challenges were also pinpointed relating to understanding the thermo-hydro-mechanical behaviour of frozen soils and implementing new constitutive relationships into numerical models to represent this behaviour. Physical models, especially those exposed to the correct stresses and environmental conditions, were accepted as providing excellent opportunities for validating and calibrating such codes.

Abstract

Temperature monitoring is important for studying the modern permafrost dynamics in mountains of Northern Transbaykalia. The authors combined the permafrost observation with the microclimatic study. The criteria were proposed to estimate the representativeness of each observing site. Middle-scale hypsometric and vegetation maps with other kinds of descriptive information were used. In choosing each monitoring site, it is necessary to take into account the site accessibility, the state of the borehole, and the extent of characterized landscape (limits of homogenous conditions of relief, vegetation, and permafrost). The measurements have shown a 0.5ºC final increase in permafrost temperatures at the 20 m depth from 1987 to 2007.

Keywords: site selection; temperature measurement; temperature observation sites; TSP program.

Introduction

In view of the International Polar Year, the Permafrost Laboratory of the Institute of Environmental Geoscience RAS was involved in the Thermal State of Permafrost (TSP) program with regard to permafrost temperature observations. The permafrost of Northern Transbaykalia is well studied; consequently there was an interest in repeating the measurement characteristics of permafrost. Notice was taken of the boreholes 20 m deep that are located in undisturbed conditions. More than 200 of such boreholes were constructed especially for temperature observations in 1970–80.

The work on logger installation in Northern Transbaykalia started in 2005. While working on logger installation, the question arose, "What principle should we use to choose boreholes and to place loggers in them?" For the rationalized work, it is necessary to zone territory and to allocate sites that are better than the others reflected by geographical conditions. For this purpose, a multifaceted approach has been chosen. Our observation points are considered to be the representative sites.

Basic Assumptions and Research Objective

The aim of the research is substantiation of representative temperature observations under the TSP program. Our purpose is the following:

1. To collect 200 boreholes from different sources constructed especially for temperature observations for 1970–80.
2. To chart the vegetation and hypsometric maps.
3. To give consideration of the borehole construction conditions and the site accessibility.

Research Area

The region of research is located south of the Siberian platform and includes the Kodar Ridge, the Udokan Ridge, and the intermountain of the Chara Depression (Fig. 1).

The coordinates of the Chara settlement are 56.9ºN and 118.4ºW. The Chara Depression extends 120 km southwest to northeast, and its width is 30–35 km. The northwest side of the Chara Depression is formed by the abrupt, almost rectilinear slopes of the Kodar Ridge; the southeast border is formed by foothills slopes of the Udokan Ridge that are smoothly de-

scending towards the bottom of the Chara Depression. There are 3 macro levels on investigated territory: the Kodar Ridge with alpine relief and with absolute heights of 3073 a.s.l. (the Peak of the BAM), the Udokan Ridge with golets (smooth mountains) and absolute heights up to 2515 a.s.l. and the Chara Depression with average heights of 600–800 a.s.l. The climate of the territory in question is characterized by extreme continentality with air temperature inversion. The monthly average air temperature in January is -23.9ºC, and in July is +12.5ºC. Average annual precipitation is 700 mm.

Method

The authors used six criteria choosing representative sites: distribution of available boreholes, relief, vegetation, permafrost, state of borehole, and site accessibility.

1. *The distribution of available boreholes*. The mountain permafrost is the science-intensive and engineering-important object of investigation. The intensive permafrost survey was conducted in the Northern Transbaykalia region by the Permafrost Institute in 1960s and by the Chitageologia, the ZabTISIZ, the Chita Institute of Natural Resources and the Moscow State University in the 1970s (Chastkevich 1966, Klimovsky 1966, Nekrasov & Chastkevich 1966, Leibman 1979, Romanovskii et al. 1989, Shesterniov & Yadrishensky 1990).

Regular observations were interrupted in the middle of the 1990s. Figure 2 presents the map showing the location of the original 200 boreholes with the 7 boreholes and monitoring sites selected.

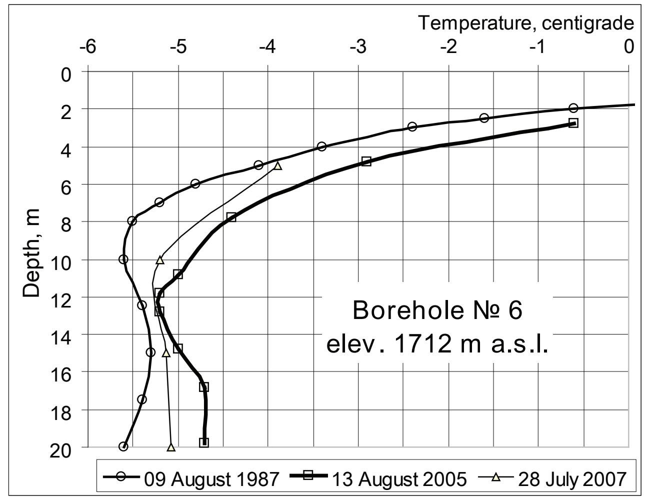

Figure 3. Temperature observation results in the borehole #6 for 1987–2007.

The boreholes are mainly located in the Udokan Ridge, where engineering projects were carried out in the 1970s. Three temperature monitoring sites have been chosen, therefore, including 20 m deep boreholes for 2005–2007. These boreholes are called #6, #38, and Peski-1. The temperature results from #6 and #38 boreholes have been obtained for 2006–2007. The measurements have shown an increase in permafrost temperatures at the scale of 0.5ºC on the 20 m depth for 1987–2006 (Fig. 3).

Figure 4 shows the invasion course of a seasonal wave of temperature fluctuations in coarse debris. The seasonal fluctuations are observed to be 20 meters deep along of low moisture content of rocks and high heat conductivity of quartzitic sandstone.

The Peski-1 borehole is located in the Chara Depression on isolated sandy desert where permafrost is absent. Thus, we have obtained temperatures concerning the Chara Sandy Desert.

There are four active layer observing points with air temperature measurements (kurum's pit – Zagryazkin-1, #5301; Ushelistiy-1; Belenkiy-1; Azarova-1) that were chosen by the authors for 2005–2007. Table 1, which summarizes the characteristics of the chosen boreholes and active layer observing points, is presented at the end of the paper.

The kurum's pit – Zagryazkin-1 (#5301) was produced by scientific and production forces in the 1980s. The authors obtained the temperature data in 2006 (Fig. 5). That allowed for typical block slope detailed information about temperature regime in the active layer where the intensive air convection and water condensation processes are usual.

The kurum's deposits occupy at least 50% of the slope area in the upper belt of The Udokan Ridge and result in a freezing effect on the underlying rocks (Romanovskii et al. 1991, Harris & Pedersen 1998, Gorbunov et al. 2004).

In 2007 three representative sites (Ushelistiy-1; Belenkiy-1; Azarova-1) were established. The active layer observing points have been chosen to proceed from the

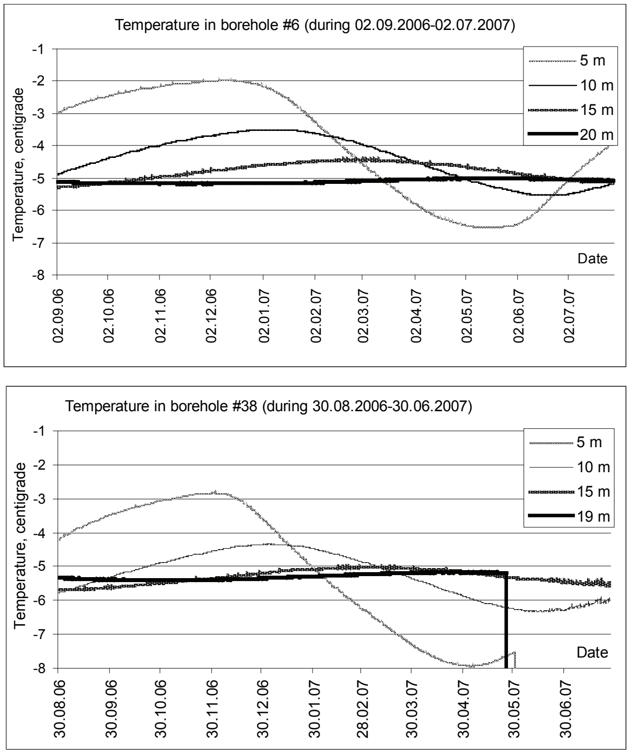

Figure 4. Temperature observations results in the borehole #6 and #38 for 2006–2007 (two channels, 5m and 19m. failed after April 2007).

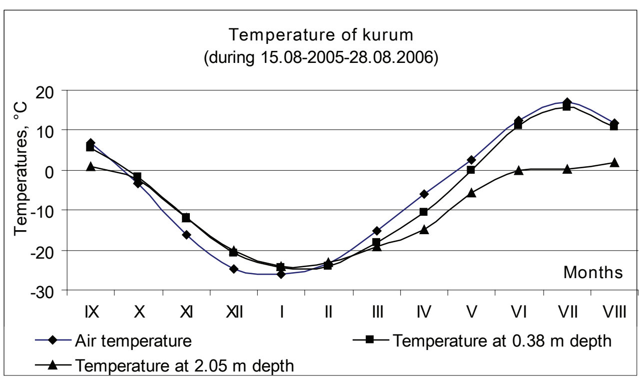

Figure 5. The mean monthly temperature data of kurum's pit in 2006.

premise that the point "Ushelistiy-1" represented the relict ice wedge polygons in the high mountain zone. The point "Belenkiy-1" took advantage of an active layer and relict ice wedge polygons in the Chara Depression. The point "Azarova-1" represented an active layer in moraine near the tongue of the Azarova Glacier in the Kodar Ridge.

The air, soil surface, and active layer temperatures were measured every 3 hours.

2. *The relief*. Whereas we study the alpine region, we take into account the geomorphology of different parts of the region. The orography is the product of tectonical and climate evolution and has a great impact on formation of natural territory conditions. That is why this territory has altitudinal landscape zonality.

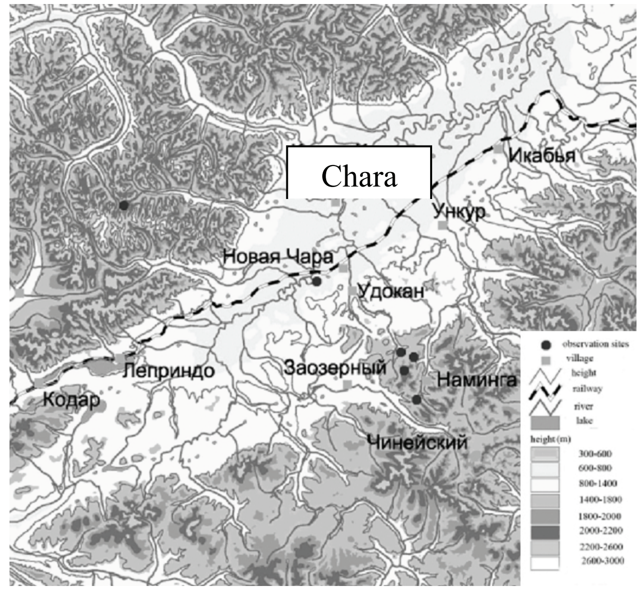

Figure 6. The hypsometric map of investigation territory.

In Figure 6, the hypsometric map is presented. The authors equipped the boreholes and active layer observing points by loggers at dominant heights.

The permafrost observations are based in a range of the heights from 730 m to 2200 m a.s.l. (see Table 1). Viz: Belenkiy-1 on 720 m a.s.l., Peski-1 on 767 m a.s.l., kurum's pit – Zagryazkin-1 (#5301) on 1155 m a.s.l., #6 on 1712 m a.s.l., #38 on 1464 m a.s.l., Ushelistiy-1 on 1651 m a.s.l., and Azarova-1 on 2036 m a.s.l. The height of temperature observation sites are shown in Figure 7.

The monitoring sites are accordingly located in the mountain altitudinal belt, in the upper part of mountain-taiga belt and at the bottom of the Chara Depression.

3. *The landscapes.* All the observing sites represent the nondisturbed landscapes. There are three dominated vegetations—such as "larch forest," "open woodland," and "alpine tundra"—that are presented in Figure 2. Our observing points are located in almost all types of vegetation. For example, the point "Belenkiy-1" is in a bog with larch; the kurum's pit (Zagryazkin-1, #5301) and #38 are in open woodland; the point "Azarova," #6 and Ushelistiy-1 are in alpine tundra. The borehole "Peski-1" is located in the unique Chara Sandy Desert. Knowledge of the cryological conditions is also possible through studying the external physionomical shape of a landscape.

4. *The permafrost*. Northern Transbaykalia is situated in a continuous permafrost zone. Cryological conditions are characterized by high heterogeneity. A local distribution of permafrost varies from sporadic to continuous thickness—from several meters up to 1200 m—and temperature from 0ºC up to -12ºC.

The permafrost conditions are different in depressions and mountains. A maximal thickness of permafrost is found at the foothills of northern expositions and at the bottoms of deep valleys in a depression. Permafrost thickness increases toward watersheds. On watersheds with the dominating

heights of 2000–2200 m a.s.l., the thickness of permafrost is 800–900 m, and temperatures are -6 ºC to -8ºC. The point "Azarova-1" was equipped by loggers here. Under peaks with the heights of 2300–2700 m a.s.l., permafrost temperatures are -10ºC … -12ºC, and thickness is 1000–1200 m (Nekrasov & Klimovsky 1978). The Chara Depression is characterized by a most severe environment that promotes continuous development of permafrost at the bottom of the depression with the thicknesses of 100–500 m, with temperatures being -1.5ºC … -6.0ºC (Nekrasov & Klimovsky 1978). In marginal parts of a depression, the thickness of permafrost does not exceed 100–200 m, and an annual average temperature of rocks in most cases is -3ºC. The taliks are distributed within the limits of the Chara Sandy Desert on the left bank of the Chara River and under the riverbeds of large rivers (rivers Chara, Verkhniy and Sredniy Sakukan, etc.). Not far from the Chara Sandy Desert the authors measured temperature in the borehole "Peski-1."

The altitudinal zonality markedly affects the formation of landscape and cryological conditions. The cryological conditions become more severe, the area of taliks decreases, and massive-island distribution of permafrost is replaced by continuous permafrost at the height over 1000 a.s.l. with the altitude increasing.

5. *The state of borehole*. Obviously the good condition of original (old) observation boreholes decreases the expenses of monitoring installation. The boreholes need the special thermal insulation collar to decrease the influence of high thermal conductivity of the steel conductor. If the collar tube is not hermetic, it is possible that ice plugging will form. All sites of actual observation are in good shape.

6. *Accessibility* (mode of transportation: helicopter, road, off-road vehicle, river, etc.). All the temperature observation sites are not far from roads. The real obstacle for the work is the coordinate data absence of the original (old) boreholes. It is difficult to find a small collar in a bush. The active layer observing points have a GPS-affixment.

Conclusions

At the first stage of the TSP program realization in Northern Transbaykalia, the authors obtained a set of observation sites that are almost all located at high-altitude levels, in all landscapes and in all permafrost conditions. This set is unique in Russia, representing the highest altitudinal level of mountain.

Besides the temperature logger installation, the authors have gathered available data on the region (maps, rows of previous monitoring data, descriptions of landscape and natural processes, etc.). This information is important in allocating representative sites on which loggers have already been placed, in estimating the priority of site installation, and in helping to correctly analyze the results of actual permafrost observation. The authors can allocate the most valuable and prime boreholes for temperature measurements analyzing the whole set of boreholes (200 boreholes).

The use of remote sensing materials has been found to be rational at all stages of cryological research and helps to map permafrost and general natural conditions of the territory in tight deadlines and with economic consideration of material resources. It will allow the saving of time and money for expeditions and will improve the accuracy and informativeness of temperature regime monitoring for Northern Transbaykalia.

The results of temperature monitoring will be published on the Internet for practical and educational purposes.

Frank Lehmkuhl
Department of Geography, RWTH Aachen University, Templergraben 55, D-52056 Aachen, Germany

Abstract

Late Quaternary glaciations in the Verkhoyansk Mountains (NE Siberia) indicate extremely dry conditions during the global Last Glacial Maximum (MIS2). According to geomorphological investigations and IRSL dating results, the last major glaciation in the mountain system occurred before 50 ka. No glaciers were present in the area during the global Last Glacial Maximum. In the early part of the Last Glacial Maximum, precipitation was sufficient for the growth of large mountain glaciers. Precipitation during the stadial is strongly dependent on the size of the western sector of the Eurasian Ice Sheet.

Keywords: glacier; palaeoclimate; Siberia; Verkhoyansk Mountains.

Introduction

The Verkhoyansk Mountains in northeastern Siberia are the easternmost mountain system on the Eurasian continent which receives precipitation mainly from the Atlantic. Therefore the area is quite sensitive to changes on the northern part of the Eurasian continent. However, paleoclimatic studies in the area are very rare and mainly limited to palynological studies (e.g. Andreev et al. 1997, Anderson & Lozhkin 2001, 2002, Anderson et al. 2002, Kienast et al. 2005). Despite that, many new results emerged from the surrounding areas like western Siberia (Svendsen et al. 2004, Hubberten et al. 2004), the Laptev Sea coast (Bauch et al. 1999, Schirrmeister et al. 2002a, b, Grosse et al. 2007) and the Russian Far East (Gualtieri et al. 2000, 2003, 2005, Brigham-Grette 2001, 2003). In this last region Lake El'gygytgyn is located and it revealed a wealth of new information about the palaeoclimate of the area east of the Verkhoyansk Mountains (e.g. Brigham-Grette et al. 2007, Melles et al. 2007).

Quaternary glaciations are good indicators of the paleoclimatic environment as they are sensitive to temperature and moisture changes on a broader timescale. Up to now there have been only a few studies available dealing with Quaternary glaciations in the Verkhoyansk Mountains (Kind 1975, Kolpakov 1979, Kolpakov & Belova 1980). Research in the area was carried out in the 60th and 70th with only poor constraints on absolute dating. A summary of these works has been presented by Zamoruyev (2004). According to these authors the area was shaped by three major glaciations during the last glacial. The last glaciations occurred during the Marine Isotope Stage 2 (MIS2) of the global Last Glacial Maximum (gLGM). Another major ice advance happened during the MIS3 around 32 ka and one in the early part of the last glacial. Every one of the glacial advances in the last glacial was smaller than the previous one. However, new absolute dating results indicate that the morainic deposits in the area are older than previously assumed (Stauch et al. 2007).

Study Area

The Verkhoyansk Mountains (Fig. 1) are located in northeastern Siberia in the zone of continuous permafrost. The mountain range stretches for about 1200 km from the Laptev Sea at 72°N to Central Yakutia at 59°N. To the west, the Verkhoyansk Mountains are bordered by the Lena and Aldan Rivers and to the east by the Jana Highlands. While in the northernmost part, in the Kharaulakh area, maximum elevation is about 1400 m a.s.l., most summits in the south reach elevations of about 2000 to 2400 m a.s.l. The highest summit (2959 m a.s.l.) is reached in the Suntar Chajata, a southern branch of the mountain system. To the west, extended lowlands with elevations between 50 and 400 m a.s.l. stretch along the Verkhoyansk Range.

The climate in the area is extremely continental. Mean monthly air temperature varies between -40°C in January and +20°C in July. Annual precipitation ranges between 220 mm in the lowlands around Yakutsk and up to 700 mm on the western flank of the Verkhoyansk Mountains; on the eastern side of the mountain range the annual precipitation is only up to 200 mm (Lydolph 1977, Shagadenova et al. 2002). In the Verkhoyansk Mountains there are only a few small glaciers, mostly in the area of the Suntar Chajata. The recent snowline is between 2200 and 2400 m a.s.l. (Koreischa 1991, Murzin 2003, Ananicheva & Krenke 2005).

The study area was located in the central Verkhoyansk Mountains between 63°10′N and 66°40′N. The area consists of four large catchment areas on the western side and several smaller ones on the eastern flank of the mountains (Fig. 1) which sum up to an overall area of 150,000 km². The Tumara and Djaunshka valleys were chosen for the field work.

Methods

For the reconstruction of former glaciations, glacial-geomorphological landforms in the central part of the Verkhoyansk Mountains were mapped. Due to the remoteness of the area, without roads and settlements, remote sensing

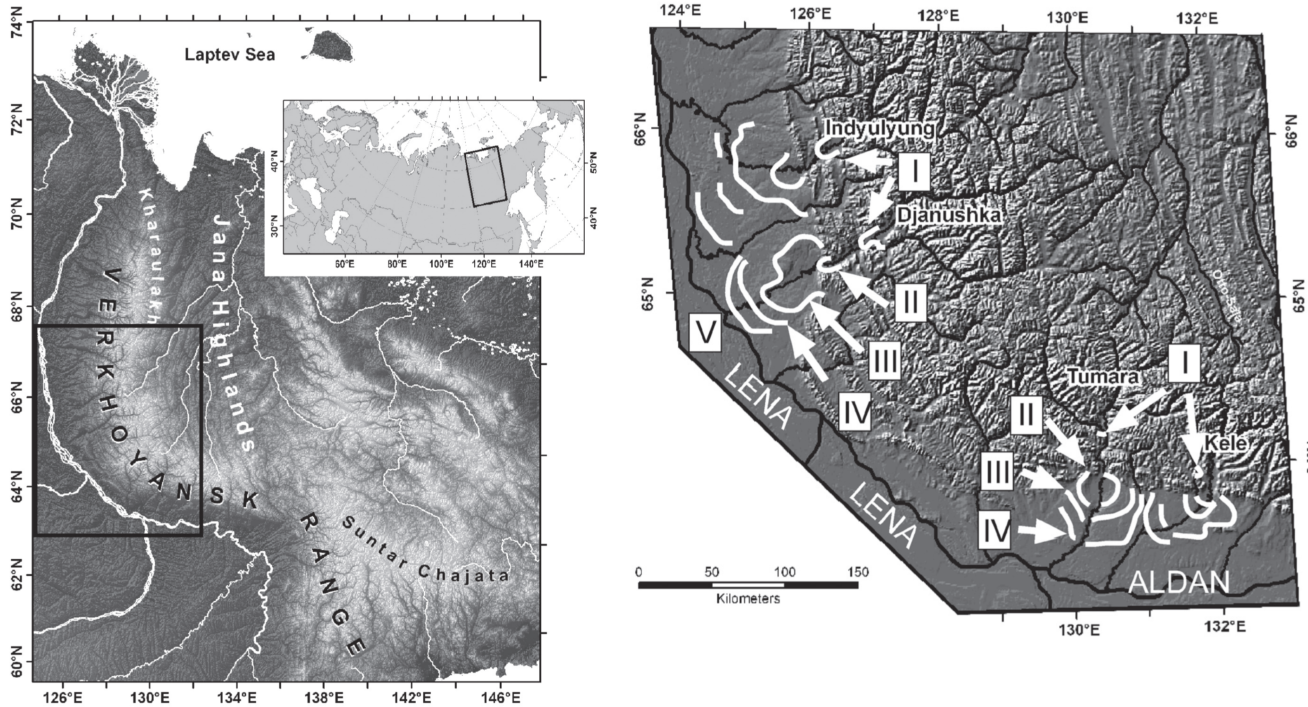

Figure 1. Study area, the Verkhoyansk Mountains (right side) and the central Verkhoyansk Mountains with the selected terminal moraines (left side).

data was utilized for the overall mapping of the region. The results of the image interpretation were in the second stage checked during two field seasons on the western side of the mountains, at which time samples for sedimentological analysis as well as for absolute dating were also taken. We used mainly aeolian cover sediments for IRSL (InfraRed Stimulated Luminescence), however at some points we also dated glacial-fluvial deposits. All samples were processed at the GGA Institute in Hannover, Germany. For a detailed description of the method and the complete table of the IRSL results see Stauch et al. (2007).

For the remote sensing analysis we used Landsat7 Data with a resolution of 30 m and 15 m respectively. A visual image interpretation approach was used for this study (Stauch 2006). This method was useful for identifying terminal moraines inside of the mountains as well as in the southern and western foreland. Besides the field work, crosschecking of the results was done with high resolution Corona images with a resolution of up to 2 m. Both methods showed that Landsat Data was sufficient for mapping of the glacial landforms in the area.

Moraines in the different catchment areas were grouped according to geomorphological criteria and relative position. The geomorphological criteria included degree of weathering and slope wash as well as the number and size of kettle lakes on the surface. Older moraines with a position most distant to the center of glaciation have a smoothed surface with low slope angles, while on younger moraines features of ice decay and moraines of small secondary re-advances are still visible. Kettle lakes are larger on older moraines than on

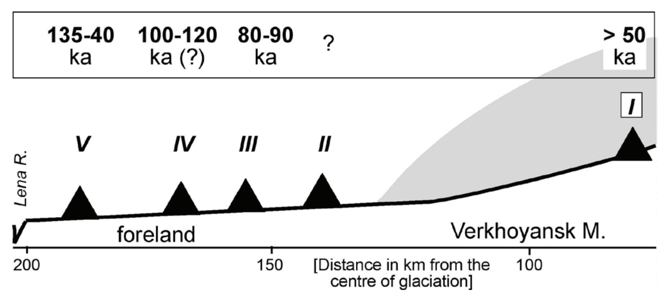

Figure 2. Schematic cross section of the western foreland and the Verkhoyansk Mountains with the ages of the terminal moraines (Stauch et al. 2007).

younger ones. This is caused by longer lasting permafrost processes, which often resemble the former ice margins. Besides morphological criteria these older moraines show distinctive differences in the mineralogical composition of the sediments (Popp et al. 2006, 2007).

Results

Geomorphological mapping revealed four to five sets of terminal moraines on the western and southern side of the Verkhoyansk Mountains. The uppermost moraines (named I, Fig. 1) are located inside of the mountains system about 50 to 80 km away from the supposed center of glaciations, while the other moraines (II to V) have been deposited either at the mountain front or in the foreland (Fig. 2). These later moraines are generally much larger in size than the ones further upstream. On the eastern site the terminal moraines

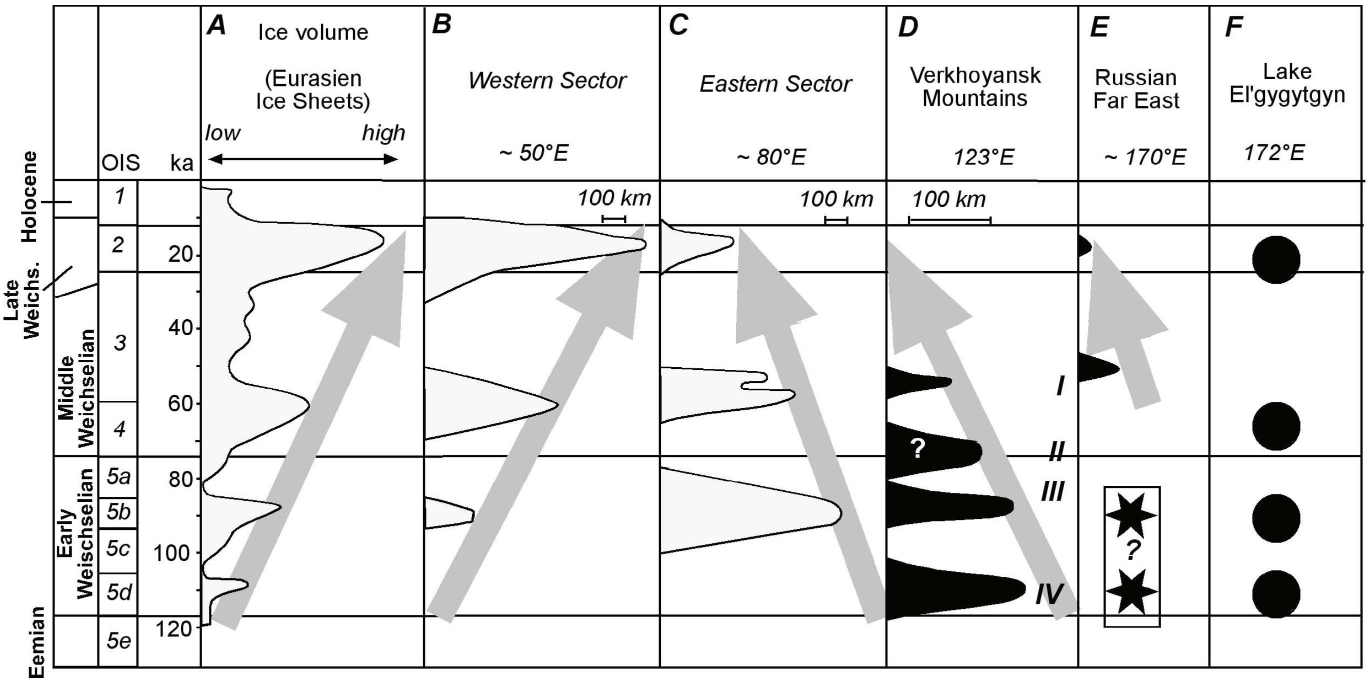

Figure 3. Time distance diagram of glaciations in the northern Asia (A-C: Svendsen et al. 2004, D: Stauch et al. 2007; E: Stauch & Gualtieri *subbm.*, Stars: Brigham-Grette 2001) and cold phases (F: dots) according to Brigham-Grette et al. (2007).

are much smaller and strongly eroded. Therefore, correlation of moraines on the eastern and western side is complicated and mainly based on the relative location of the sediments to the supposed center of glaciations.

However, dating of the moraines revealed that they are much older than previously assumed. Moraine I is older than 50 ka (Fig. 2). Aeolian cover sediments on a glacio-fluvial fan directly upstream of Moraine I in the Tumara catchment has an IRSL age estimate of 52.8 ± 4.1 ka (V09, Stauch et al. 2007). In the Djanushka catchment aeolian sands have been deposited above lacustrine sediments about six kilometers downstream of moraine I. These lacustrine sediments were formed sometime after the retreat of the glacier. The aeolian sediments on the top gave an IRSL age estimate of 39.7 ± 3.1 ka (Dj01). As no terminal moraines could be identified upstream of moraine I in any of the landforms in the northernmost, we suggest that the last studied catchment areas, except some small dubious glacial advance in the Verkhoyansk Mountains occurred before 50 ka. None of our results indicate a glaciation during the global Last Glacial Maximum during the MIS2.

Up to now no absolute ages for the second moraine are available. Aeolian sediments on top of the moraine point to a formation before 46.8 ± 3.1 ka (V17). However, this moraine is older than moraine I according to its stratigraphic position.

The formation of Moraine III presumably finished around 80 to 90 ka. This age estimation is based on two samples. In the Tumara catchment, glacio-fluvial sand in between the till gave an age of 86.9 ± 6.8 ka (V25). At the Djanushka River sand above Moraine III was dated to 92.3 ± 6.5 ka (Dj22).

Four IRSL samples have been dated at Moraine IV in the Tumara catchment. Glacio-fluvial sand at the top of the morainic sediments gave an IRSL age estimate of 97.6 ± 6.8 ka (V29). However, aeolian silt covering these sediments yielded IRSL ages of 123 ± 10 ka (V28) and 107 ± 10 ka (V27). Fluvial sediments on top of glacio-fluvial gravel in front of the moraine resulted in an IRSL age of 107 ± 10 ka. Despite the somewhat dubious due age in one of the profiles, we suppose that the formation of the moraines was completed between 100 and 120 ka.

For the outermost Moraine V two samples from glacial deformed sand between two thin layers of till resulted in IRSL ages of 135 ± 9 ka (DJ30) and 141 ± 10 ka (Dj31).

Discussion

Throughout the late Quaternary, glaciations in the Verkhoyansk Mountains became smaller indicating a reduction in precipitation during the different glacial phases. Comparing the results from the Verkhoyansk Mountains with neighboring regions indicates some continental trends in northern Asia (Fig. 3). Svendsen et al. (2004) compared the development of the western (Finland and western Russia) and the eastern (Arctic Russia, Siberia) sectors with the overall ice volume of the Eurasian Ice Sheets (British Scandinavian and Barents-Kara Ice sheets) throughout the last glacial. Taking all Ice Sheets together there is an overall trend in a growing ice volume during the pace of the last glacial. This trend is also reflected in the waxing of the Ice Sheet in the western sector, where the largest ice extent was reached in the later phase of the glacial during the MIS2.

The eastern sector of the Eurasian Ice Sheet developed the other way round, a large glaciation in the early part of the last glacial and a considerably smaller one during the MIS2. A similar trend can be observed in the Verkhoyansk Mountains. However, while there are multiple glaciations in the early part of the glacial, no glaciation occurred during the last 50 ka. East of the Verkhoyansk Mountains only a few absolute datings are available (Stauch & Gualtieri subbm.). Studies of e.g. the Pekulney Mountains (Brigham-Grette et al. 2003) or the Koryak Mountains (Gualtirie et al. 2000) point to progressively smaller glaciations during the last glacial. The last glaciations occurred during the MIS2. Glacial advances in the early phase of the last glacial are still in debate (Brigham Grette 2001). Similar to the glacial advances in Eastern Siberia, several cold phases have been recognized in a core of Lake El'gygytgyn (Brigham-Grette et al. 2007).

The main factor controlling glaciations in Eastern Siberia was the amount of available precipitation, as much of the continent up to the Verkhoyansk Mountains depends (and depended) on the moisture-bearing winds from the west. During the glaciations this moisture was blocked depending on the size of the western sector of the Eurasian Ice sheet. In the early part of the last glacial, the western part of the Ice Sheet was relatively small leading to major glaciations in western Siberia (eastern sector of the Eurasian Ice Sheet) and to mountain glaciations in the Verkhoyansk Mountains. During the MIS2 the western part of the Eurasian Ice Sheet reached its maximum extent of the last glacial blocking most of the moisture. Therefore, the eastern sector of the Eurasian sector was comparable small, while no glacier developed in the Verkhoyansk Mountains despite very low temperatures. Models of western Siberia show similar results (e.g., Siegert & Marsiat 2001, Siegert & Dowdeswell 2004).

East of the Verkhoyansk Mountains in eastern Russia, the Pacific was at least an additional moisture source which, in turn, led to several mountain glaciations. In Western Siberia and the far east of the Asian continent at least little moisture was available. The environment in Eastern Siberia was cold and very dry during the MIS2.

Acknowledgments

The authors would like to thank the Deutsche Forschungsgemeinschaft (DFG; Le 730/10-1,2) for funding the project. Thanks also to Manfred Frechen for the IRSL dating, and all the Russian and German colleges we worked with in the Verkhoyansk Mountains.

The Fate of Greenland's Permafrost: Results from High-Resolution Transient Climate Simulations

Abstract

Simulations with global circulation models (GCMs) clearly indicate that major climate changes for Greenland can be expected during the 21st century. Due to their coarse resolution, contemporary global climate models (GCMs) have so far been unable to give a realistic representation of the dynamics of the Greenland ice sheet as well as the permafrost underlying the ice-free regions. Even relatively high-resolution regional climate models (RCMs) may fail in this respect. To improve climate projections, we have therefore conducted a transient simulation for the period 1950–2080 for the whole of Greenland with very high resolution. Based on these simulations, we present modeled changes in permafrost in an unprecedented high resolution.

Keywords: climate change; Greenland; permafrost; regional climate model.

Introduction

There is ample observational evidence for recent warming in high latitudes. Observed changes include air (Moritz et al. 2002) and soil temperature (Majorowicz & Skinner 1997, Osterkamp & Romanovsky 1999, Romanovsky et al. 2002, Osterkamp 2003), vegetation cover (Sturm et al. 2001), sea ice (Bjorgo et al. 1997), glacier mass balance (Arendt et al. 2002) and ice sheets (Rignot & Kanagaratnam 2006). Many of these changes affect the permafrost body (perennially frozen ground) and the seasonally thawed layer between it and the surface, the active layer. Climate change scenarios (e.g., IPCC 2007) indicate that warming due to anthropogenic activities will be greatest in polar regions. Changes involving permafrost may affect infrastructure and regional ecosystems due to thawing of the ground and development of thermokarst depressions (Romanovskii et al. 2000), or they may contribute to the release of large amounts of greenhouse gases.

Model studies with comprehensive coupled ocean-atmosphere general circulation models (AOGCMs) show that the area of the Northern Hemisphere underlain by permafrost could be reduced substantially in a warmer climate (Smith & Burgess 1999, Anisimov et al. 2001, Nelson et al. 2001, Stendel & Christensen 2002). However, thawing of permafrost, in particular if it is ice rich, is subject to a time lag due to the large latent heat of fusion of ice, which implies that permafrost in relict form can persist in deep layers for centuries or even millennia as in western Siberia. State-of-the-art AOGCMs are unable to adequately model these processes for three reasons: even the most advanced subsurface schemes rarely treat depths below 5 m explicitly; soil thawing and freezing processes cannot be dealt with directly due to the coarse resolution of present AOGCMs; and the required simulations covering millennia cannot be conducted due to computer power limitations.

It is important to note that any attempt to model subsurface processes needs information about soil properties, vegetation, and snow cover; but these are hardly realistic on a typical GCM grid. Furthermore, simulated GCM precipitation is often underestimated, and the proportion of rain and snow is incorrect (e.g., Christensen & Kuhry 2000). One possibility to overcome resolution-related problems is to use regional climate models (RCMs). Such an RCM, HIRHAM4 (Christensen et al. 1996), has until now been the only one used for the entire circumpolar domain (ACIA 2005), and it has also been used in this study. No specific treatment of soil freezing and thawing is done in HIRHAM, so the same limitations as for the GCM apply, and so far only studies based on frost indices have been conducted. As for coarser-scale models, these simulations also lack sufficient information about soil properties.

Instead of calculating a degree-day-based frost index from RCM data, we use the regional model to create boundary conditions for an advanced permafrost model. This approach, described in Stendel et al. (2007) in a proof-of-concept study, is novel in two aspects. Firstly, the RCM (and therefore the permafrost model) runs on an unprecedented horizontal resolution of 25 km for the entire region covering Greenland and the surrounding seas. Secondly, while most comparable studies have used "time-slices" due to computer limitations, we here present a fully transient simulation covering the period 1950–2080.

Model Hierarchy and Downscaling Procedure

The models used in this study are briefly described below. The driving AOGCM is the state-of-the-art, coupled ocean-atmosphere model ECHAM5/MPI-OM1 (Roeckner et al. 2003, Marsland et al. 2003, Jungclaus et al. 2006). All the forcing data for the Greenland simulation have been taken from a transient simulation with this model (May 2007) at T63 resolution (~1.8° by 1.8°). ECHAM5 no longer requires a flux correction, as opposed to previous versions

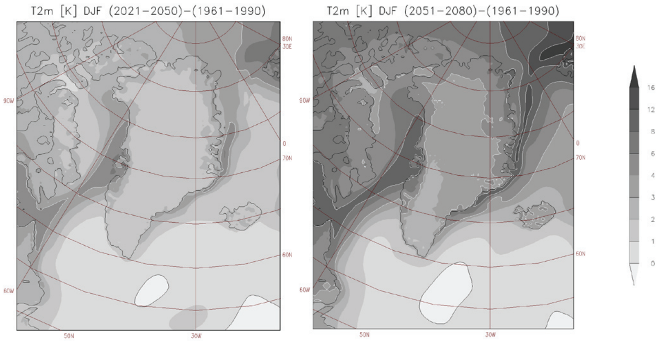

Figure 1. Simulated mean near surface (2 m) air temperature change [K] in HIRHAM4 in winter (December–February). Left panel: 2021–2050 minus 1961–1990, right panel: 2051–2080 minus 1961–1990. Isolines every 4 K.

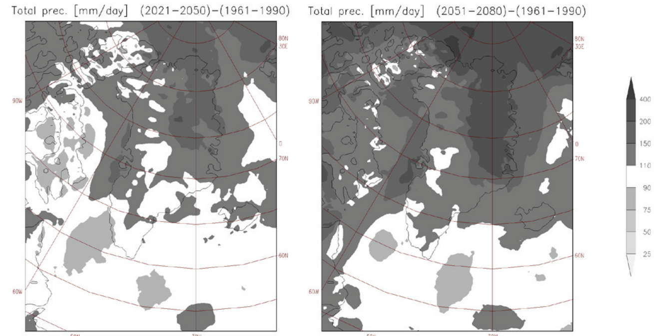

Figure 2. Change in annual precipitation expressed in percent of present-day (1961–1990) precipitation for 2021–2050 (left panel) and 2051–2080 (right panel).

of this model. Walsh et al. (2008) found in a comparison study between 14 of the CMIP3 participating models, that ECHAM5 is a top ranking model with respect to simulating present day conditions in the Arctic, including seasonal sea ice distributions.

The regional model is HIRHAM4 (Christensen et al. 1996), which is based on the adiabatic part of the HIRLAM (High-Resolution Limited Area Model) short-range weather forecast model (Källén 1996). For climate modeling purposes, the standard physical parameterisation of HIRLAM was replaced by that of the global climate model ECHAM4 (the predecessor of ECHAM5), so that HIRHAM4 can be thought of as a high resolution limited area version of ECHAM4. The boundary forcing from the global model (see previous paragraph) is updated every six hours in a region 10 grid points wide with a simple relaxation of all prognostic variables. It has been shown that HIRHAM4 is able to realistically simulate present-day climate (e.g., Christensen et al. 1998).

Varying concentrations of well-mixed greenhouse gases (CO_2, CH_4, N_2O, CFC-11, and CFC-12) as well as ozone (O_3), and sulphate aerosols (SO_4) have been prescribed from observations over the period 1861–2000 and according to the SRES A1B scenario (Nakićenović et al. 2000) thereafter. In this scenario the CO_2 concentration in 2100 is near 700 ppm, and the globally averaged warming with respect to present-day climate is 3.5°C.

To model regional permafrost, we have used the GIPL 1.1 model (Geophysical Institute Permafrost Lab) of the University of Alaska Fairbanks (Sergeev et al. 2003), which is a one-dimensional, spatially distributed, physically based multi processor numerical model for the solution of the non-linear heat transfer equation. The model solves for ground temperatures and active layer thickness. The input data for GIPL 1.1 are air temperature, snow depth and density, soil composition, water content and thermal properties, as well as characteristics of vegetation cover, geomorphologic features, and the geothermal flux as a bottom boundary.

Future Climate Evolution

As discussed above, the driving model for the 25 km HIRHAM simulation is a coupled atmosphere-ocean model; that is, the atmosphere is forced by modeled SSTs and sea ice concentrations rather than by observed ones. This implies that in order to assess variability and change, the considered periods need to be long enough; that is, cover several decades. From the transient simulation covering the complete period 1950–2080, we compare two thirty-year averages for periods in the 21st century (2021–2050 and 2051–2080) to modeled present-day conditions (1961–1990).

Temperature

Figure 1 shows seasonal changes in 2 m air temperature over Greenland for the two periods with respect to present-day conditions. For 2021–2050 a general temperature increase of 3°C in winter and 2°C in summer (not shown) is found. In winter locally larger values up to 6°C along the west coast and 4°C along the east coast and further northeast to Svalbard are simulated, which are related to regions covered with sea ice under present-day conditions but not in future climate. For the second period (2051–2080), warming accelerates considerably, with an increase of 7–8°C along the west and 12°C along the east coast in winter and a maximum increase of more than 18°C in winter at Svalbard's northeast coast, a region which has also been prone to large, recently-observed temperature anomalies.

The predicted temperature changes along the coast of Greenland are larger than in available GCM simulations (including ECHAM5, which provided the driving data for this simulation). We note that sea ice is not a prognostic variable in HIRHAM but is rather interpolated from the driving model. In ECHAM and HIRHAM any sea ice in a grid box is thawed first before near-surface temperatures can increase further. When sea ice retreats, there will be grid cells in HIRHAM free of ice earlier than in ECHAM, just because of the grid size (which is roughly 50 times larger in the GCM). These changes in sea ice cover and the projected increase in the positive phase of the North Atlantic Oscillation (Stendel et al. 2007, Stendel et al. 2008) lead to an increase in wind speed and changes in heat transport from the ocean, compared to the driving model, in particular along the east coast.

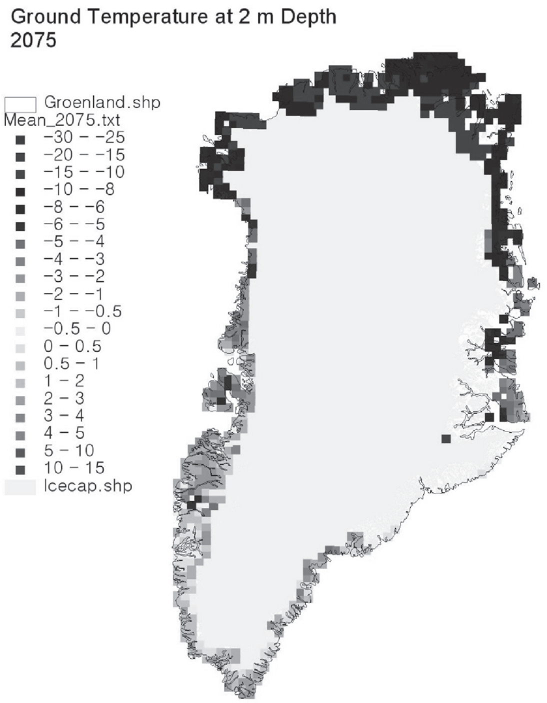

Figure 3. Ground temperatures (°C) at 2 m depth obtained with GIPL for exposed bedrock forced with HIRHAM4. Snapshot for 2075.

As a result, late summer sea ice disappears around 2060 in our simulation (not shown). Winter sea ice generally retreats northward by 100–200 km until 2050 and further (300–400 km) by 2080. Around Svalbard, sea ice totally disappears (even in winter) after 2070.

Precipitation

In Figure 2 precipitation changes are shown. In agreement with ACIA (2005) and Christensen et al. (2007), an increase in precipitation is projected for most of Greenland. With respect to present-day conditions, 15% more precipitation over western and 40% over interior and eastern Greenland are predicted for 2021–2050, while there is an increase of 30%–40% over western and interior and about 60% over eastern Greenland for 2051–2080. A distinct decrease in both snowfall amount and frequency is projected along the coasts except in the north, whereas more snow is projected on the lower parts of the ice sheet, in particular along the east coast (not shown). No information about changes on the ice sheet can be modeled, since it is treated as passive even in the contemporary models. That means that snow is allowed to accumulate on the ice sheet until a predefined maximum snow cover is reached, and no thawing or ablation is taken into account so that in practice the ice sheet is covered by a layer of snow of constant thickness throughout the year.

Permafrost

Rising temperatures, increasing precipitation, and a decrease in the number of snow days all contribute to conditions favorable for permafrost retreat; a decrease in snow depth and duration has the opposite effect. How fast

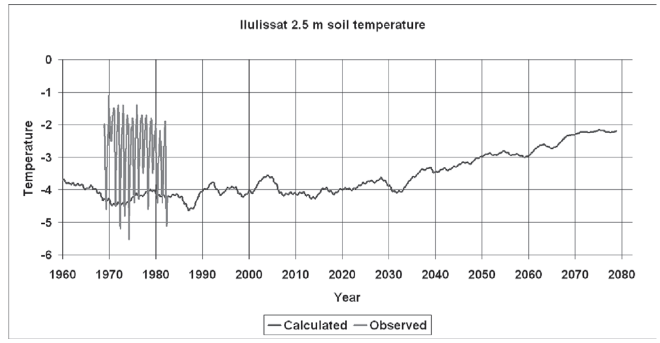

Figure 4. Soil temperature at a depth of 2.5 m in Ilulissat. Blue curve: GIPL 1.1 forced with HIRHAM4. Red curve: observations (van Tatenhove & Olesen 1994).

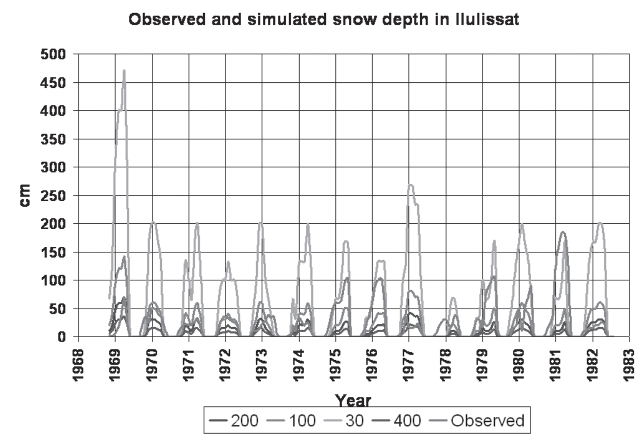

Figure 5. Observed and simulated snow depth (cm) in Ilulissat for mass densities of 30, 100, 200, and 400 kg m^{-3}.

changes in permafrost will take place furthermore depends on soil and vegetation properties, which are not known well on the spatial scale of interest for large parts of Greenland. We have run GIPL 1.1 using variations in snow thermal conductivity and organic layer thickness (Daanen et al. poster, this meeting). As an example, Figure 3 shows a snapshot of the temperature at 2 m depth for 2075.

Figure 4 shows the simulated and observed temperature evolution at 2.5 m depth for Ilulissat, taken from observations during the period 1968 to 1981 (van Tatenhove & Olesen 1994). A cold bias in the model data is obvious. As a consequence, the active layer in the model is too thin, and the permafrost table is too close to the surface, resulting also in a damping of temperature variability compared to the observations.

The model grid point representing Ilulissat is situated on the ice sheet, so an adjacent grid point, 25 km west, was chosen for comparison. This demonstrates that a horizontal resolution of 25 km is not sufficient to successfully model permafrost processes. Despite the strong warming signal in the atmosphere, the warming at the permafrost level is quite moderate. By the end of the period, temperatures at 2 m depth are above or just below freezing south of Maniitsoq and Tasiilaq, respectively, but remain below 0°C further north. This result points out the importance of a realistic simulation of snow depth. The model slightly underestimates the snow cover compared to observations (Fig. 5). However, modeled snow cover is given in water equivalent and thus crucially depends on the mass density. Referring to Raab and Vedin (1995), a density on the order of 100 kg m^{-3} (newly fallen snow) gives reasonable results most of the time. There are, however, indications for winters with much smaller density on the order of 30–50 kg m^{-3}, the cold winters of 1975 and 1981 for example. High values up to 300–400 kg m^{-3} apply at the end of the winter. Of course, warm atmospheric conditions and a decrease in snow cover will eventually lead to permafrost degradation and thawing. However, since Greenland is comparably cold also in summer (when compared to Alaska), and due to the large thermal inertia of the frozen ground, only a part of this warming will be realized within the next decades.

Conclusions

Most state-of-the art GCMs project warming on the order of 2°C–3°C in the southern and larger warming (around 7°C) for the northern part of Greenland. A transient climate simulation at an (for Greenland) unprecedented horizontal resolution of 25 km has been conducted, which was forced by a GCM with a rather high resolution (T63; i.e., roughly 1.8° in latitude and longitude). Our regional model shows considerably stronger temperature increase in regions where sea ice retreats than the driving global model, with largest differences and largest changes along the east coast. Most of Greenland, especially the northeast, is projected to receive more precipitation. In particular at lower elevations, an increasing percentage of this precipitation can be expected to fall as rain rather than snow under present-day conditions. According to the model, present-day permafrost is rather cold in the Ilulissat region, which we have chosen as an example. With ongoing warming, the increase in rainfall events and decrease in snow fall, depth, and duration will lead to a warming of permafrost. Given the existence of marine permafrost along the west coast of Greenland, permafrost degradation can be expected to start at the end of this century.

Detection of Frozen and Unfrozen Interfaces with Ground Penetrating Radar in the Nearshore Zone of the Mackenzie Delta, Canada

Abstract

Multi-frequency Ground Penetrating Radar (GPR) surveys were conducted within the nearshore zone of the Mackenzie Delta to determine the spatial distribution of frozen and unfrozen sediment. Late winter GPR surveys over zones of bottom-fast and floating ice indicate that significant spatial variations in the thermal state of sediments exist. Where ice was bottom-fast, two laterally-continuous high amplitude reflections were verified to represent a transition in thermal state of sediment. These thermally-related interfaces closely correlate with changes in ground temperatures from above freezing to below -0.5°C. At locations where bottom-fast ice thickness was less than 1 m complete freezeback of the active layer occurred. Where bottom-fast ice thickness was greater than 1 m thaw exceeded freezeback of the active layer and a near-surface talik was identified. The depth of seasonal frost decreased towards zones of floating ice, beneath which no near-surface thermal interfaces were resolved.

Keywords: bottom-fast ice; ground penetrating radar; nearshore zone; seasonal frost; thermal interfaces.

Introduction

In the nearshore zone of the Mackenzie Delta (Fig. 1), the occurrence of seasonal frost and the sustainability of permafrost are closely related to the presences of bottom-fast ice (Dyke 1991, Kurfurst & Dallimore 1991, Wolfe et al. 1998). At locations where seasonal landfast ice comes in contact with the sediment bed (bottom-fast ice), heat is readily conducted from the underlying sediment. Several factors control the onset of bottom-fast ice and therefore the extent of heat exchange and ground freezing. Of particular importance are water bathymetry and those influences affecting ice growth (e.g., snowpack thickness). The ice contact time, in part, controls freezeback of the active layer and permafrost cooling (Stevens 2007). The outer delta, seaward of the delta front, is characterized by a shallow-water platform of gentle slope and subtle changes in water depth. As a result, complex thermal structures occur beneath seemingly similar regions of bottom-fast ice.

Under such nearshore conditions, subsurface characterization of the distribution of frozen and unfrozen sediment becomes difficult when solely relying on point-specific measurements such as drill and ground-temperature data. These datasets, although important, can lead to inaccurate correlation between data points and the oversimplification of the current subsurface conditions where rapid changes occur.

The thermal state of ground in this region is important to oil and gas development, as the stability of infrastructure in permafrost environments is greatly dependent on engineering designs that are specific to the existing and naturally changing thermal conditions.

In order to improve the subsurface understanding of ground conditions in the coastal zone, we used Ground Penetrating Radar (GPR) to detect thermal interfaces. Similar GPR surveys conducted over ice-covered rivers (Delaney et al. 1990, Arcone et al. 1992, Arcone et al. 1998) and lakes (Arcone et al. 2006) have identified sub-ice reflections that relate to frozen-unfrozen boundaries.

In this paper we discuss the sources of thermal interfaces detected with GPR in sediments, and characterize the spatial complexity of frozen and unfrozen transitions located beneath bottom-fast ice within the Mackenzie Delta coastal zone.

Detection of frozen and unfrozen sediment

Among the electrical, electromagnetic, and reflection-based geophysical methods utilized for the study of frozen ground, GPR in particular is considered to be a reliable and effective method for identifying thermal interfaces that indicate a change in thermal state (Moorman et al. 2003). In general, two aspects of frozen ground contribute to the wide use and success of GPR in cold regions: the decreased signal attenuation (losses) related to reduced ionic conduction as the phase change of pore water to ice takes place, and the large dielectric contrast that exists between frozen and unfrozen materials (Table 1), which typically causes a highly reflective interface.

The dielectric constant (k) of a material is a function of its ice and liquid water content. As interstitial ice begins to form in the pores of freezing sediments, both the liquid water content and the dielectric constant decreases (Table 1). This results in a large reflection coefficient (-0.34) between

Table 1. Typical dielectric properties of frozen and unfrozen materials. The volumetric unfrozen water content (θuf) for clay is given at various temperatures. (Sources: Patterson & Smith 1981, Davis & Annan 1989).

Material	Dielectric constant	Attenuation dB/m
liquid water	80	0.1
pure ice	3-4	0.01
unfrozen sand	20-30	0.03-0.3
(-1.5°C) frozen sand	4	2
(-0.5°C) clay (θ uf =40%)	27	65
(-1 °C) clay (θ uf =25%)	12	60
(-2 °C) clay (θ uf =17%)	8	47

frozen (*k = 6)* and unfrozen (*k = 25*) sediment (Stevens 2007). As such, the dielectric gradient is mainly controlled by the temperature gradient, textural characteristics of the sediment, and pore-water chemistry.

Study Area

The Mackenzie Delta is located within the western Canadian Arctic (Fig. 1a). Permafrost beneath the upland Pleistocene delta can be in excess of 500 m thick; however, beneath the modern delta plain, permafrost is generally less than 100 m thick (Taylor et al. 1996) with the exception of where channels and lakes restrict cooling of the ground (Smith 1976). Seaward of the delta plain, a shallow-water platform of water depths less than 2 m extends for approximately 17 km. Winter ice growth in this region is commonly in excess of 1 m, and therefore seasonal ice freezes to the sediment bed (bottom-fast ice) over extensive nearshore areas. The thermal regime beneath shallow water in this area has been shown to be regulated by bottom-fast ice, as heat is readily conducted from the ground during the period of ice contact (Dyke 1991).

GPR surveys were conducted from an ice surface over a distributary bar at the mouth of Middle Channel in late March. The area surveyed extended from within Middle Channel to a nearshore location adjacent to Garry Island (Fig. 1b). Fresh water (<0.2 mS/m) and ice dominate this site due to its close proximity to the outflow from Middle Channel. Similarly, pore-water salinity analyzed from sediment cores indicates values below 4 ppt (5 mS/m) within the upper 5 m of sediment. Sediment cores also indicate an overall coarsening upwards sequence of sediment, ranging from silty clay to sandy silt. The low electrical conductivity of ice and water promotes subsurface propagation of EM energy at this site. However, similar application of GPR would be hindered in coastal environments dominated by seawater.

Data Acquisition

A total of 154 line km of GPR data was collected in March of 2005, 2006, and 2007. The GPR surveys were conducted using a PulseEKKO 100 with 100 MHz antennas and a Noggin Plus system with both 500 MHz and 250 MHz antennas. Data from each system were recorded on individual data loggers. The radar systems and corresponding antennas were configured in an array so that simultaneous acquisition of the data could take place by towing the systems at a constant rate of 5 km/hr (Fig. 2). In order to acquire a high density of GPR traces (5 cm/trace) at the towing speed of 5 km/h, low stacking and short time window settings were used. Spatial positioning of each trace was recorded with either a Wide Area Augmentation Service (WAAS) corrected or real-time kinematic GPS unit. The processing of the GPR data included enhancement of weaker reflections using an Automatic Gain Control (AGC).

The subsurface transition in material properties from ice to water and frozen and unfrozen sediment corresponds to significant changes in the propagation velocity of radar waves. This study uses an average velocity of 0.16 m/ns for ice, 0.03 m/ns for water, 0.15 m/ns for frozen sediment, and 0.10 m/ns for unfrozen sediment, based on CMP

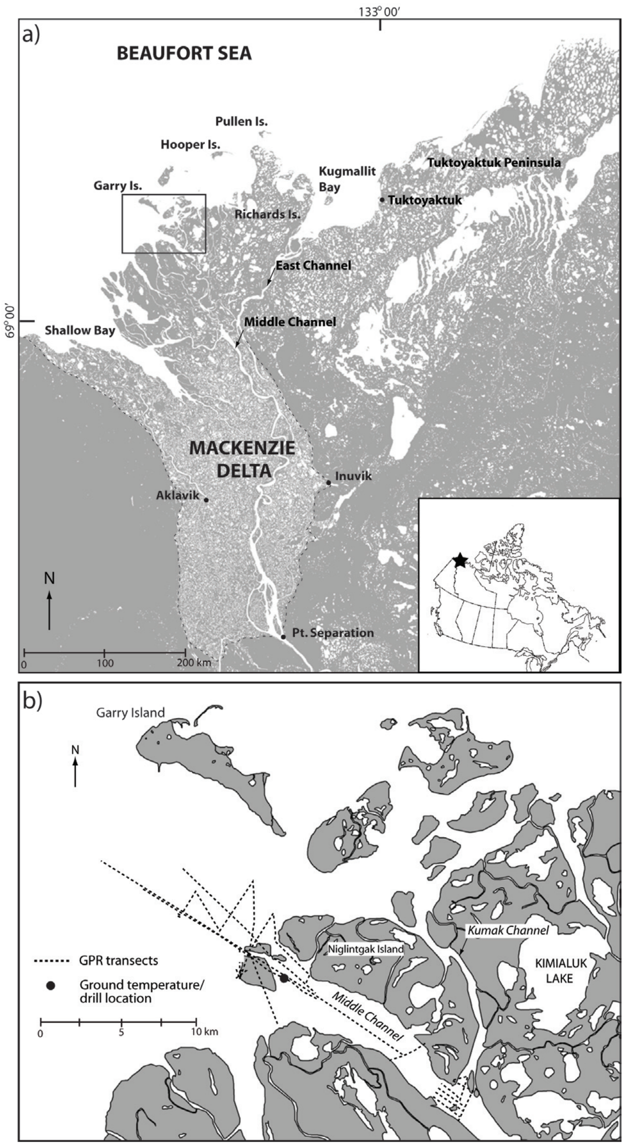

Figure 1. Study area map: a) regional view of the Mackenzie Delta located in the western Canadian Arctic and b) site map showing the orientation of GPR transects surveyed over the distributary bar at the mouth of Middle Channel.

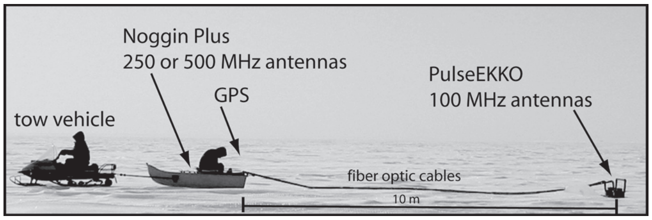

Figure 2. Multi-frequency GPR setup towed behind a snowmachine. GPR systems include a PulseEKKO 100 with 100 MHz antennas and a Noggin Plus systems with 250 and 500 MHz antennas. Positional data was acquired with GPS for each radar trace.

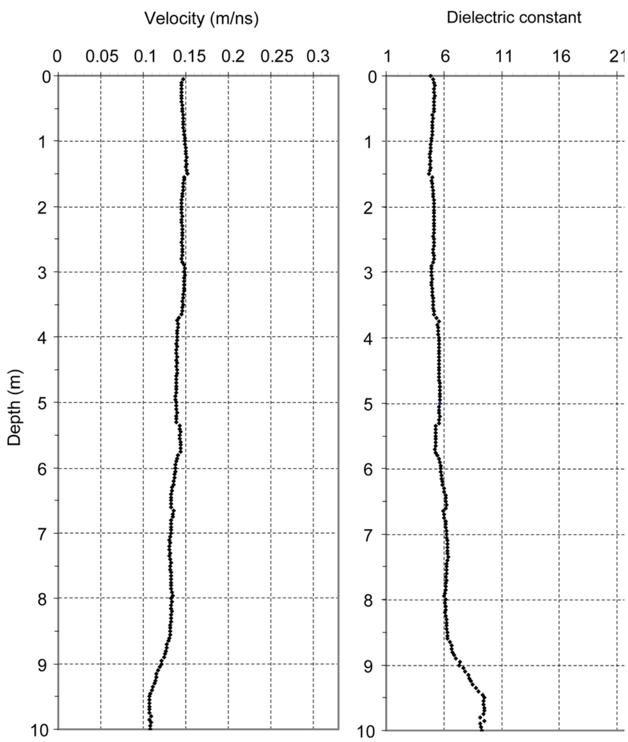

Figure 3. Calculated wave velocities and dielectric constants in frozen sediment obtained from cross-borehole measurements. The average wave velocity in the upper 5 m of sediment was 0.15 m/ns.

measurements, direct drill verification, and cross-borehole radar measurements conducted within the area. The GPR propagation velocities calculated from cross-borehole surveys were relatively consistent within the upper 5 m of sub-bottom sediment and therefore reflect the values used for depth conversions (Fig. 3).

Ground temperature measurements used for this study were recorded up to 10 m beneath zones of bottom-fast ice. Measurements were made every eight hours with RBR™ data loggers and YSI thermistors. The thermistors are accurate to ±0.1°C. Information gained from two years of ground temperature data collected within the study site supports the GPR findings and aids in further radar interpretation where such subsurface verification was not present.

Results and Discussion

Figure 4 shows the GPR trace response to changes in ground temperatures and the thermal state of sediment beneath bottom-fast ice. At this locality, borehole (GSC 2007-301-063) indicates two thermal interfaces 3 m and 5.5 m in depth. Unfrozen saturated sediment in this depth range corresponds to ground temperatures between -0.06°C and -0.48°C. Although these sediments are cryotic, the complete lack of ice bonding observed in core suggests a freezing-point depression.

The radar trace response indicates relatively high amplitude reflection events that correspond to the upper and lower thermal interfaces (Fig. 4). These interfaces exhibit opposing wavelet phase under constant antenna directivity. In this study, antennas were orientated to produce a + - + wavelet phase from the base of the ice. This allowed for a + - + reflection wavelet when transitioning from frozen to unfrozen sediment and - + - phase from unfrozen to frozen sediment. In theory, different reflection polarity occurs when wave impedance is caused by the transition from materials of high-to-low versus low-to-high dielectric constant (Arcone et al. 2006).

In Figure 4, the depth of signal penetration achieved with 250 MHz is limited to the first frozen-unfrozen interface, as a result of high signal attenuation in the unfrozen sediment. The signal attenuation exhibited in fine-grained saturated sediment results from the interaction between the polar water molecules and the charged sediment surfaces. However, greater penetration depths were obtained with lower antenna frequencies (e.g., 100 MHz) which allowed for multiple frozen–to-unfrozen transitions to be imaged up to 10 m in depth.

The upper thermal interface was identified in a cross-sectional profile as a laterally continuous reflection (Fig. 5). Internal reflections resolved from within the zone of frozen sediment represent sedimentary structure. The upper thermal interface was verified to represent the depth of seasonal frost with temperature data. Beneath zones of bottom-fast ice, seasonal frost develops as a result of seasonal cooling in the ground that is prompted by ice contact with the sediment bed (Dyke 1991). Seasonal frost typically extended less than 3 m below the ice surface.

At greater depths, an additional frozen-unfrozen interface (lower thermal interface) was detected using 100 MHz antennas (Fig. 6). This lower thermal interface represents the approximate position of the permafrost table. At locations where the permafrost table remains detectable by late winter, seasonal thaw exceeds freezeback of the active layer and a talik is present.

Similarly, more isolated zones of unfrozen sediment relating to the presence of taliks result from bathymetric depressions in the sediment bed (Fig. 7). At this location, the talik zone corresponds to an area where ice thickness is in excess of 40 cm. The deeper water limits the ice contact time with the sediment bed, as the duration of winter ice growth is extended. Subsequently, seasonal cooling of the ground is less, and thaw exceeds freeze back. These sites demonstrate the relationship that exists between ice thickness and the spatial complexity of frozen-unfrozen zones beneath bottom-fast ice.

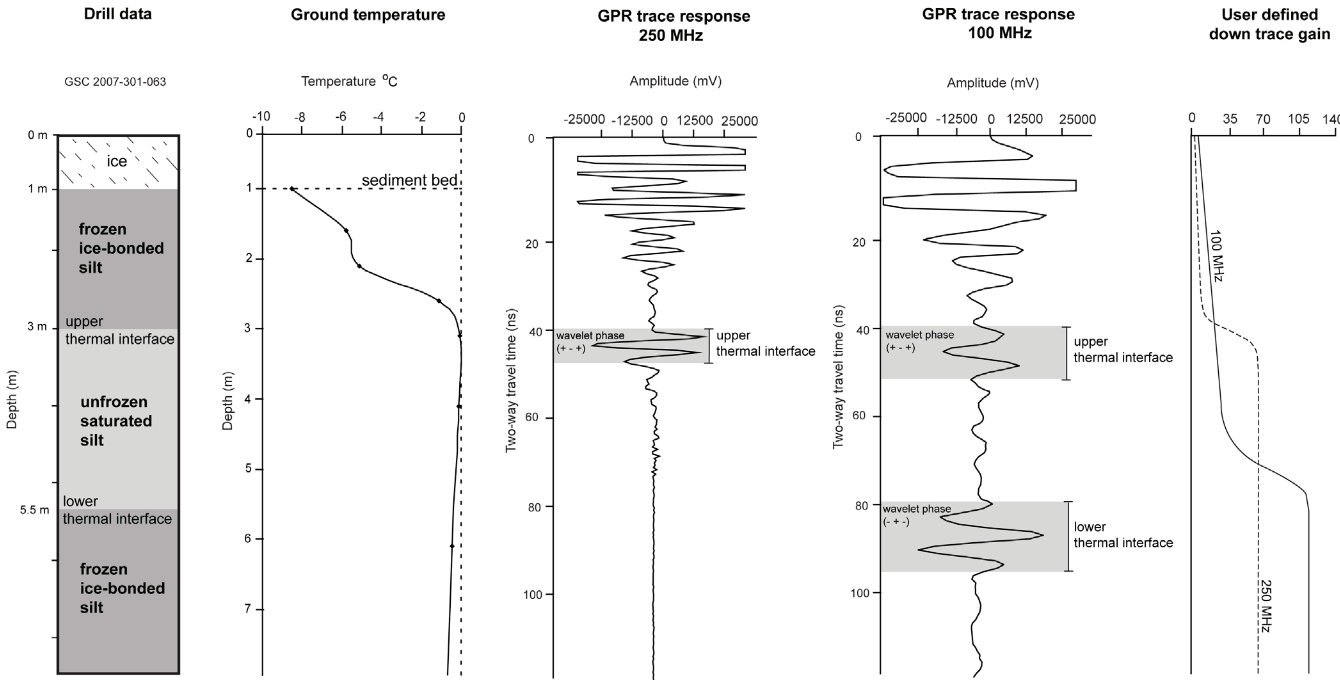

Figure 4. Comparison between drill data, ground temperatures and GPR trace response for 250 and 100 MHz antennas. Drill data at GSC 2007-301-063 indicates a frozen-to-unfrozen interface at 3 m and an unfrozen-to-frozen interface at 5.5 m. The zone of unfrozen sediment corresponds to ground temperatures between -0.06 and -0.48°C. The GPR trace response to these conditions shows two reflective events; an upper thermal interface resolved at 40 ns with 250 MHz, and a lower thermal interface identified at 80 ns with 100 MHz antennas.

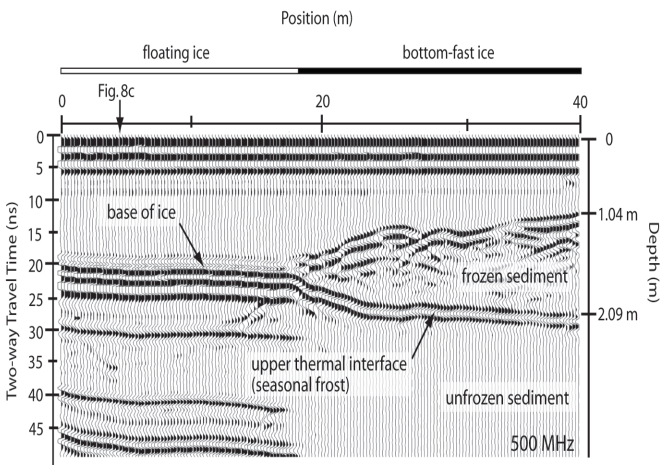

Figure 5. A 500 MHz GPR profile across zones of bottom-fast and floating ice. Beneath the bottom-fast ice an upper thermal interface representing the depth of seasonal frost was detected at 2 m below the ice surface. Ice-bottom multiples are present from 40-50 ns beneath the zone of floating ice.

Interpretations of GPR profiles collected over zones of bottom-fast and floating ice indicate a complex cryostratigraphy with multiple near-surface transitions from frozen to unfrozen sediment occurring over short distances (e.g. <10 m) by late winter. Typically, where bottom-fast ice thickness was less than 1 m, complete active layer freezeback has occurred (Fig. 8a); whereas beneath bottom-fast ice greater than 1 m thick, a talik existed between seasonal frost and the permafrost table (Fig. 8b).

This reflects conditions where seasonal thaw exceeds freezeback of the active layer over one year or a number of years. At locations occupied by floating ice, near-surface sediments were unfrozen to the depth of penetration of the GPR (Fig. 8c). The depth of seasonal frost also decreased towards zones of floating ice, as lateral heat flow restricts the surrounding sediments from freezing.

In general, a strong relationship between bottom-fast ice thickness and nearshore cryostratigraphy exists. As previously noted, the increased duration of ice growth in areas of deeper water restricts the extent of seasonal frost in the ground. This relationship between ice thickness the development of seasonal frost are demonstrated in Figures 6 and 7. The thermal region of the permafrost body is also affected where thaw exceeds complete freezeback of the active layer, as seasonal cooling of the permafrost body is minimal (Stevens 2007). Using this information, the interpretation of GPR profiles also allows the identification of sites where permafrost is potentially degrading.

The variability that exists in the near-surface distribution of frozen and unfrozen sediment may also be influenced by seasonal changes in the rate of ice growth and localized sediment erosion and accretion, which alter the previous water depth.

The GPR reflections from thermal interfaces relate to change in state of pore water, as verified with both drill and ground temperature data (Fig. 4). Therefore, the ability to coherently resolve these two interfaces may be limited where marginally bonded sediments and gradual changes in the dielectric contrast occur over a depth range greater than the transmitted wavelength. Similarly, only under thermal conditions where ice nucleation occurs near 0°C, will GPR reflections correlate with the zero degree isotherm.

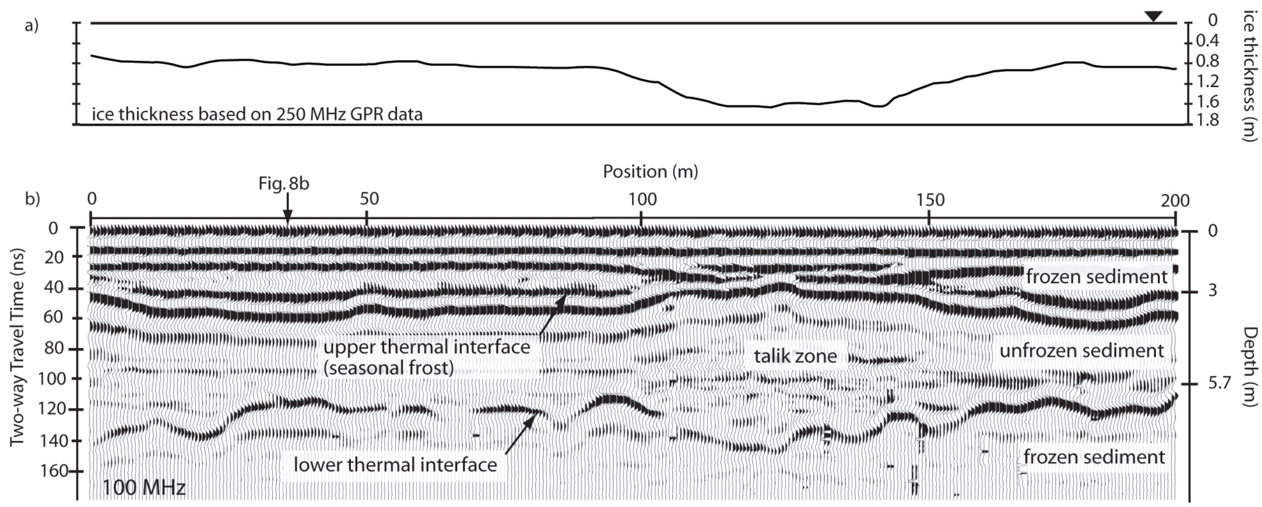

Figure 6. a) Profile of ice thickness obtained across a 200 m section of bottom-fast ice and b) corresponding 100 MHz GPR profile showing both an upper and lower thermal interface which defines a talik zone between ~3 m and 5.7 m.

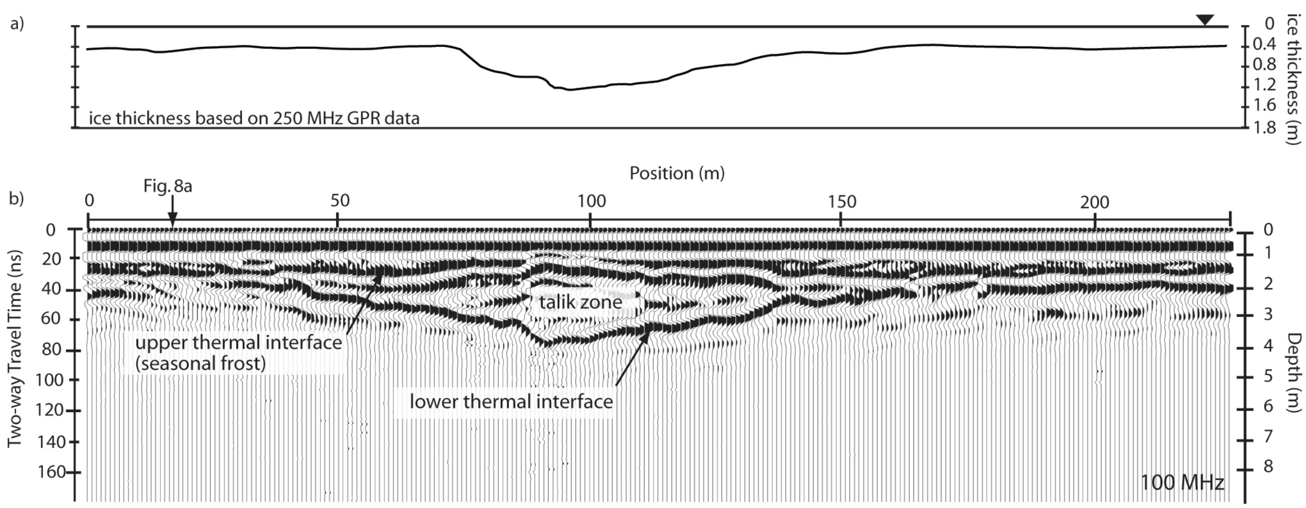

Figure 7. a) Profile of ice thickness obtained across a 225 m section of bottom-fast ice and b) corresponding 100 MHz GPR profile showing the location of an isolated talik. At this location, the talik zone corresponds to ice thickness greater than 40 cm.

Thus, the width of the freezing fringe that is determined by the temperature gradient becomes important to reflection characteristics.

Based on the ground temperature profile presented in Figure 4, a large temperature gradient exists at the upper thermal interface (i.e., the transition from the seasonally frozen to underlying unfrozen sediment). This results in a narrow freezing fringe and a sharp interface between frozen and unfrozen material. This is in contrast to the permafrost table, which exhibited a lower temperature gradient over an equivalent subsurface distance. Therefore, the lower temperature gradient has the potential to cause some misinterpretation of the permafrost table due to more subtle changes in the dielectric properties over the wavelength. In addition, a freezing-point depression would offset the ice nucleation temperature and the recorded position of the permafrost table. As GPR can only resolve changes in the thermal state of pore water and cannot directly detect ground temperatures, the latter information can only be inferred.

Conclusions

Ground penetrating radar surveys conducted within the nearshore zone of the Mackenzie Delta were effective in resolving thermal interfaces up to 6 m beneath zones of bottom-fast ice. With 250 MHz antennas, the depth of penetration was limited to an upper thermal interface which corresponds to the extent of seasonal frost. In contrast, an upper and lower thermal interface delineating talik zones were resolved with 100 MHz antennas. Thermal interfaces closely correlate with frozen-unfrozen transitions of sediment and changes in ground temperatures from above freezing to below -0.5°C.

Complete freezeback of the active layer was exhibited beneath bottom-fast ice less than 1 m thick in contrast to locations where ice was greater than 1 m thick, beneath which talik zones were identified. Sediments were unfrozen at the sediment-water interface where ice remained floating.

The multiple thermal interfaces detected beneath bottom-

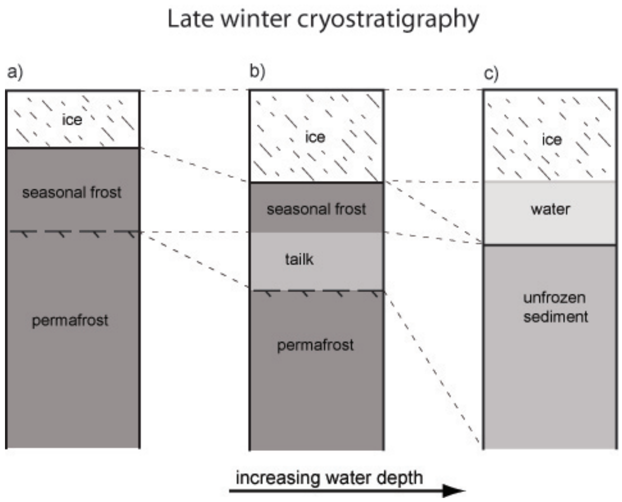

Figure 8. Schematic illustration of late winter cryostratigraphy interpreted from GPR data: a) bottom-fast ice less than 1 m thick characterized by complete freezeback of active layer; b) bottom-fast ice greater than 1 m thick characterized by a talik where thaw exceeds freezeback of the active layer; and c) floating ice where sediments are perennially unfrozen within the upper 3 m of the sediment bed.

fast ice suggest a complex thermal regime that exists at scales not easily characterized by point-source drill and ground-temperature datasets. However, multi-frequency GPR surveys provide high resolution reflection-based data which can detect vertical and spatial variations in the thermal state over large coastal regions. Such subsurface datasets become critical to further understanding permafrost conditions and freeze-thaw processes in the coastal zone.

Acknowledgments

This research was financially supported by the Natural Resources Canada and NSERC. Logistical support was provided by Shell Canada, Chevron Canada, Devon Energy, and the Aurora Research Institute. We also acknowledge Dustin Whalen, J.C. Lavergne, and Jen Bode for assisting with data collection.

Abstract

Cooperation between soil scientists from Canada, European Union, Russia, and the USA has resulted in an Atlas of Northern Circumpolar Soil which brings together soil data for all northern countries to better understand soil resources in these regions. The Atlas aims to raise public awareness of the value of soil in the north and support further research in this area (for example, the European Union's Thematic Strategy for Soil Protection). The Atlas contains a richness of information on soil diversity, the mapping and classification of permafrost-affected soil, the role of soil in the global carbon cycle, and atmospheric concentrations of biospheric greenhouse gases in the past and the future. The publication has fostered cooperation between several countries and bridges the gap between soil science, the permafrost community, policy makers, educators, and the general public. The Atlas is a contribution of the European Union to the International Polar Year 2008.

Keywords: atlas; climate change; cryosols; permafrost; soil.

Introduction

The Arctic plays a key role in the global environment. The region accumulates a huge mass of ice which controls sea level, heat exchange in the atmosphere, and the cold oceanic currents driving atmospheric and oceanic processes. NASA observation shows that perennial Arctic sea ice, which normally survives the summer melt season, has shrunk by 14% between 2004 and 2005. The melting of the ice cap indicates a warming of the marine environments. On the continental land, such a climatic warming will lead to a degradation of the permafrost, which affects the behavior of terrestrial ecosystems including humans (e.g., sinking houses, weakening roads, runways, and pipelines).

While there is considerable research interest in the Arctic region on socioeconomic and broad environmental issues, there is a growing awareness of the importance of soil in the northern circumpolar region. Soil is a surface layer which has resulted from the interaction of climate, relief, parent material, vegetation, and time. As a natural body, soil supports basic physical, chemical, and biological processes in ecosystems and provides principle ecological services for humans. Being sensitive to environmental changes, soil in northern regions is projected to undergo the greatest impact from climate warming. The consequences of changes to the principle soil-forming processes regulating biogeochemical cycles and ecosystems functioning are uncertain at present. In order to draw a reliable picture on the future changes, soil scientists have over the last decades focused efforts to improve the basic and applied knowledge of the circumpolar soil.

One of the specific features of the north circumpolar region is that it is occupied by developed countries (USA, Canada, EU, and Russia) with strong national traditions in soil classifications, survey, and mapping. The diversity of national traditions results in a mosaic of soil inventories, which make joint analysis of soil resources difficult. This situation is a serious constraint for the communication and implementation of agreed environmental policies in the region. Soil scientists have attempted to overcome this gap by focusing on the development of a common circumpolar soil database. All national soil terms and data in this area were combined, correlated, and presented in a common harmonized GIS-compatible database (Tarnocai et al. 2001, Cryosol Working Group 2004). The database has enabled the first estimate of the carbon stock in cryosols (Tarnocai & Broll 2008, Tarnocai et al. 2007, Tarnocai et al. 2006, Tarnocai et al. 2003). It was found that soil in the circumpolar region accumulates about 30% of the world's soil organic carbon. The release of the database stimulated a fundamental review of the knowledge on the permafrost-effected soil. This basic revision has been outlined in Kimble et al. (2004).

However, the soil database, its analysis and related scientific publications address professionals and are too specific for the general public. To bring available information to the latter, a group of scientists from Canada, European Union, Russia, and the USA have collaborated to produce a high quality Atlas on soil in the northern circumpolar regions that is easily readable and graphically stimulating. This publication intends to raise public awareness of the value of soil in northern latitudes supporting further research in this area - for example, Soil Thematic Strategy for Soil Protection in Europe (COM (2006)231, COM(2006)232).

The compilation of the Atlas is a contribution to the Polar Year (IPY) 2007-2008 collaborative science program. This work is included in the IPY CAPP Project #373. It contributes to multidisciplinary approach, incorporating physical and biological sciences, social sciences, and a large education component.

The objective of the paper is to introduce the Atlas of Northern Circumpolar Soil with special emphasis on:

1. Methods and data used;
2. Content of the Atlas;
3. Demonstrate major findings and conclusions.

Methods and Materials

The Atlas is a compilation of different data originating from published and unpublished sources. A substantial portion of the data, including maps, texts, photos, and graphs, is new and was produced specifically for the Atlas. The cartographic coverage originates from a variety of sources: 1) for the North America, Greenland, Mongolia, and part of Kazakhstan: the Northern and Mid Latitude Soil Database (Cryosol Working Group 2004); 2) for Northern Eurasia and Iceland: the Soil Geographical Database of Eurasia (Van Liedekerke et. al. 2004); 3) for China and part of Kazakhstan: Digital Soil Map of the World (FAO 1990). All these databases have been combined to create a single database that covers a circle with the North Pole in the center and limited by 50°N latitude to the south. The database has been translated into the international World Reference Base correlation system (IUSS 2006).

In addition to maps, the Atlas contains explanatory texts illustrated by photographs and graphics that are specially written to address those who are interested in learning more about northern soil characteristics and environments.

Technically, the Atlas is a book of 144 A3 pages illustrated by a mix of text, colored maps, pictures, diagrams, and photographs.

Results

The Atlas (Fig. 1) consists of the following main sections:

1. Introduction
2. The Northern Environment
3. Soil in Northern Latitudes
4. Soil Classification
5. Soil Maps
6. Northern Soils and Global Change
7. Conclusions and Future Perspectives
8. Additional Information

Figure 1. Cover page showing the extent of the northern circumpolar area addressed by the Atlas.

Introduction

This section contains the list of authors, includes acknowledgements, outlines the scope of the Atlas, and presents an overview of EU policy for soil protection within the context of the International Polar Year.

The northern environment

This section is intended to provide the reader with a range of general information on the circumpolar region through a series of documented thematic maps (i.e., sea ice extent, mean annual temperature, mean annual precipitation, permafrost extent, soil temperature, relief, parent material, land cover, population density, permafrost, and patterned ground). Data for this section come from well-distinguished sources. For example, the soil temperature map originates from the US Department of Agriculture; the vegetation patterns were extracted from the Global Land Cover 2000 database; while information on permafrost is provided by the International Permafrost Association.

Soil in northern latitudes

The scope of this section is to provide a basic understanding of what is soil and, in particular, soil in northern regions. The section outlines the main soil functions, especially those related to the principle soil-forming processes in northern latitudes with specific attention being given to cryogenic processes associated with freeze-thaw cycle, cryoturbation, polygonal cracking, and stone sorting. The section also describes soil biodiversity in cold climates.

Soil classification

This section introduces the most widely-used national soil classification systems in the circumpolar region (e.g., Canadian, USA, and Russian). Special attention is paid to the latest version of the World Reference Base for soil classification (IUSS 2006). All classification systems are illustrated by examples of their main concepts, taxonomic systems, and description of the principle soil types. One page of the Atlas is devoted to the correlation and comparison of different classification systems. Examples demonstrate that soil inventories based on the varying concepts used in different soil classifications result in a markedly different outputs (e.g., Cryozems in Russian soil classification are exclusively restricted to highly cryoturbated soils that cover only a part of the Gelisols Order in the USDA Soil Taxonomy, Cryosols in Canadian system and WRB).

The different number of the highest level taxonomic classes is another example of the conceptual differences between national soil classifications: Soil Taxonomy (USDA) uses twelve Orders; the Canadian soil classification system exploits ten soil Orders; the Russian soil classification contains fifteen soil Divisions while the WRB system assigns all soil types to thirty two Reference Soil Groups.

As the conceptual inconsistency is difficult to overcome, many scientists suggest comparing national soil classifications on the basis of physically measured soil parameters (e.g., pH, organic carbon content, base saturation, etc.). Unfortunately this approach has some limitations as soil characteristics are measured differently in different countries. This inconsistency is because of the national traditions, the availability of equipment, economic reasons, etc. For example, the determination of soil organic carbon (SOC) according to the methodology proposed by Walkley–Black (Canada) or Turin (Russia) is based on "wet combustion" (carbon oxidation is performed by dichromate solution). This method recovers about 70%-80% of the total SOC content. Other countries use a dry combustion method, where the soil is heated to 950°C in an oven. In this method the recovery of SOC is 100%. Similar differences can be found in many other analytical methods, such as the detection of soil texture, soil pH, cation exchange capacity, etc. Therefore, an understanding of the methodologies used to measure soil characteristics is crucial for the correlation of national soil classifications.

Other variations in soil characteristics arise from differences in ecological and land-cover interpretations in different countries. For example, the thickness of the peat layer is one of the criteria used to distinguish forest from bog in land cover mapping. In Canada, this threshold is 40 cm, while being 30 cm in Russia. As a result, maps of peat areas using the two approaches look substantially different.

In spite of the differences in national classification schemes and the lack of full coincidence between soil terms, the occurrence of the soil in the same natural zone could be a good basis to correlate soil classifications. For example, Mollisols (the USDA Soil Taxonomy), Chernozems (in Canadian and WRB systems) and Humic-accumulative soils (Russia) are formed under steppe and the prairies vegetation. Therefore, these differently termed soils have many common characteristics and could be regarded as being very close.

The section also contains a description of the Reference Soil Groups of the WRB, illustrated by maps showing the broad distribution patterns of each reference group together with high-quality photographs of characteristic soil profiles and associated landscapes. The section is concluded by examples of soil surveys in the Arctic.

Soil maps

The heart of the Atlas contains 30 plates of soil maps at a scale of 1:3,000,000. The map legend is based on the second level units of the WRB (IUSS 2006). This is the first application of the revised WRB system for this territory. It is important to emphasize that the maps were harmonized at the border between some countries (e.g., USA (Alaska) and Canada, Russia and Finland, Russia and China). All maps contain short explanatory texts aiming to draw the attention to the specific features of this particular circumpolar area.

A short section is devoted to other regions for the world where cold soil can be found, and includes some information on the soil types of Antarctica. The section concludes with an overview of the circumpolar soil database and introduces the basic principles of Geographic Information Systems (GIS) and its use in the Atlas.

Northern soils and global change

This section provides information on the relationship between soil and global change, in particular, climate change. A brief overview of glacial periods is used to introduce the concept of palaeosols that illustrate the ability of soil to preserve indications of past climate change.

The section progresses to consider the role of the circumpolar region in the global carbon cycle, which is highly debated at present. Besides general information, this section demonstrates the special role of the organic and mineral soil types in the north for the sequestration of organic carbon. Through cryoturbation and other pedogenic processes, organic carbon can be moved deep in the soil and preserved from decay by the permafrost for very long periods of time (Fig. 2).

Figure 2. Organic matter translocation by cryoturbation. East European tundra near Vorkuta, Russia. Cryoturbation in permafrost-affected soils removes peat, litter, wood debris, and other kinds of organic matter (fragments of H horizon – the darker parts in the above profile) from the surface deeper into the soil leading to preservation of organic matter in deeper, colder, and less biologically active layers (photo by M. Drewnik).

Such special mechanisms make cryosols and organic-rich soil a unique instrument to mitigate greenhouse gas concentration in the atmosphere. The Atlas explains the processes for the decomposition of vegetation residues and the associated emissions of carbon dioxide and methane, and pays special attention to the potential evolution of organic and mineral soil under present and future climate warming scenarios.

The variation in the characteristics of soil in the northern circumpolar region is striking. The Atlas illustrates this richness through a series of plates devoted to the soil types of Scandinavia, Iceland, Greenland, Canada, Alaska, and Central Siberia.

Conclusions and future perspectives

The last section considers future perspectives for soil in northern areas, raising attention to the need for soil conservation in the area. One page is devoted to the high value of the Atlas as an educational resource. This is supplemented by a glossary of terms, contact information for soil scientists in northern countries, and references for those who wish to know more about the unique world of northern circumpolar soils.

Summary

The Atlas of Northern Circumpolar Soil is the first document of its kind to bring together soil data for all the northern countries in a style designed to better explain and protect soil resources in these areas. The Atlas has fostered cooperation between several countries and bridges the gap between soil science, the permafrost community, policy makers, educators, and the general public.

Core support for the project has been provided by the European Commission's Joint Research Centre (JRC).

Abstract

The Quaternary geology of the coasts of Yenisey Gulf is characterized by the prevalence of marine saline sediments. As a rule, the upper parts of coastal sections are of continental origin. Active denudation processes take place in locations with ice-rich sediments, especially where tabular ground ice and ice wedges are present. Massive ground ice bodies with 2–15 m of visible thickness were found in late Pleistocene marine sediments at the Taimyr coasts of Yenisey Gulf. Ice-rich sediments are widespread; they form the "Ice Complex" at the top part of the Quaternary section of west Taimyr. The "Ice Complex" sediments form a geomorphic surface with a height of about 12–15 m a.s.l. These sediments were formed during late Pleistocene sea regression, at a time when the mouth of the Yenisey River was about 300 km to the north from its present location. Ice-rich syngenetic Holocene sediments accumulated mostly at slopes and bottoms of thaw-lake basins and other depressions associated with thawing of Pleistocene ice wedges and tabular massive ice bodies.

Keywords: grain size; heavy minerals; ice wedges; ion composition; quaternary sediments; tabular massive ice.

Introduction

Ground ice studies help to obtain significant paleogeographical information. Huge syngenetic ice wedges, forming specific "Ice Complex" (or "Yedoma") sediments, and tabular massive ice with thicknesses up to 50 m, are unique natural formations. According to most recent publications, "Ice complex" silty sediments of late Pleistocene are polygenetic; they were formed due to aeolian, fluvial, slopewash, nival, and solifluction processes.

"Ice Complex" sediments have been studied mainly in central and northern Yakutia; similar sediments were observed also in Chukotka, West Siberia, Taimyr, Alaska, and Canada (Péwé 1975, Katasonov 1978, Popov et al. 1985, Carter 1988, Romanovskii 1993, Shur et al. 2004). Many publications are also based on studies of tabular massive ice bodies, but numerous hypotheses on their origin are still controversial (Streletskaya et al. 2003). Sections where both tabular and syngenetic ice-wedge bodies can be observed have a special value (Danilov 1969, Trofimov & Vasilchuk 1983, Vasilchuk 2006, Kunitskiy 2007).

Coastal bluffs of the Yenisey Gulf are formed mostly by Quaternary marine and littoral sediments with tabular massive ice bodies (Danilov 1969, Soloviev 1974, Danilov 1978). The upper part of the section is formed by continental sediments with huge ice wedges (Karpov 1986).

Beginning in 2004, we studied permafrost at the coasts of the Yenisey River and Yenisey Gulf between Dudinka and Dikson. This area is located within the continuous permafrost zone (Fig. 1). Our work was aimed at solving the problem of the history of permafrost development during the Pleistocene and Holocene. The purpose of our research included the study of cryogenic structure, chemical and mineralogical composition; estimation of ice content, salinity, grain size, organic carbon content, and age of the Quaternary sediments.

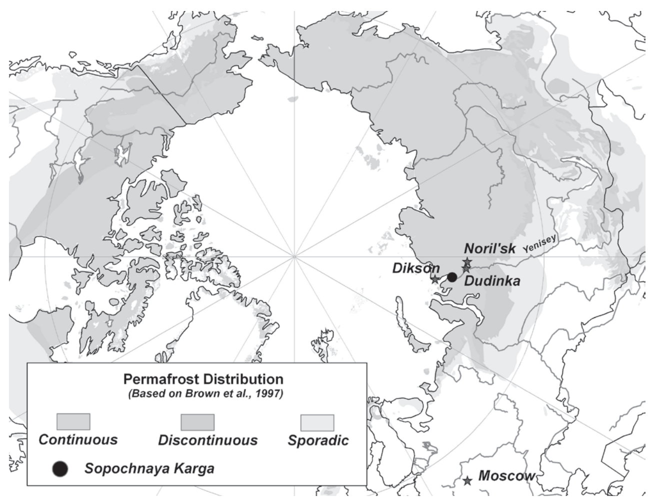

Figure 1. Location of the study area.

During field work, several sections of Quaternary sediments with different types of massive ice were studied (Streletskaya et al. 2005, Streletskaya et al. 2007, Shpolyanskaya et al. 2007). Our research of ground ice and sediments included field investigations and laboratory analyses (chemical, faunistic, micro-pollen and spores, oxygen-isotope, grain size and mineralogical, radiocarbon dating).

Results

One of the most interesting sections was studied in the 30–35 m high coastal bluff located near the "Sopochnaya Karga" Polar Station (71°57′N, 82°41′E), where the tabular massive ice body with a visible thickness of 10–12 m was observed (Fig. 2). This body is overlain by taberal (thawed and refrozen) clayey silts 8–10 m thick. The upper part of section is formed mostly by ice-rich syngenetically frozen silt with a belt-like cryostructure; the cryostructure between ice belts varies from reticulate and ataxitic (suspended) to micro-lenticular. The gravimetric moisture content reaches 80% and more. This layer includes ice wedges that vary from 0.4 m to 3.0 m in width.

The isotope composition (^{18}O) of the intrasedimental ice lenses reaches -17.50‰ to -17.73‰, while the composition of wedge ice varies from -19.04‰ to -20.92 ‰. Wedge ice mineralization reaches 22.04 mg/l, while the silts, including ice wedge, are fresh.

The horizon with ice wedges is underlain by dark-brown peat 1.0–1.5 m thick. The peat transforms with depth into brown organics-rich clayey silt with lenticular-braided, ataxitic (suspended), and micro-lenticular cryostructures (Fig. 2B). Radiocarbon dating of peat samples showed the age 7320 ±130 yr BP (GIN 13056) and 8050 ±60 yr BP (GIN 13055). Thus, radiocarbon dating indicates a Holocene age for the ice wedges.

Peat and peaty silt horizons are underlain by dark-grey silty clay with numerous inclusions of pebbles and boulders. This horizon, which is 10–15 m thick, overlies the body of tabular massive ground ice. Silty clays are characterized by

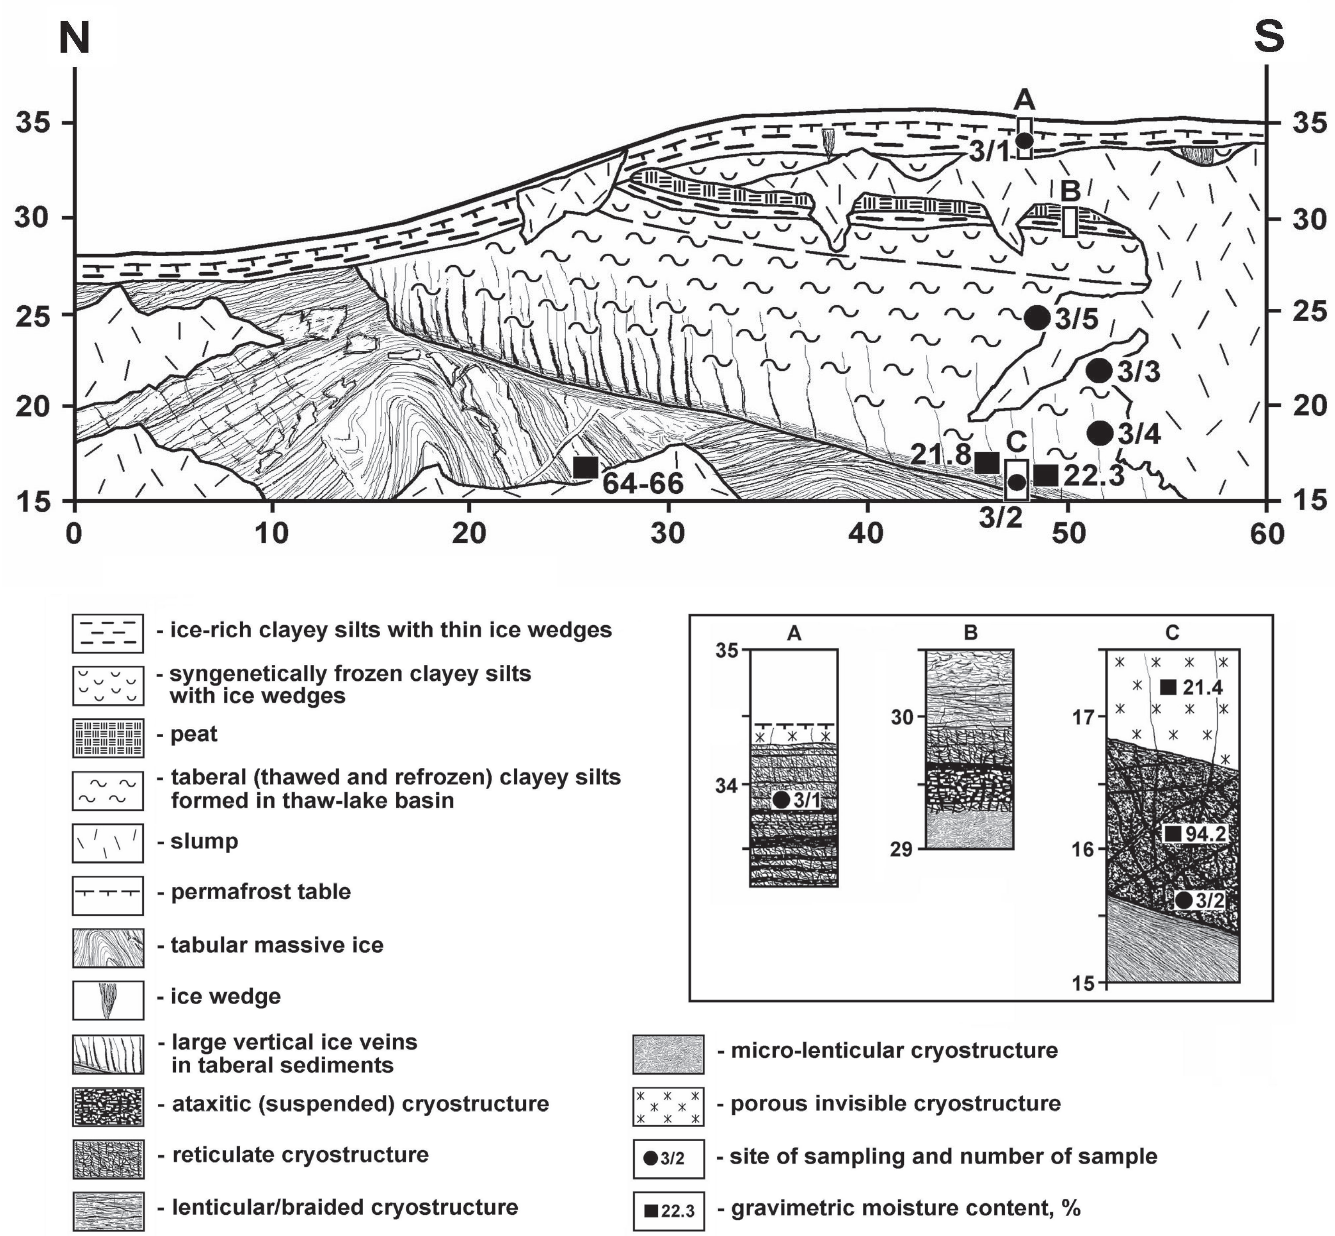

Figure 2. Cryostratigraphic section #3 in the area of "Sopochnaya Karga" Polar Station. Horizontal and vertical scales in meters. A, B, C – details of cryogenic structure.

porous cryostructure; their average gravimetric moisture content is about 22%. At the bottom part of this horizon, above the boundary with the massive ice, thick ice veins, wedging out upwards, were observed. Close to the boundary incline (parallel to the boundary), an ice-rich horizon with the thickness up to 1.2 m was observed. This horizon is characterized by ataxitic (suspended) cryostructure; its gravimetric moisture content reaches 94%.

Silty clays are fresh in general, but their ion composition changes with depth (Fig. 2, samples 3/5, 3/3, 3/4). Bicarbonate-ions and sulfate-ions amounts increase from 0.46 up to 1.92 mg-eqv/l and from 0.18 up to 1.82 mg-eqv/l, respectively. Chlorine-ion content increases from 0.30 up to 0.98 mg-eqv/l. At the boundary with the massive ice body (Fig. 2C, sample 3/2), silty clays contain more soluble salts (salinity is about 0.14%), and contents of bicarbonates and sodium exceeds the contents of all other ions.

A tabular massive ice body is characterized by frequent alternation of folded layers of pure ice and relatively ice-rich soil, with a cryostructure that varies from micro-ataxitic (micro-suspended) to micro-porphyritic (porous visible) with a gravimetric moisture content of 64–66%.

Mineralization of pure ice varies from 46.74 mg/l to 247.87 mg/l. Ion composition shows the prevalence of bicarbonate-ions, which reaches 92% near the upper boundary of the massive ice body and 81.8% at its base. Among cations, sodium-ions prevail, their content increasing towards the center of the massive ice body; ice mineralization and amount of soil inclusions decrease in the same direction. The isotope composition (^{18}O) of the massive ice reaches -22.84‰ to -23.15‰; these values are similar to the composition of wedge ice.

In the section of the other coastal bluff (Fig. 3), also located in the area of “Sopochnaya Karga” Polar Station, three horizons of Quaternary sediments with a total thickness of about 12 m were observed.

The upper part of the section to a depth of 6.2 m is formed by syngenetically frozen silts of alluvial-lacustrine genesis (Fig. 3A). The silts include ice wedges up to 2 m wide. The isotope composition (^{18}O) of the wedge ice varies from -24.46‰ up to -24.84‰. The silts are underlain by ice-poor fine sands and coarse gravelly laminated sands (Fig. 3). At the boundaries of the wedges, strong upward tilting of sands was observed (Fig. 3B). Gravimetric moisture content of

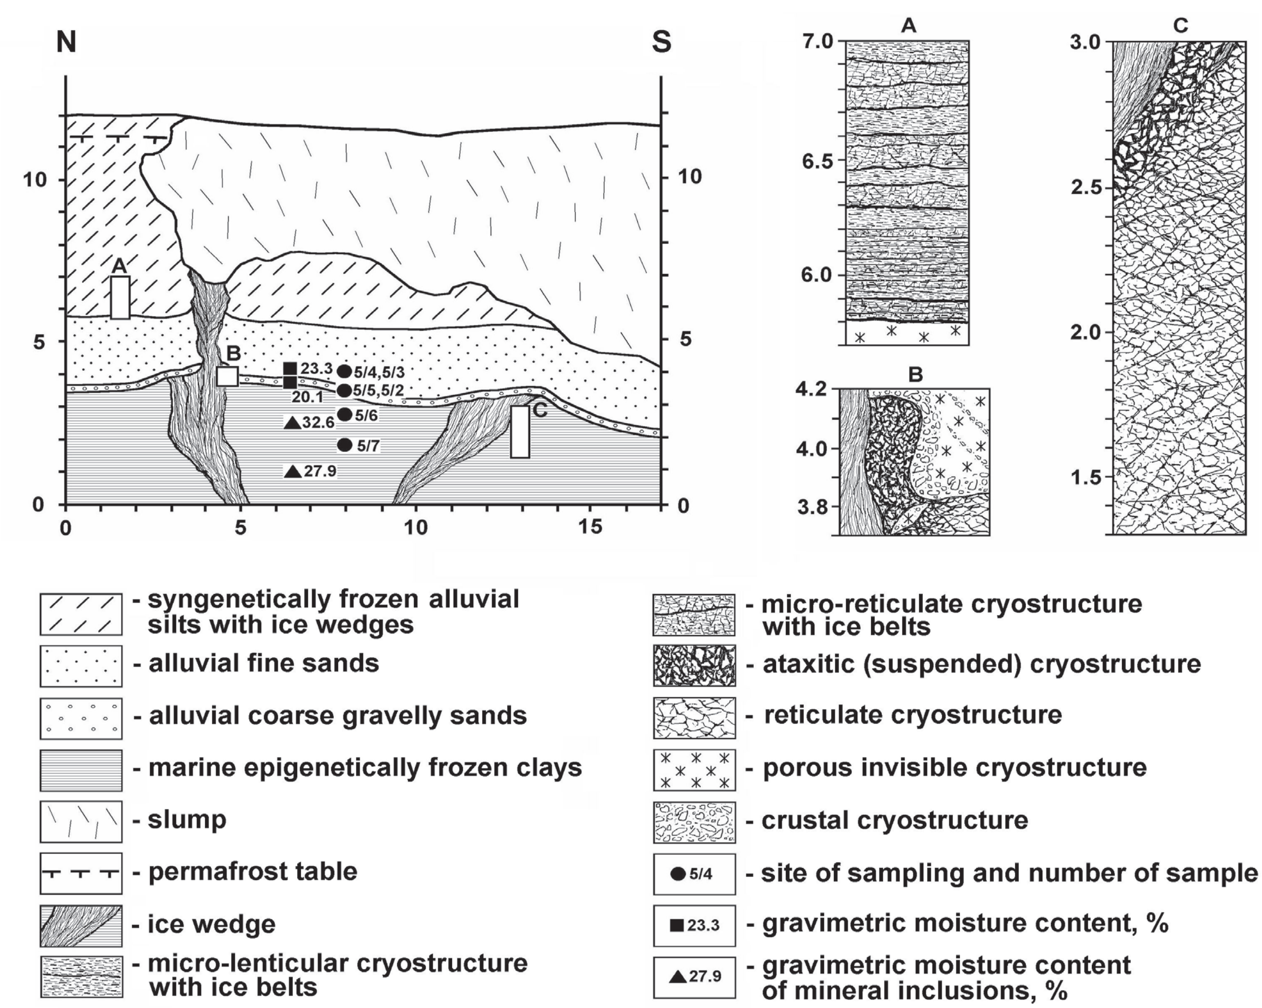

Figure 3. Cryostratigraphic section #5 in the area of “Sopochnaya Karga” Polar Station. Horizontal and vertical scales in meters. A, B, C – details of cryogenic structure.

sands reaches 20–23%. Both silts and sands are fresh. Ion composition shows the prevalence of bicarbonate-ions and sodium-ions.

From a depth of 8.5 m and downward to sea level, dark-gray clays were observed. The clays include ice wedges up to 2 m wide. Sufficient increase in the ice content was observed near the boundaries of the ice wedges (Fig. 3B, C). The clays are saline (salinity is about 0.5%), and the composition of soluble salts is characteristic for marine conditions (chlorine-ion content is 70–85 mg-eqv%, sodium-ion content is 97 mg-eqv%).

Discussion

Analysis of obtained data allows for reconstruction of the freezing conditions of studied strata. In both sections we can see evidence of transformation from marine to continental conditions, which resulted in freezing of Late Pleistocene marine sediments, formation of tabular massive ice, and deposition of syngenetically frozen "Ice Complex" sediments.

We believe that the tabular massive ice body, studied at section #3, could be formed due to an injection of water-soil slurry into epigenetically frozen strata of marine clay. The alternative hypothesis of possible massive ice origin is glacial; it is based on similarity of the studied ice body with the basal ice of modern glaciers (Kanevskiy et al. 2006).

In general, mineralization of the tabular massive ice body is typical for closed taliks: freezing from different directions results in the increase of mineralization near the margins of freezing body. The ion composition is also similar to ion composition of sub-lake taliks. In the studied section, Na/Cl ratio is 3.0–3.7. For example, in sub-lake taliks in Yakutia, this ratio varies from 3.2 to 7.5 (Anisimova 1981).

Development of the thermokarst process resulted in partial thawing of the tabular massive ice body, formation of a thaw bulb beneath the lake, and accumulation of taberal sediments. These sediments formed as a result of thawing and refreezing of epigenetically frozen marine clay. Taberal origin of silty clays can be proved by the absence of lamination, typical for lacustrine sediments, and increase of soluble salts content with depth. Such distribution of soluble salts indicates the process of salts migration towards the freezing front. Originally these sediments were formed at the littoral; marine-type composition of salts transformed to continental as a result of thawing of sediments.

Marine origin of these sediments was also confirmed by complex mineralogy and grain size analysis (Surkov 1993, Surkov 2000). According to this method, the origin of sediments can be distinguished by the patterns of distribution of heavy minerals relating to size and shape of grains (for example, grains of marine sands are better rounded and have a flat shape). Standard patterns for different types of sediments were developed (Surkov 2000); comparison with these patterns allows definition of the origin of sediments and condition of sedimentation.

A study of heavy minerals from the silty clay layer (section #3) shows that this horizon originally was formed in littoral conditions with alongshore currents and big wave activity. Minerals from the tabular massive ice body are well-sorted; the stable assemblage of heavy minerals (magnetite, ilmenite, garnet) indicates a constant source of denudation during the sedimentation process.

Micro-faunistic analysis shows that the foraminifer complex is typical for the low-salinity Arctic basin, which existed presumably in the end of Eemian and after the Eemian stage of the late Pleistocene (Streletskaya et al. 2007). Therefore, the sediments overlaying massive ice and the soil inclusions in the ice itself have the same marine origin and differ sufficiently from the upper horizon with ice wedges.

We believe that talik freezing, triggered by elimination or migration of the lake, started from the surface. An ice-rich layer parallel to the boundary with tabular massive ice (Fig. 2C) was formed due to freezing from below of water-saturated soils at the base of the talik. Simultaneously with the freezing of the talik, the formation of syngenetically frozen soils with micro-lenticular cryostructure started at the surface. The complex mineralogy and grain size analysis of heavy minerals shows that sorting of such minerals as magnetite, ilmenite, garnet, and pyroxene is typical for continental conditions of floodplains with numerous peaty ponds. The prevalence of flat quartz grains with a specific wing-like shape reflects the role of aeolian transportation in sedimentation process (Surkov 1993, Surkov 2000).

Peat accumulation at the bottom of the thaw lake basin during the climatic optimum of the Holocene resulted in the active layer reduction and formation of an ice-rich intermediate layer (Shur 1988) about 0.6 m thick (Fig. 2B). The peat layer was buried beneath syngenetically frozen slope sediments. Termination of slope sedimentation resulted in the formation of the contemporary intermediate layer with thin ice wedges (Fig. 2A).

The formation of silt with syngenetic ice wedges (section #5) started during marine regression at the end of the late Pleistocene, when the mouth of the Yenisey River moved northward more than 300 km in comparison with its contemporary position (Stein 2002). At this period, ice wedge growth occurred in west Siberia, at the west and east coasts of Yamal Peninsula (Forman 2002, Kanevskiy et al. 2005, Vasilchuk 2006), in central parts of Yamal Peninsula, and at Gydan Peninsula (Bolikhovskiy 1987), in different parts of Taimyr at Cape Sabler (*Anthropogen* 1982, Derevyagin et al. 1999) and Labaz Lake (Siegert et al. 1999).

Before syngenetic permafrost formation, the epigenetic freezing of marine clays started, accompanied by frost cracking. In section #5, the transition from sub-aquatic to sub-aerial condition is marked by strong oxidation of the top part of the marine clays sequence; the thickness of the oxidized layer is about 1 m. Clays have a reticulate cryostructure; the size of mineral blocks increases with depth, while their moisture content decreases. It indicates slowing of the freezing rate with depth.

The formation of clays in this section occurred in conditions of marine sedimentation below the level of wave sorting. Properties and composition of the clays show similarity with the silty clays from the previous exposure (Streletskaya et al. 2007).

A break in sedimentation, during which relatively large epigenetic ice wedges formed in the marine clay, was followed by a period of erosion activity. Erosion processes led to truncation of the upper part of clay strata. We could observe several evidences of very cold climate at this period: absence of significant thermokarst features at the surface of truncated ice wedges; light isotope composition of the wedges. The patterns of heavy minerals distribution in overlying sands are shown at the Figure 4. Study of the gravelly sands patterns reveals far transportation of grains by high-energy river flow. Heavy minerals composition and distribution are similar to contemporary alluvial sediments of the Yenisey River in the area of Dudinka city; they differ from contemporary beach deposits of Yenisey Gulf (Streletskaya et al. 2005).

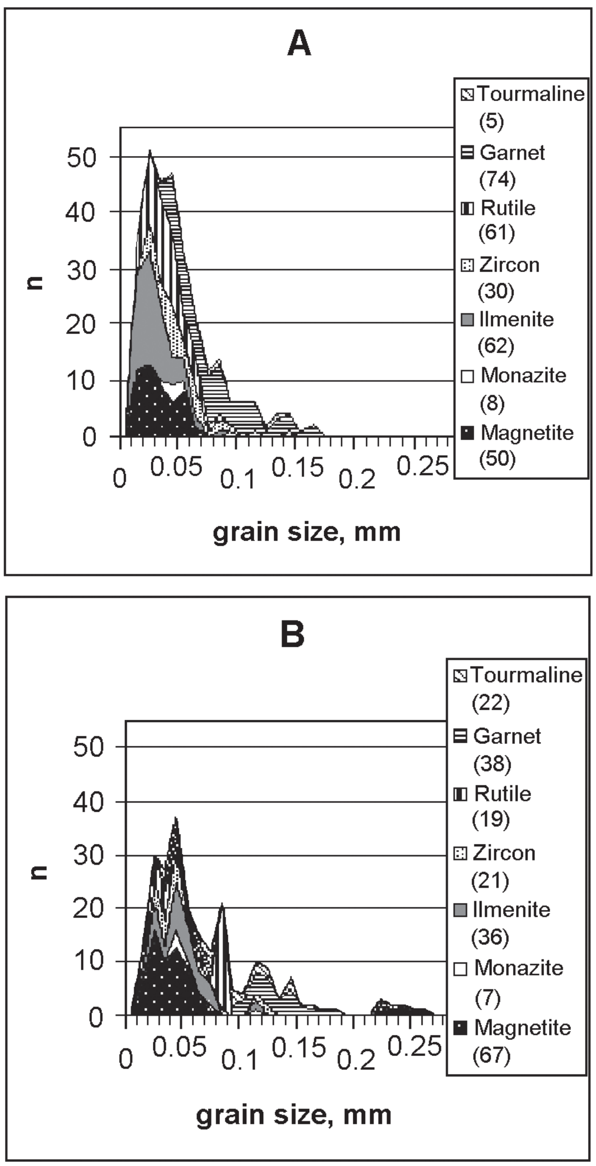

Figure 4. Patterns of heavy minerals distribution vs. thickness of grains (C-axis), Sopochnaya Karga, section #5. Amount of grains is shown in parentheses. A – fine sands; B – coarse gravelly sands.

During the period of alluvial sands accumulation, the growth of part of the ice wedges was terminated (right wedge, Fig. 3). A high sedimentation rate and relatively coarse composition of soils resulted in low ice content and an abrupt decrease in the width of ice wedges still continuing their growth.

We believe that syngenetically frozen silts at the top part of this section have an alluvial-lacustrine genesis. The pattern of heavy minerals distribution showed that they were formed at the floodplain of the big river. The main evidences of a syngenetic type of freezing are the rhythmic cryogenic structure (Fig. 3A); a prevalence of micro-lenticular and micro-reticulate cryostructures; and the occurrence of undecomposed rootlets.

Conclusions

At the coasts of Yenisey Gulf, tabular massive ice bodies are included in littoral clayey sediments of the late Pleistocene, while large syngenetic ice wedges are typical for Late Pleistocene–Holocene continental deposits. Ice-rich sediments are widespread; they form the “Ice Complex” at the top part of the Quaternary section of west Taimyr. The wedges, up to 12 m high, started their development at the end of the late Pleistocene as epigenetic wedges, and continued their growth at the period of syngenetic permafrost formation. They have the same age as thin till deposits of the last glaciation. It confirms the relatively small scale of the last glaciation in Taimyr (Svendsen 2004). Ice-rich syngenetic Holocene sediments accumulated mostly at slopes and bottoms of thaw-lake basins and other depressions associated with thawing of Pleistocene ice wedges and tabular massive ice bodies.

Acknowledgments

We are particularly grateful to Dr. Evgeny Gusev and Dr. Fedor Romanenko for their field assistance, Dr. Boris Vanshtein and Dr. Alexandr Surkov for lab analysis of soil samples, and Dr. Hanno Meyer for lab analysis of isotope composition of ice samples. The work was supported by the “Leading scientific schools of Russia” project 500.2008.5 and by Tyumen Regional Academy.

Thirteen Years of Observations at Alaskan CALM Sites: Long-Term Active Layer and Ground Surface Temperature Trends

Dmitry A. Streletskiy, Nikolay I. Shiklomanov, and Frederick E. Nelson
Department of Geography, University of Delaware, Newark, USA
Anna E. Klene
Department of Geography, University of Montana, Missoula, USA

Abstract

Active layer monitoring is an important component of efforts to assess the affects of global change in permafrost environments. In this study we used data from 13 (1995–2007) years of spatially oriented field observations at a series of 16 representative Circumpolar Active Layer Monitoring (CALM) sites in northern Alaska to examine temporal and spatial trends in active layer thickness and its relation to climatic, surface, and subsurface conditions. The observation strategy consisted of measuring active layer thickness on regular 1-ha and 1-km^2 grids representative of environmental conditions on Alaska's North Slope. The measurement program also involves continuous air and soil temperature monitoring, periodic frost heave and thaw subsidence using Differential Global Position System (DGPS) as well as landscape, vegetation, and soil characterization. This paper showcases CALM observation procedures and analysis designed to monitor processes and detect changes not anticipated in the original CALM protocol of the early 1990s.

Keywords: active layer; Alaska; CALM; Circumpolar Active Layer Monitoring; surface temperature; thaw subsidence.

Introduction

The active layer is the most dynamic part of the permafrost system and undergoes many changes in its properties during each annual cycle. These fluctuations involve variations of ice/water content, thermal conductivity, density, mechanical properties, and solute redistribution (Ershov 2002), all of which are of critical importance for many natural phenomena and processes in permafrost and periglacial environments (French 2007). Most biological and hydrological activities in arctic soils are confined to the layer of seasonal thaw (Hinzman 1991). Active layer monitoring is an important component of efforts to assess the effects of global climate change in arctic environments. The Circumpolar Active Layer Monitoring (CALM) program is a network of sites at which data about active layer thickness (ALT) and related climatic, vegetation, and soil parameters are collected. The CALM network involves more than 160 sites underlain by permafrost in polar regions and selected mountainous environments (Brown et al. 2000, Nelson et al. 2004).

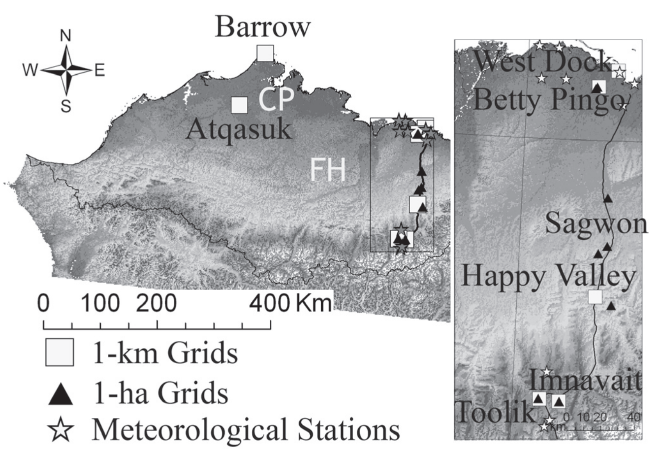

Figure 1. Geographic distribution of Alaskan CALM observational sites used in the present study. Gray tones represent elevation, with brighter shades indicating higher elevations. Physiographic provinces are indicated by white lettering: CP – Coastal Plain, FH – Foothills. Black font is used for name specific sites mentioned in the text.

In this study we used data from 13 years (1995–2007) of extensive, spatially oriented field observations at a series of 16 CALM sites on the North Slope of Alaska to examine landscape-specific temporal trends in active layer thickness and air and soil temperature. CALM strategies are evolving constantly, and this paper showcases CALM observation procedures and analysis designed to monitor processes and detect changes not anticipated in the original CALM protocol of the early 1990s. Details of the analyses and results will be presented in a series of manuscripts currently in preparation.

Study Area

Of the 41 CALM-designated sites in Alaska, 29 are located on the North Slope (Shiklomanov et al. 2008). In this paper we report observed long-term trends of air and ground surface temperature and active layer thickness from 16 sites with continuous records for 13 years (1995–2007).

The sites selected for analysis are distributed along the primary climatic gradient in northern Alaska (Fig. 1). The sites span the regional spectrum of vegetation and terrain conditions in two dominant physiographic provinces: the Arctic Coastal Plain in the north and the Arctic Foothills in the south (Wahrhaftig 1965).

The elevation of the Arctic Coastal Plain increases gradually from north to south, reaching about 100 m at its southern edge. Poor drainage and low relief create conditions for development of thaw lakes. Thaw lakes and thaw-lake basins occupy from 20% to 50% of the area. The coastal plain is dominated by wet sedge polygonal tundra on soils associated with windblown loess deposits (Walker et al. 2003).

The Arctic Foothills province extends between the Arctic Coastal Plain and the Brooks Range and is characterized by hills and plateaus divided by river valleys. The area was glaciated during the Pleistocene, and surface deposits are mostly glacial till with discontinuous loess cover (Bockheim et al. 1998). Differences in underlying deposits create distinct geochemical contrast in soils, leading to differences in vegetation species and organic layer thickness (Walker et al. 1998). Based on soil pH, areas of tundra can be subdivided into acidic (pH <5.5) and nonacidic (pH >5.5) classes. Soils in nonacidic tundra have thinner organic horizons, a significantly thicker active layer, and greater cryoturbation than soils of acidic tundra (Bockheim et al. 1998)

The entire study area lies in the zone of continuous permafrost. The only areas possibly without permafrost are occupied by deep bodies of water that fail to freeze to the bottom in winter (Péwé 1975).

Methodology

Of the 16 CALM sites used in the analysis described in the next section, 9 consist of 1-ha plots established to represent relatively homogeneous examples of the landscape categories found in particular physiographic provinces. The selection of landscapes was guided by a regional landcover map derived from Landsat imagery (Auerbach et al. 1996). The map depicts 5 primary landscape units: wet tundra (WET), moist acidic tundra (MAT), moist nonacidic tundra (MNT), shrublands (SHR), and barrens. Characteristics of the 1-ha sites were described by Shiklomanov & Nelson (2003), and Klene et al. (2001b); their geographic distribution is shown in Figure 1. Beginning in 1995, the active layer has been probed at least annually at the 1-ha sites. The procedure involves pushing a metal rod, calibrated in cm, to the point of refusal, interpreted in most cases to be the frost table. Thaw depth measurements at each site were obtained by probing at 5 m intervals along the plot's two perpendicular and one diagonal transect, resulting in 71 points per plot per probing date. Air and soil surface temperature were measured continuously at two-hour intervals over the 1995–2007 period (data are available for the 1996–2006 period) with an array of Onset™ portable data loggers. At each site one logger is mounted on a mast, with thermistors placed approximately 2 m above the ground in a radiation shield. Seven to ten loggers are distributed over each of the 1 ha plots, with thermistors placed at the vegetation/soil interface at locations representative of microtopographic conditions (Klene et al. 2001b, Klene et al. 2008).

Periodic thaw depth measurements were also conducted at 7 surveyed and georeferenced 1-km^2 grids over the period 1995–2007. These sites were established in northern Alaska during the 1980s and 1990s to monitor long-term ecosystem change (Brown et al. 2000). Four grids (Barrow, Atqasuk, Betty Pingo, and West Dock) are situated on the Arctic Coastal Plain, and the remaining three (Happy Valley, Imnavait Creek, and Toolik Lake) are in the Arctic Foothills (Fig. 1). The 1-km^2 grids were selected to represent more generalized conditions found in each physiographic province. Detailed descriptions of the 1-km^2 sites were provided by Hinkel and Nelson (2003). Each grid consists of a square array of surveyed permanent stakes separated by 100 m, yielding an 11 × 11 array of sampling nodes on each grid. Sampling was conducted by manual probing at each stake, yielding a maximum of 121 data points per grid per probing date. The active layer was not measured at locations where grid points intersect rocks or deep water. A significant portion of the Toolik and Imnavait sites are underlain by coarse glacial material that is impenetrable for metal probes. These sections of the Toolik and Imnavait grids were excluded from the analysis.

Each grid is instrumented for air and ground surface temperature measurements using equipment similar to that at the 1-ha sites. In addition, at each 1-km^2 site ground temperature is monitored at hourly intervals at the standard depths of 0, 5, 10, 15, 20, 25, 30, 35, 45, 70, 95, and 120 cm using Campbell Scientific™ and Measurement Research Corporation instrumentation. Periodic, spatially oriented frost heave and thaw subsidence measurements using Differential Global Position System (DGPS) were initialized in 2001 at 2 Coastal Plain 1-km^2 sites and 1 Foothills 1-ha site (Little et al. 2003, Streletskiy et al. 2005). Measurements are performed twice each year at the beginning (June) and the end (August) of the thawing season, using a hierarchical nested sampling design (Nelson et al. 1999). A series of additional sites were instrumented for measuring air and soil surface temperature at locations chosen to facilitate adequate geographic coverage.

Analytical Results

Air temperatures trends

Air temperature trends from individual sites were analyzed using procedures outlined in Shiklomanov & Nelson (2002). In this paper we present monthly air temperatures, integrated over physiographic provinces.

Regionally, air temperature increases from north to south. Mean annual air temperature over the study period varied between -9.2°C and -12.0°C on the Coastal Plain and between -7.3°C and -10.3°C in the Foothills. Mean summer air temperature (June–August) on the Coastal Plain varies between 5.5°C and 8.7°C, while at Foothills it ranges from 6.8°C to 11.7°C. This climatic pattern demonstrates the pronounced influence of the Arctic Ocean during the summer, throughout the Coastal Plain. Province-specific 12-year (1995–2006) records of mean, minimum, and maximum annual air temperature, as observed at CALM sites, are shown in Figure 2. There is a slight decline in mean and maximum annual air temperature for the Coastal Plain and in maximum annual air temperature for the Foothills.

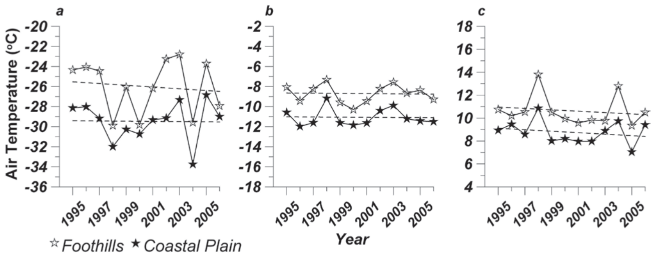

Figure 2. Twelve-year (1995–2006) records of annual minimum (a), mean (b), and maximum (c) monthly air temperature as observed at CALM Coastal Plain and Foothills sites.

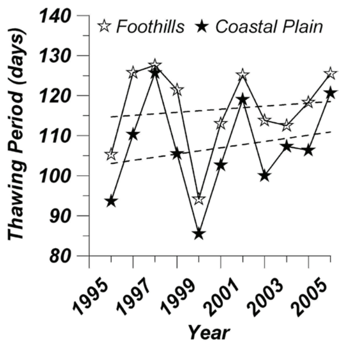

Figure 3. Province-specific 12-year (1995–2006) records of the duration of thawing period, as observed at CALM sites.

Duration of thawing period

The duration of the thawing period was estimated based on analysis of mean daily air temperature at individual sites by counting consecutive days with temperatures above 0.5°C. Results were averaged by physiographic province.

On average, the thawing period on the Coastal Plain is almost 10 days shorter than in the Foothills. However, this difference ranges from 2 to 16 days, depending on the year. Province-specific 12-year records of thaw-period duration, as observed at CALM sites, are shown in Figure 3. Both provinces experienced an increase in the duration of thawing, attributable to both the earlier initiation of the thawing and later freezing.

Effect of vegetation on ground surface temperature

Analysis of ground surface temperature was aimed primarily at evaluating the effects of vegetation and the characteristics of different landscape units on the ground thermal regime. The daily air and soil-surface temperature data obtained at the homogeneous 1-ha sites were used to calculate average differences between surface and air temperature (ΔT) for the warm period (June–August). To evaluate the effect of vegetation on the ground thermal regime further, the landscape-specific values of empirical summer n-factors were calculated. The n-factor, defined operationally as the ratio of the degree-day sum at the soil surface to that in the air (Carlson 1952), has been used in cold regions engineering since the 1950s to estimate soil surface temperature from air temperature records. Estimation of n-factors has been found to be a useful, simple approach for estimating the attenuation of climatic signals by vegetation cover (Klene et al. 2001a, b, Kade et al. 2006). An analysis of winter n-factors for the study sites is presented elsewhere in this volume by Klene et al. (2008).

Table 1. Landscape-specific 12-year (1995-2006) average values of ΔT and n-factors, as estimated from air and ground surface temperature measurements at representative 1-ha CALM sites.

Landscape Unit	Coastal Plain ΔT, °C	Coastal Plain N-factor	Foothills ΔT, °C	Foothills N-factor
Barrens	1.0	1.20	1.6	1.22
MNT	-1.2	0.78	-2.6	0.71
MAT			-3.8	0.52
Shrublands			-3.1	0.57
WET	-2.2	0.66	-2.3	0.74

Values of ΔT and n-factors obtained at individual sites were averaged to represent individual landscapes and physiographic provinces. To account for interannual climatic variability, the annual landscape- and province-specific values of ΔT and n-factor were averaged over a 12-year (1995–2006) period and are presented in Table 1.

The vegetated surfaces in both physiographic provinces show negative values of ΔT and n-factor values of less than unity, indicating the cooling influence of vegetation on ground temperature during the warm period. The distinct values of ΔT and n-factor indicate the distinct thermal influence of landcover types characteristic of the Coastal Plain and Foothills physiographic province. The moist acidic tundra (MAT) of the Foothills province has the largest negative value of ΔT (-3.8°C) and the smallest value of n-factor (0.52). The smallest negative ΔT value (-1.2°C) and highest n-factor value (0.78) were found in moist nonacidic tundra (MNT) of the Coastal Plain. Regionally, values of ΔT and n-factor for similar landscape units vary from north to south in response to the increase in density of the vegetation cover. This effect is evident from differences in ΔT and n-factor for moist nonacidic tundra in two physiographic provinces. The thermal influence of MNT is greater in the Foothills than on the Coastal Plain.

Unvegetated surfaces, which consist of sand, gravel, and bedrock along streams and atop hills and mountains, show positive values of ΔT and values of n-factors of more than unity, indicating a warming influence of barren surfaces on ground thermal regime.

Annual thawing propagation

The annual dynamics of thawing were evaluated by analyzing thawing intensity curves for four 1-km^2 sites. The Barrow and Atqasuk sites were selected to represent the Coastal Plain, while Happy Valley and Toolik are representative of the Foothills. The thawing intensity curves were constructed by calculating a daily increase in thaw depth as a portion of the maximum annual active layer value. The daily values of thaw depth for each site were estimated using ground temperature observations from an array of 12 thermistors, distributed vertically from the surface to 1.2 m depth. The daily depth of thaw penetration was assumed to coincide with the interpolated position of the 0^{o}C isotherm. For the silty soils characteristic of northern Alaska, the correspondence between thaw depth, as determined by

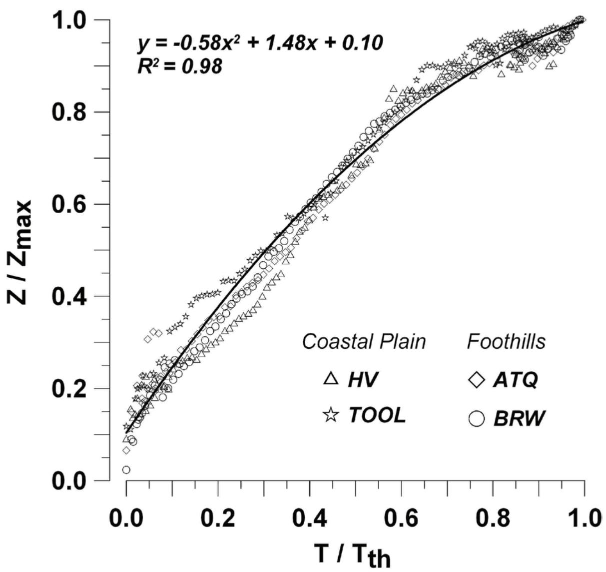

Figure 4. Site-specific 12-year averages of thawing intensity for two coastal plain (Barrow BRW and Atqasuk ATQ) and two foothills (Happy Valley HV and Toolik TOOL) locations. Z is thaw depth at time T and Z_{max} is annual maximum thaw depth achieved over the thaw period T_{th}.

mechanical probing, and the position of the 0°C isotherm is generally quite good (Brown et al. 2000).

The analysis of annual thawing intensity curves indicates that, depending on site and year, 95% to 99% of maximum thaw propagation is reached by mid August, when annual CALM ALT observations by mechanical probing are starting at northern Alaska sites.

To evaluate the physiographic province-specific intensity of annual thaw penetration, independent of interannual variability in climatic conditions, relative increases in thaw depth were plotted as a function of relative time: $Z/Z_{max}=f(T/T_{th})$, where Z is the thaw depth at time T and Z_{max} is the annual maximum thaw depth achieved over thawing period T_{th}. Site-specific 12-year averages of thawing intensity for two coastal plain (Barrow (BRW) and Atqusuk (ATQ)) and two foothills (Happy Valley (HV) and Toolik (Tool)) locations are shown in Figure 4. The thawing intensity curves for all four locations are similar, indicating that the relationship between annual thaw depth propagation and dimensionless time is uniform for different surface, subsurface, and climatic conditions. Figure 4 demonstrates that regardless of location, 44% of annual thaw occurs during the first quarter of the thawing period; during the first half of the thawing period thaw depth reaches 70% of its maximum; after three-quarters of the thawing period, thaw depth is at 88% of its maximum; and that 96% of the active layer has thawed after 90% of the thawing season. These numbers correspond closely to values obtained at three drastically different locations in Russia (Yakutsk, Vorkuta, and Igarka) by Pavlov (1984). The best-fit quadratic equation, presented in Figure 4, can be applied to estimate active layer thickness using thaw depth measurements performed at different times during the summer.

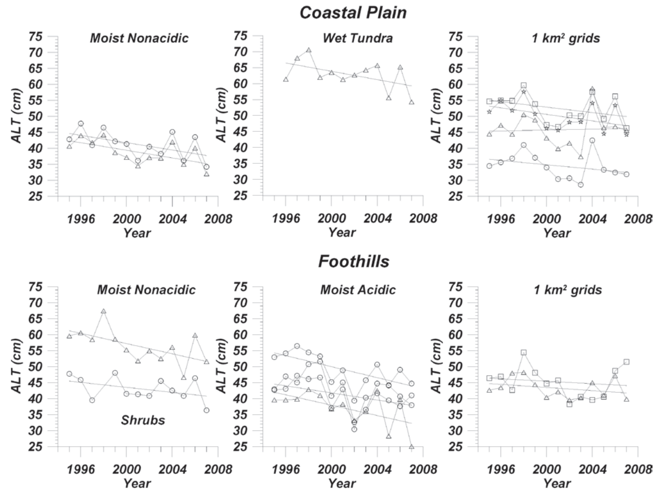

Figure 5. Site-specific 13-year (1995-2007) records of annual active layer thickness. Nine 1-ha sites are grouped by landscape category characteristic of two physiographic provinces. Six 1-km² sites are grouped by physiographic provinces. The Imnavait 1-km² site is not shown due to data quality issues.

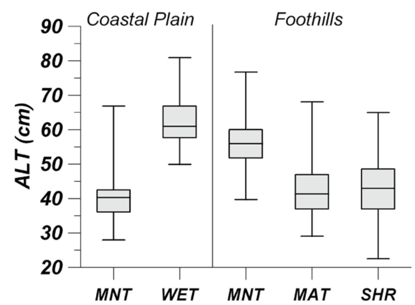

Figure 6. Statistical distribution (box plot) of ALT values for different landscapes characteristic of the two physiographic provinces.

Interannual variability of active layer thickness

The interannual dynamics of active layer thickness were evaluated by analyzing annual, site-specific averages of thaw depth values obtained at the end of the thawing period.

Site-specific 13-year (1995–2007) records of annual active layer thickness for different landscape categories and physiographic provinces are shown in Figure 5. The records indicate a declining active layer trend over the 1995–2007 period for all coastal plain and foothills sites, which generally corresponds to a decline in summer temperature over the same period (Fig. 2c). The maximum values of ALT were recorded in 1998, 2004, and 2006, the years that experienced the warmest summers (Fig. 5). The general agreement between ALT and summer air temperature records stipulates a strong degree of climatic forcing on ALT.

Landscape-specific active layer characteristics

Previous studies, conducted at Alaska CALM sites (Nelson et al. 1998, 1999, Nelson & Hinkel 2003), demonstrated the existence of landscape-specific thermal differences manifested through similar magnitudes of thaw propagation. Although thaw depth can experience significant interannual

Table 2. Landscapes- and province-specific values of active layer thickness.

Landcover categories	Coastal Plain	Foothills
Moist nonacidic tundra	40.0	56.4
Moist acidic tundra		40.5
Moist low shrub tundra		43.0
Wet graminoid tundra	62.9	49.1

variability in response to climatic forcing (Fig. 5), the presence of landform elements shows spatial regularity at the landscape scale and results in landscape-specific thaw depth patterns that repeat on an interannual basis (Nelson et al. 1998, Hinkel & Nelson 2003). Figure 6 shows statistical distributions of ALT, averaged over the 1995–2007 period for different landscapes characteristic of the two physiographic provinces. The landscape- and province-specific mean values of ALT are presented in Table 2.

To evaluate the landscape-specific thermal response to climatic forcing, annual ALT values from representative 1-ha sites were correlated with the square root of degree-days of thawing (DDT), estimated from site-specific air temperature records and accumulated by the date of thaw depth measurements (Shiklomanov & Nelson 2003). A plot of square root of DDT against thaw depth (Fig. 7) yields distinct linear landscape-specific relations, indicating differences in thermal landscape sensitivity to climatic forcing.

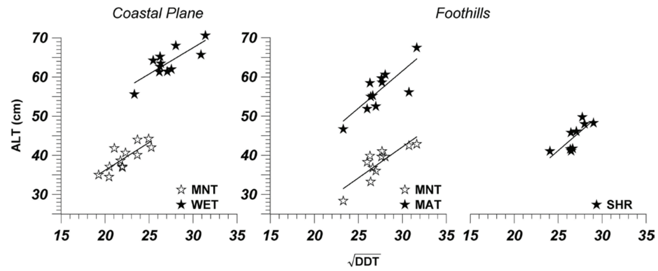

Figure 7. Plot of square root of air DDT against thaw depth for several 1-ha sites characteristic of dominant landscapes in the coastal plain and foothills provinces. Each data point represents annual end-of-thawing season measurements for the 1995–2006 period.

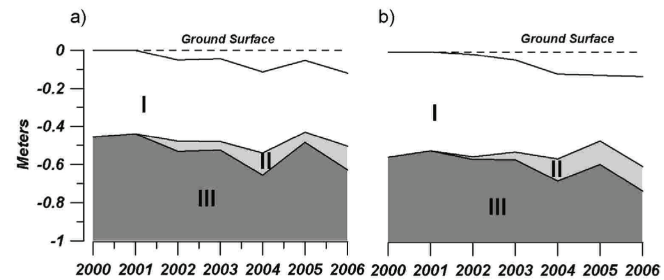

Figure 8. Annual changes in position of ground surface and ALT as measured by mechanical probing for representative Coastal Plain (a) and Foothills (b) CALM sites. I- ALT as measured by probing; II- ALT, corrected for ground subsidence; III-permafrost.

Ground subsidence

Because thaw penetration into an ice-rich layer at the base of the active layer is accompanied by loss of volume (thaw consolidation), straightforward measurement of active layer thickness by such methods as mechanical probing may not always yield accurate estimates of changes in the permafrost system. Periodic thaw subsidence measurements using DGPS technology allowed us to address this problem effectively. Figure 8 shows the results of active layer and ground subsidence measurements over the 2001–2006 period at two locations representative of the coastal plain and foothills physiographic provinces. Total subsidence over the 5-year period was 12 cm at the coastal plain site and 13 cm at the foothills site.

To account for ground subsidence in the active layer record, the annual changes in the position of the ground surface relative to the level in the year 2000 were added to the active layer measurements produced by mechanical probing (Fig. 8). Results from the two sampling locations indicate a monotonic increase in thaw penetration between 2001 and 2006.

Conclusions

The results of 13 years of active layer, air, and ground temperature observations at CALM sites in north-central Alaska indicate that: (1) there is a slight decline in mean and maximum annual air temperature on the Coastal Plain and in maximum annual air temperature in the Foothills. The period of observations was characterized by an increase in the length of the thawing period in both physiographic provinces; (2) the spatially oriented ground surface temperature observations within representative landscapes facilitate evaluation of the effect of ground cover on the ground thermal regime. The distinct values of ΔT and n-factor indicate the distinct thermal influence of landcover types characteristic of the Arctic Coastal Plain and Arctic Foothills physiographic provinces; (3) The results of active layer observations obtained by mechanical probing over 1995–2007 period indicate a pronounced decreasing trend in ALT for all landscape types characteristic of dominant physiographic provinces; (4) Although thaw depth can experience significant interannual variability in response to climatic forcing, the presence of landform elements shows spatial regularity at the landscape scale and results in landscape-specific values of active layer thickness. However, the annual rate of thaw propagation is similar for sites characterized by different surface, subsurface, and climatic conditions; (5) The results of DGPS survey indicate that soil consolidation accompanying penetration of thaw into an ice-rich stratum at the base of the active layer has resulted in subsidence of the surface, accounting for the lack of apparent thickening of the active layer, as traditionally defined.

Abstract

A large part of the source region of the Yellow River (Hunag He) in the northeastern margin of the Tibetan Plateau is underlain by perennially or seasonally frozen ground which has experienced rapid warming in the past decades. Since 2002, we have investigated permafrost distribution in the area to evaluate permafrost degradation and its impacts on groundwater hydrology. It suggested the drastic shrinkage of permafrost area within last the 20 to 30 years, which corresponds to the more than 100 m rise in the lower altitudinal limit of permafrost. This is most likely causing the desertification of the ground surface. In this study, based on the half-century meteorological data from a local observatory, the thermal history of permafrost in the area is investigated by means of a numerical method. The results indicate that some warm permafrost could have existed in the middle of the last century. Considering the time scale of global warming, there is high possibility that the relict permafrost (perennially frozen part beneath the supra-permafrost talik) has widely degraded during the last decades.

Keywords: global warming; numerical modeling; permafrost degradation; Tibet.

Introduction

Recent global warming has raised the temperature of permafrost, which has resulted in the deepening of the active layer and the reversed temperature profile in the high latitudes (e.g., Lachenbruch & Marshall 1986, Harrison 1991, Osterkamp & Romanovsky 1999, Osterkamp 2005, Smith et al. 2005). Warm permafrost in the marginal zone appears to be more sensitive; for instance, the permafrost in Mongolia and the Tibetan (Qinghai-Xizang) Plateau shows rapid thinning in recent decades (e.g., Sharkhuu 1998, Jin et al. 2000).

The source area of the Yellow River (Huang He), located in the northeastern margin of the Tibetan Plateau, appears to be a region broadly underlain by such warm permafrost. Recent studies have reported desertification (degradation of the grassland and meadow vegetation) of the plateau (Wang et al. 2001, Zhang et al. 2004). This has been mainly attributed to the degradation of permafrost (Peng et al. 2003), because there has been no significant change in precipitation during the last half-century (Yang et al. 2004). This study examines this process.

Whereas a few recent reports have indicated rapid degradation of permafrost in the source area of the Yellow River (Zhu et al. 1995, Zhu et al. 1996; Jin et al. 2000, Wang et al. 2000), a large part of the area was considered to have been underlain by permafrost at least until the 1980s (Wang 1987, Wang et al. 1991, Zhou et al. 2000), despite limited evidence. The timescale of the permafrost degradation is therefore of concern to us, to assess the urgency of this environmental change.

In order to verify ongoing degradation of permafrost, we investigated the present geothermal conditions in the source area of the Yellow River (Ikeda et al. 2007, Matsuoka et al. 2004, 2005, 2006), as part of an interdisciplinary research project to model the groundwater circulation and predict near-future water resources of the whole Yellow River basin.

On the basis of the acquired data from field investigations, this paper discusses the ground temperature history of the region using one-dimensional numerical model. The goal of the study is to find a suitable initial condition of the permafrost thickness and to examine its sensitivity to given parameters.

Study Area and Field Study

The fieldwork was undertaken along the R214 road that connects Xining and Yushu in the southeastern part of Qinghai Province (Fig. 1). The elevation varies from 3260–4790 m a.s.l., crossing the boundary between the permafrost and seasonal frost areas (Wang 1987, Zhu et al. 1995). The main study area, Madoi County, is located on an uplifted peneplain composing the northeastern part of the Tibetan Plateau. In this area, valley-fill alluvial plains are widespread between 4200–4300 m a.s.l., and hills rise up to 500 m from the surrounding plains.

The plateau area lies in a transitional zone between

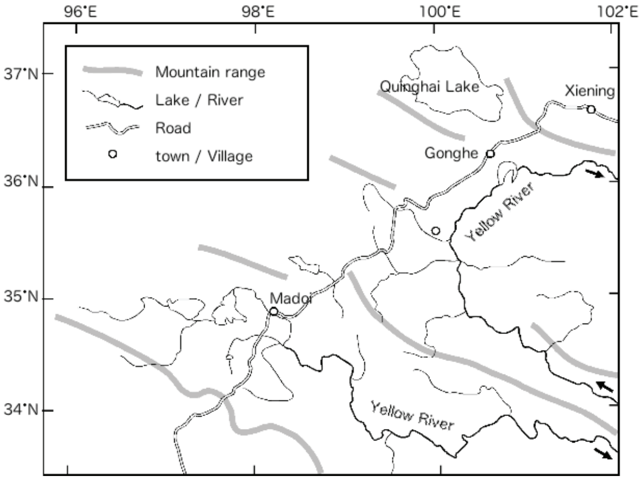

Figure 1. Map of the study area.

Figure 2. Meteorological Station at Madoi borehole site.

discontinuous and sporadic permafrost. Long-term meteorological records at Madoi (98°13′E, 34°55′N, 4273 m a.s.l.; Fig. 1) for 1953–1980 show a cold, dry climate with a mean annual air temperature (MAAT) of -4.1°C, an annual thermal amplitude ranging from -16.8°C in January to 7.5°C in July, and an annual precipitation of 304 mm (Zhou et al. 2000). Decadal mean air temperatures increased by 0.7°C from the 1960s to the 1990s (Yang et al. 2004). More recent records (2001–2005) show further rising MAAT to -2.0°C with an annual thermal amplitude ranging from -13.6°C in January to 9.1°C in July and steady annual precipitation of 304 mm (after WeatherOnline Asia Limited, China). The low precipitation is reflected in shallow winter snow cover (Matsuoka et al. 2005). These conditions favor deep seasonal freezing, whereas the seasonally frozen layer, 2.6 m deep at Madoi, was completely thawed in June 2005 (Matsuoka et al. 2005).

Outcomes from the field study are summarized in previous papers (e.g., Ikeda et al. 2004, Ikeda et al. 2007). Permafrost distribution in the area was examined by ground temperature monitoring and geophysical soundings. Miniature temperature loggers were distributed in the area and recorded year-round ground surface temperatures at hourly intervals. The presence of permafrost was examined from the surface by refraction seismic sounding and one-dimensional (vertical) direct current (DC) resistivity sounding. In addition, a monitoring station was set up at Site Madoi (Fig. 1) with a 8 m-depth borehole for temperature monitoring and meteorological instruments (Fig. 2). During the installation of this borehole, the near-surface stratigraphy of the alluvial plains was directly observed with the recovered cores.

The result suggests that relatively stable permafrost occurs widely above 4300 m a.s.l., that permafrost is mostly absent below 4200 m a.s.l., and that the widespread alluvial plains between 4200–4300 m a.s.l. lack permafrost or have degrading permafrost below a supra-permafrost talik. In contrast, at least until the 1980s, 70%–80% of the plateau surface, that is, the area except for lakes, streams, and nearby swamps, was classified into permafrost terrains (Wang 1987, Wang et al. 1991). Several pits excavated on alluvial plains near Madoi showed that permafrost was generally 15–20 m thick, and the permafrost table lay at about 5 m depth in the early 1980s (Wang 1987). This indicates that permafrost at some places on the plateau began degrading before the 1980s, because the seasonal frost depth rarely exceeds 3 m in the study area (Wang et al. 2000, Matsuoka et al. 2005). From our field study permafrost was completely absent at Site Madoi and its surroundings, indicating that the reported permafrost had considerably disappeared around Madoi after the 1980s, and currently faces a rapid loss of permafrost area, since the elevations mostly belong to a transitional condition between permafrost and seasonal frost environments.

Numerical Modeling

Data

Combining observations and available dataset, the following data were used or referred to for modeling:

(A) data from the borehole (Site Madoi)
(hourly data from 12.08.2004 1500h to 03.08.2006 1000h);

- air temperature, humidity, wind, and snow depth;
- borehole temperature at 7 depths(0.03, 0.3, 1.3, 2.3, 4.3, 6.3 and 7.8 m);
- soil moisture by TDR (0.3, 0.6 and 0.9 m);
- thermal diffusivity, conductivity, heat capacity (0.1 m);

and

(B) other dataset

- monthly mean air temperature at the Madoi meteorological station from 1960 to 2006, and
- 2000-year reconstruction of Northern Hemisphere air temperature (from Jones & Mann 2004).

Model settings

As noted above, we conduct numerical experiments to calculate ground temperature history. The system is one-dimensional thermal conduction with phase change driven by one side (ground surface), so we have to solve an inverse problem of diffusion equation to determine initial values.

Though ground surface temperature history (GSTH) has been commonly reconstructed by the inversion of ground temperature profiles (e.g., Cermak 1971, Lachenbruch &

Marshall 1986, Wang 1992), borehole temperatures are only available for the top 7.8 m, with 7 data points at the study site, too shallow for millennia-scale GSTH reconstruction. Instead, we use the permafrost thickness or complete thaw of the permafrost to compare the model output and observation. Here we seek the initial condition of permafrost at the instant of 1960, the condition in which permafrost survived until the 1980s and its condition and thaw by 2006.

Model settings are shown schematically in Figure 3.

For model equation, the formulation of normal one-dimensional heat conduction is used. Ground temperature variation is described by the following heat conduction equation:

$$\frac{\partial T}{\partial t} = \frac{\partial T}{\partial z}\left(\kappa \frac{\partial T}{\partial z}\right)$$

where T is temperature, t is time, z is depth, and κ is thermal diffusivity, which has different values for frozen and unfrozen soil. Latent heat was considered by introducing an apparent heat capacity. During phase change, the heat capacity of the soil increases, reflecting the amount of latent heat of the soil. Phase change is assumed to occur between 0°C and -0.5°C.

As for finite difference equations, the Multi-point Explicit scheme (Saitoh 1974) was used to solve the equations. Since this is an explicit scheme, grid and time spacing should satisfy the stability condition. In this study the spatial grid and the time step were set to 0.2m and 1 hour, respectively.

Soil properties are set basically according to the observed data. Reflecting the low precipitation, soil water content is constantly low and winter snow depth is also shallow (max. 16 cm). Such conditions yield less sensitivity of ground temperature to the soil water conditions. Volumetric soil water content is assumed to be 10% based on TDR measurements on site. The assumed thermal conductivities of frozen and unfrozen soils are shown in Table 1.

Boundary conditions

To drive the model, upper and lower boundary conditions are needed. The lower boundary condition is given as a flux: based on the global heat flow database (Pollack et al. 1993), constant geothermal heat flow 50mW/m^2 is assumed at the bottom of domain for the whole calculated period. This assumption is not extreme because the whole plateau lies on the stable and old continental crust, with no volcanoes. The area is also located well away from local tectonic activities (e.g., fault system), so a standard value of heat flow was taken. The domain of calculations has 500 m in depth, which is deep enough to guarantee the assumption mathematically.

For the upper (i.e., ground surface) condition, hourly temperature dataset is given to the surface grid, reflecting the seasonal variation and long-term climate change. We used 3 cm-depth temperatures in 2005–2006 at the Madoi station, to which long-term temperature anomalies from the annual mean value are added as an offset. Namely, the surface temperature is given as:

T_S(year, date, hour) = $T_{S,P}$(date, hour) + *Anm.*(year),

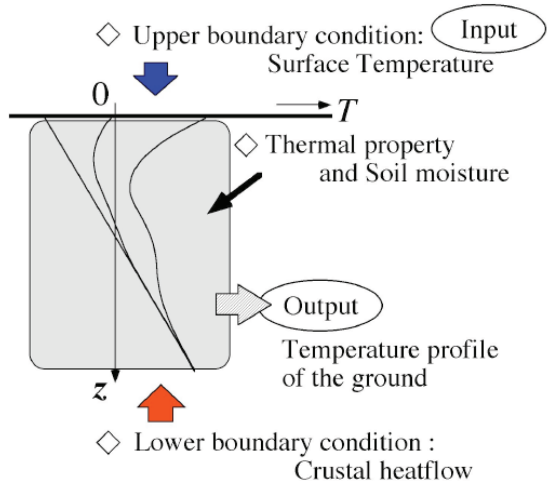

Figure 3. Settings of the one-dimensional model.

Table 1. Thermal conductivities of the soil (Wm^{-1}K^{-1}).

	Depth	Unfrozen	Frozen
Surface	<0.5 m	0.6	0.6
Gravel sediment	<10 m	1.2	1.7
Basement rocks	≥10 m	2.5	3.2

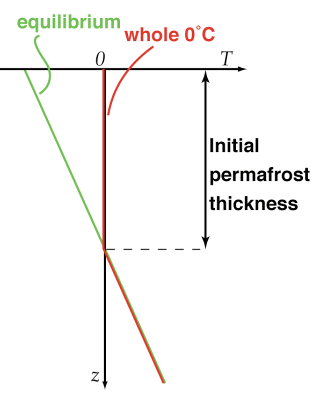

Figure 4. Prescribed initial temperature profile.

where T_S is the ground surface temperature at a certain year/date/hour given to the model, $T_{S,P}$ is the hourly temperature measured on site (i.e., present value), *Anm.* is the anomaly of the annual mean temperature from the present value, for each year. For the period after 1960, monthly mean air temperatures were used to calculate the offset, whereas reconstructed and smoothed data (Jones & Mann 2004) were used for the period before year 1960.

Initial conditions are prepared for two types of runs, illustrated in Figure 4. (1) "Warm permafrost run" is prescribing the initial temperature profile with a certain thickness of warm permafrost at 0°C (i.e., corresponding to the case that the thaw process is in progress). The initial thickness of the warm permafrost is treated as a parameter for this run. (2) "Paleoclimate run" is the long-term calculations based on the reconstructed paleoclimate data for the last 2000 years, which are expected to have reasonable temperature profiles for assumed climate history (see Fig. 5). The offset

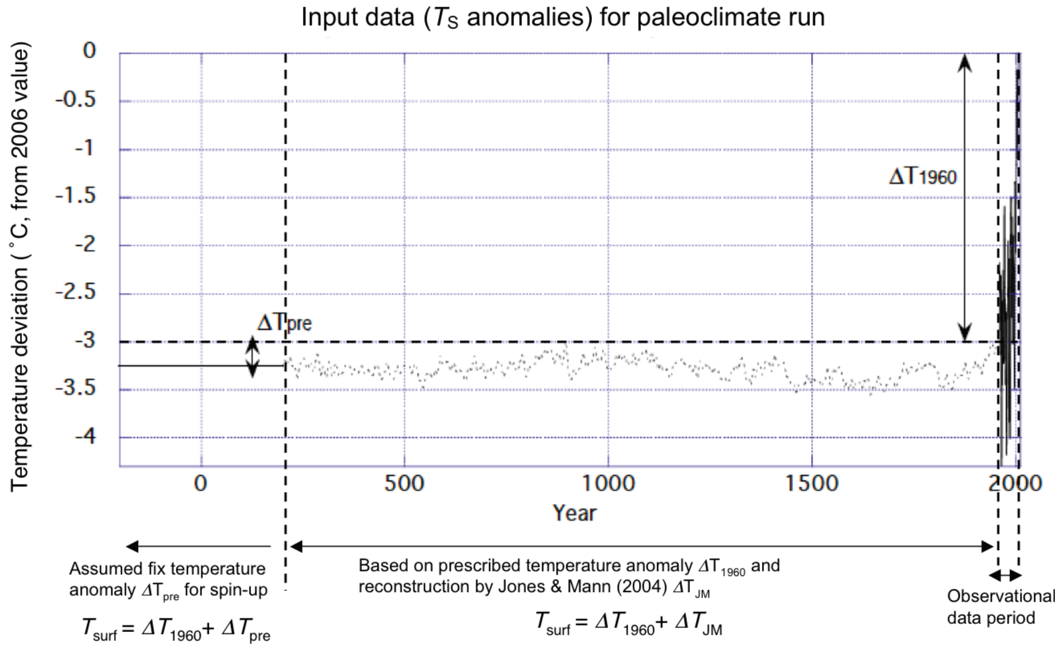

Figure 5. Surface temperature condition for model.

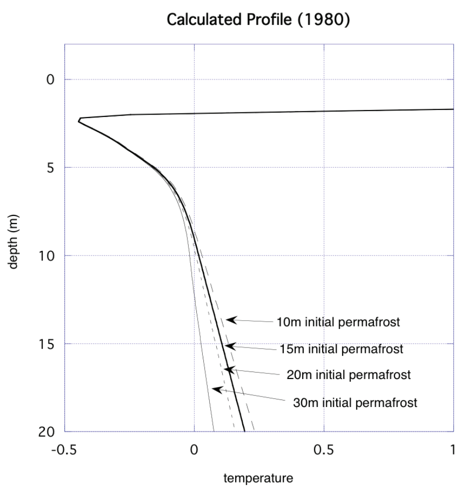

Figure 6. Calculated temperature profiles 1980, starting at warm permafrost conditions.

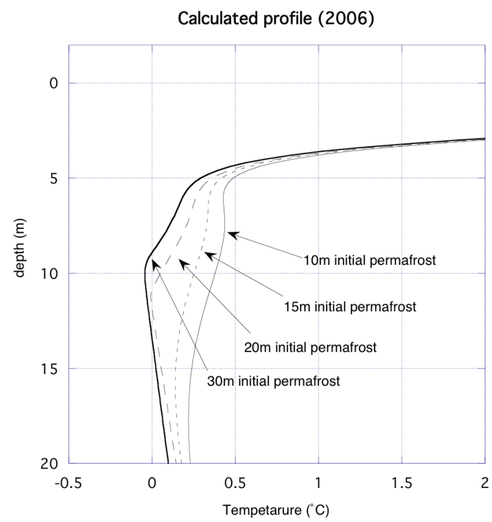

Figure 7. Calculated temperature profiles 2006, starting at warm permafrost conditions.

for the pre-1960 period (ΔT_{1960}) is treated as a parameter to examine the effect of long-term climate, although the 10-year mean (period: 1960–1970) of observed temperature anomaly at Madoi Station can be considered as a standard value.

Soil water content and snow conditions in the paleo-climate runs are assumed to remain unchanged. Recorded precipitation since 1960 was stable in long term, which is partly supports this assumption. The dry condition of the area is considered to be a general geographical setting, mainly due to the blockade of vapor supply by the Himalaya Mountains.

Results

Warm permafrost run

This case is to examine what thickness of warm permafrost can be thawed since 1960. Figures 6 and 7 show the summer temperature profiles in 1980 and 2006 in the model. Permafrost in 2006 can only exist with initial permafrost deeper than 20 m (see Fig. 7).

On the other hand, Figure 6 shows that the permafrost exists for all cases (initial permafrost ≥10 m?) in 1980. Difference in the initial condition produces a slight difference in temperature gradient significantly affects the survival time of permafrost. From this calculation ca. 15 m of permafrost can exist in the 1980s to meet the result of present observations (i.e., it may thaw out by present).

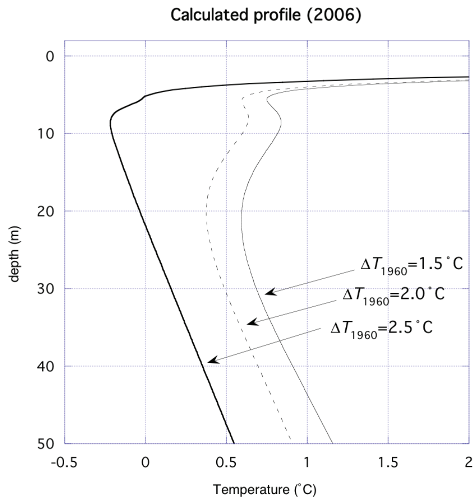

Figure 8. Calculated temperature profiles 2006, under the paleotemperature conditions.

Paleoclimate run

From the parameter study of this run, the effect of pre-1960 climate history to the present condition is examined. Figure 8 shows the temperature profile at 2006 (as before); three profiles correspond to different values of ΔT_{1960}: 1.5°C, 2.0°C, and 2.5°C.

Although the 10-year mean of observed temperature anomaly during the 1960s was 2.5°C, this condition appears to be too cold, leaving thick permafrost (more than 20 m) at 2006. However, as shown in this plot, change in this long-term offset by 0.5°C changes the story completely: the other two cases cannot keep permafrost until the present condition.

In this modeling, the applied trend of paleotemperature is based on the averaged climate for the Northern Hemisphere, which may need reconsideration.

Discussion

Results of this study give a quantitative idea of the timescale of permafrost degradation, which implies that the recent warming climate has played a strong role in causing substantial change in the study area. Although the response of the ground temperature should have delay from the surface (e.g., 10 m-depth temperature lags ca. 10 to 100 years), "Paleoclimate run" shows that the current permafrost condition is strongly affected by the recent climate change. Further accumulation of field and paleoenviroment data would be helpful to discuss more details.

A number of respects have to be improved in modeling. We focus on two topics: thermal properties and paleotemperature input.

One of the uncertainties in modeling lies in thermal properties of the ground. The near-surface layer especially can have a large range of seasonal, and also spatial variation, due to the existence of organic material and differences in the soil water content. In our modeling, the observed values were applied to the near-surface organic layer (Table 1), and they show small seasonal variations through a year, reflecting the dry condition at the observation site. Spatial representativeness of such dry conditions was partly confirmed by the field measurement by portable TDR.

On the contrary, a seasonal difference in thermal conductivity (frozen/unfrozen) appears in wet conditions, which allow more heat flow in winter through the ground surface, compared to summer. This effect cools down the ground temperature effectively in consequence. Therefore, drought of the ground surface can trigger a feedback to cause further thaw of the permafrost.

With respect to the input paleoclimate data, the local paleotemperature history through the last millennia may have significantly larger variability than the reconstruction by Jones and Mann (2004), which was averaged for the whole Northern Hemisphere. Comparing the reconstruction and the recorded temperature since 1960, the hemispherical average has a similar trend with the recorded data, but absolute value of the variation is a few times larger. In general, quantitative paleotemperature data are lacking in the inland continent, but reliable paleoclimate data is essential for further modeling.

Conclusions and Outlook

Ground temperature of the permafrost in the source region of the Yellow River basin was calculated based on the instrumental data, and the response of permafrost to the warming climate was examined quantitatively. The existence of the permafrost in the 1980s, which has been suggested from the previous works, is supported from the modeling results in the case that the permafrost was already the warm (~ 0°C) when it was observed.

It should be noted, however, such a thermal condition of the permafrost is relatively difficult to achieve in dry conditions. If the ground is wet and contains more ice in the permafrost, the thawing process should be slower, and the current distribution of the permafrost, basically lacking up to 4300m, would become hard to explain.

There are still uncertainties in the paleoenvironment of Tibetan plateau, and it is of importance for the prediction of future response of the permafrost to the ongoing climate change. In combination with the paleoclimate study, for example, the reconstruction from lake sediments will be the next step to put the arguments forward. Commencement of deeper borehole temperature measurement, which allows the inversion of surface temperature history (e.g., Pollack & Huang 2000), may also be a candidate of the method to reveal local paleoclimate.

Acknowledgments

We acknowledge Drs. C. Gao, Z. Han, and Mr. J. Ding for logistical help and field assistance. The study was supported by a national program "Sustainable Coexistence of Human Nature and the Earth" founded by the Ministry of Education, Culture, Science, and Technology. We are also thankful for fruitful suggestions by reviewers and the editor.

Permafrost in the *Bibliography on Cold Regions Science and Technology*

Sharon N. Tahirkheli
American Geological Institute, Alexandria, VA, USA

Abstract

The *Bibliography on Cold Regions Science and Technology* has covered approximately 22,000 publications on permafrost and contains an additional 6000 references to the related topic of frozen ground. Permafrost publications are distributed throughout the global scientific literature and are found in peer-reviewed journals, government reports, theses/dissertations, and conference publications. Almost half of the permafrost literature is found in conference proceedings. Coverage of master's theses and doctoral dissertations in the *Bibliography* is limited to a total of two hundred, primarily from U.S. and Canadian institutions. As geographic distribution of permafrost is concentrated in the polar and high-altitude regions of the world, it is no surprise that 9000 publications have been identified in the Russian language. The rest of the literature is published around the globe, including Europe, Canada, the United States, China, and Japan in the north, and Argentina in the south.

Keywords: bibliography; permafrost; publications.

Introduction

The *Bibliography on Cold Regions Science and Technology* is a part of the Cold Regions Bibliography Project (CRBP), jointly sponsored by the U.S. National Science Foundation and the U.S. Army Cold Regions Research and Engineering Laboratory. As part of its scope, the *Bibliography* includes references to publications on all scientific and technical aspects of permafrost including distribution, properties, impacts of current climate change, cold-weather construction, engineering challenges, soil mechanics, hazards, and land use. This paper explores the coverage of permafrost throughout the history of the *Bibliography on Cold Regions Science and Technology* by considering the terminology used, the distributed geographic and linguistic sources of permafrost publications and the variations over time of the frequency of publications.

History of the *Bibliography*

Bibliography on Snow, Ice and Permafrost

The current CRBP evolved from the SIPRE Project. SIPRE stood for the Snow, Ice and Permafrost Research Establishment of the U.S. Army Corps of Engineers and Project was primarily concerned with publishing an annotated bibliography covering snow, ice, and permafrost. Produced at the Library of Congress beginning in 1951 and published as SIPRE Report 12, the *Bibliography on Snow, Ice and Permafrost* was carefully limited to the properties of snow, ice, and permafrost. Only on rare occasions were background materials on peripheral topics included. The objective of the SIPRE Project was to assist SIPRE and other government agencies that were concerned with "various phases of research on the properties of snow, ice and frozen ground." (Library of Congress 1953)

Volumes 16–22 underwent several name and format changes. The SIPRE Report 12 became CRREL Report 12, the *Bibliography on Snow, Ice and Permafrost* became the *Bibliography on Snow, Ice and Frozen Ground* and finally, with Volume 23, the current title, *Bibliography on Cold Regions Science and Technology,* was adopted. With the name changes came an expansion of coverage and an increased emphasis on engineering in a cold environment "including the varied disciplines of engineering and broad coverage of the physical sciences. The disciplines and subject matter remained varied and covered every topic relating to cold regions imaginable" (Liston 2002).

Bibliography on Cold Regions Science and Technology

The CRBP was managed by the Library of Congress until the late 1990s and was published in print as CRREL Report 12 beginning with Volume 23. In 2000, the American Geological Institute (AGI) began compiling the *Bibliography* and producing the current online web-based version of the *Bibliography*. Under the terms of the CRBP Cooperative Agreement between AGI and the U.S. National Science Foundation, all of the publications covered in the CRBP must be obtained and examined. Citations of publications from other bibliographies are helpful in identifying publications for consideration but cannot be used to develop references without access to the original.

The *Bibliography on Cold Regions Science and Technology* now contains more than 218,700 references and is freely available to users via the Internet at http://www.coldregions.org The present-day scope of the *Bibliography* includes "references to scientific and engineering research related to material and operations in a winter battlefield, the nature and impact of cold on facilities and activities, cold-related environmental problems, and the impact of human activity on cold environments" (American Geological Institute 2007).

While permafrost is not explicitly mentioned in the coverage statement, all aspects of permafrost continue to be considered relevant to the *Bibliography* and are included. With the explosion in climate and global change studies, and with the surge in publications expected to result from the International Polar Year 2007–2008, the future expectation is that the number of permafrost publications will show a marked increase over the next several years.

Finding Permafrost in the *Bibliography*

Terminology

An examination of the original volumes of the *Bibliography* quickly reveals that the subject indexes included "permafrost" and "frozen ground" as entries. As the *Bibliography* evolved to the use of a thesaurus of controlled terms, "permafrost" and "frozen ground" remained consistent in their usage as entry points (Engineers Joint Council 1969). This greatly simplifies the attempt to locate the relevant literature within the online database. To locate references to "permafrost" and/or "frozen ground" in the web-based database of the *Bibliography*, the terms were searched directly as part of the entire bibliographic record. This search included "permafrost" and "frozen ground" as parts of the titles, abstracts, keywords, conference titles, publisher names, or notes.

It is useful to note that the controlled vocabulary used in the production of the *Bibliography* contains the following specific types of permafrost as potential additional identifiers: continuous permafrost; discontinuous permafrost; sporadic permafrost; and subsea permafrost. Processes and concepts related to permafrost can also be directly accessed; for example, permafrost heat balance; permafrost origin; permafrost thickness.

For purposes of this study, only the more general terms were chosen. 27,732 references were retrieved with almost 22,000 references containing "permafrost" and close to 6000 containing "frozen ground." Thus 12.6% of the references in the *Bibliography on Cold Regions Science and Technology* are relevant to "permafrost" or "frozen ground."

Publication Date

Overall distribution by date of publication

Permafrost and frozen ground publications were one of the three primary topics in the earliest volumes of the *Bibliography*. Total publishing numbers, however, were substantially lower. For example, in 1955 only 76 publications on permafrost and/or frozen ground were included in the *Bibliography*. Numbers increased dramatically by the late sixties with 470 publications referenced in 1966, and the totals peaked in 1978 and 1983 with 1111 items in both of those years. The rate of publication in the permafrost field has declined slightly from those highs, but varies between 450 to 750 items per year.

When considered as a percentage of the total number of publications added to the *Bibliography* each year, the permafrost/frozen ground publications have varied from as little as 5.73% in 1995 to as much as 27.55% in 1977 with an overall average of 13.52% based on the publication years 1970–2007. Table 1 presents the dates of permafrost/frozen ground publications as a percentage of the total number of publications added to the *Bibliography on Cold Regions Science and Technology*.

Table 1. Percentage of *Bibliography* by date of publication.

Date of Publication	Percentage total references in the *Bibliography*
1970	10.32%
1974	17.27%
1978	17.42%
1982	20.53%
1986	13.08%
1990	10.16%
1994	7.06%
1998	7.36%
2002	7.92%
2006	12.85%
Average percentage	13.52%

Permafrost/frozen ground publications as a percentage of the total number of publications referenced in the *Bibliography* in a given year. Average percentage based on 1970–2007.

Table 2. Publication type.

Type of Publication	Total Count By Type*
Serial	12,818
Conference	10,925
Book	3,437
Report	1,500
Patent	192
Thesis/Dissertation	160
Map	33

*Total will not equal number of permafrost references because some items have multiple types and others have no type provided.

Publication Type

Overall distribution by type of publication

Permafrost and frozen ground publications are found not only in the peer-reviewed literature, but also in what is often referred to as gray literature—government reports, theses/dissertations, and conference publications. References included in the *Bibliography of Cold Regions Science and Technology* are currently tagged as one or more of the following types: serial, book, conference, report, thesis/dissertation, patent, or map. The earlier volumes of the *Bibliography* that were originally produced for a print publication do not always contain equivalent information; however, procedures were developed to determine whether an item was a journal article, map, patent, monograph, conference paper, or technical report. Out of the total references, 940 items could not be categorized and, while not entirely equivalent, for the purposes of this study, monographs were grouped under books.

An examination of the permafrost references in the *Bibliography of Cold Regions Science and Technology* by type of publication (Table 2) reveals several points of interest.

Primary publication types

The primary type of publication included in the

Bibliography that contains permafrost papers is labeled serial. Serials may be of two types: peer-reviewed journals and monographic serials. While serial is the predominant type, conference publications are a very close second, reflecting the importance of these publications to this discipline. More than one-third of the permafrost/frozen ground publications are drawn from conference proceedings. It is worthwhile to note that the *Bibliography*, with a few rare exceptions, does not include abstracts from meetings—only proceedings.

The International Permafrost Conference proceedings are good examples of the significance of conference papers in the literature. The first International Permafrost Conference was held in 1963 and the proceedings contained 102 papers. With 100 or more papers produced at each meeting, the nine conferences represent a major component of the total permafrost literature.

A random selection of twenty papers from conferences produces items from the following workshops and symposia: International snow science workshop; International Congress of the International Association for Engineering Geology and the Environment; USA/CIS joint conference on Hydrologic issues of the 21st Century; Jahrestagung der Schweizerischen Geomorphologischen Gesellschaft; XI glyatsiologicheskii symposium; and the AGU 2004 fall meeting open Northern Eurasia Earth Science Partnership Initiative science session.

Other publication types

Books and book chapters comprise 12.8% of the total permafrost literature while technical/government reports are a healthy 5.8%. Patents, maps, and thesis/dissertations combined are barely a blip in the totals of types of publications. While this may be appropriate for patents, maps and theses/dissertations seem to be underrepresented in the *Bibliography*. The theses/dissertations that are included are primarily from the United States and Canada—not what would be expected if all theses/dissertations on permafrost and frozen ground were included. Maps were seldom included in the *Bibliography* until the CRBP compilation moved to the American Geological Institute. (Tahirkheli 2004)

Document availability

Because of its history in support of research for SIPRE and the Cold Regions Research and Engineering Laboratory, the CRBP was always concerned with the availability of the documents cited in the Bibliography. The Library of Congress provided a microfiche service that provided copies of uncopyrighted materials to requestors. The need to have the documents immediately available has impacted the coverage of the CRBP. Some types of publications such as maps and thesis/dissertations could have been included more frequently without this requirement. Currently, the bibliographers compiling the *Bibliography* cannot include a thesis/dissertation unless the item is easily accessed by the users of the *Bibliography*. For theses/dissertations, this usually means that the document must be available through a microfiche service. With the wider dispersion of electronic publications, this restriction has been relaxed somewhat, and the inclusion of online theses/dissertations is now possible.

The Permafrost Young Researchers Network web site http://www.pyrn.org/ contains approximately 230 citations under consideration for inclusion in the *Bibliography* in the future, depending on availability of the title.

Country/Language of Publication

Distribution by country

Permafrost and frozen ground publications are widely distributed around the globe. Current serial, book, and conference publications added to the *Bibliography* are tagged with an indicator of the country of publication. The earlier volumes of the *Bibliography* and current theses/dissertations and technical reports do not always contain this information; however, procedures were developed to determine the country of publication whenever possible. Approximately 1100 items could not be assigned to a source country. The rest of the permafrost publications identified in the *Bibliography on Cold Regions Science and Technology* were selected by the country of publication and the results are presented in Table 3.

Primary countries producing permafrost publications

Permafrost publications have been identified from 44 separate countries; however, the Former Soviet Union and Russia are the primary sources with a whopping 44.8% of

Table 3. Country of publication.

the total. The United States is not even a close second with 20.4% and Canada is a distant third with 8.4%.

While both the geographic distribution of permafrost and the distribution of publishing on the topic of permafrost is concentrated in the polar regions (USSR/Russia, Canada, United States), there are significant numbers of permafrost publications being published in countries with high altitude areas including parts of China, Switzerland, and Italy. There are even scattered publications from India and South Africa.

Distribution by language of publication

Distribution by language of publication for permafrost/frozen ground publications is highly concentrated in three languages: Russian, English, and Chinese, which account for 97% of all publications. This distribution only partially mirrors the distribution of publications by country of publication and emphasizes the dominance of Russian and English for the permafrost literature. The languages of the texts are presented in Table 4 in order of prevalence.

Only twenty languages were identified within the *Bibliography*. The language of the text was determined for every permafrost/frozen ground publication.

CRBP Sources

Or, how does the CRBP obtain the publications cited in the Bibliography?

As indicated by the charts of languages of the texts and countries of publication, many sources are necessary to be as complete in coverage as possible. The CRBP uses many online databases and relevant bibliographies. For permafrost, the *Permafrost and Frozen Ground Bibliography, 1978–2003* (available from the Frozen Ground Data Center at the National Snow and Ice Data Center) is a rich source of potential documents (http://nsidc.org/fgdc/biblio/). Of course, as indicated earlier, the CRBP or one of its partners must actually examine the publications and is further required to digitize any uncopyrighted materials that are included.

The CRBP obtains publications in all of the following ways:

Libraries. Both major government and university library collections are mined for possible relevant publications. Some of the libraries mined regularly include:

- U.S. Army Cold Regions Research and Engineering Laboratory Library
- Institute for Arctic and Alpine Research Information Center
- U. S. Geological Survey Library System
- University of Texas at Austin
- Stanford University

Publishers. Many publishers provide both publications and metadata directly to abstracting and indexing services like the one producing the Bibliography.

Open-access Web publications. Many publications are now appearing on the web and are openly available to all users.

Bibliographic partnerships (where several organizations produce similar bibliographies). Partnerships are often formed to assist in broader access to pertinent publications. The American Geological Institute participates in at least a dozen bibliographic partnerships including a significant collaboration with the Scott Polar Research Institute.

Scientists and authors. Interested researchers provide direct information regarding their publications to the *Bibliography* and either links to full-text as posted on their personal web pages or reprints of their articles.

Current opportunities and challenges in maintaining comprehensive coverage

With the growth of web publishing, CRBP faces both new opportunities and challenges. Information about publications is sometimes easier to obtain, and it may even be freely accessible on the web. Publishers often provide citation information electronically. eliminating the need for expensive and time-consuming data entry. On the other hand, some publications appear on the web today and are gone or moved tomorrow. A publication may be launched and die before the publisher communicates with the community about its existence. Even the definition of what a publication is has become somewhat blurred.

The CRBP is continuously adapting to these changes. Suggestions, as well as notification of new publications, are welcome.

International Polar Year 2007–2008

Plans for the Bibliography on Cold Regions Science and Technology

The International Polar Year Publications Database (IPYPD) is in the process of identifying and indexing any permafrost/frozen ground publications that result from the International Polar Year 2007–2008 (IPY). A network of five organizations is collaborating to attempt to compile and provide access to all IPY-related publications through a single database. This network includes the Arctic Science and Technology Information System (ASTIS), the Cold Regions Bibliography Project (CRBP), the Scott Polar Research Institute (SPRI) Library, the Discovery and Access of Historic Literature of the IPYs (DAHLI) project, and National Information Services Corporation (NISC). The IPYPD will include publications that result from research as well as publications that relate to outreach and education. The IPYPD, as part of the IPY Data and Information Service (IPYDIS), is attempting to use the IPY Data Policy to require that researchers report their publications to either ASTIS, CRBP or the SPRI library. Each of these organizations will include records for IPY publications in their existing databases, which are part of the Arctic & Antarctic Regions database distributed by NISC.

Of course, the total number of permafrost/frozen ground publications that will result from the IPY is unknown at this time. Based on previous publishing rates from earlier IPYs, the IPYPD expects an estimated 20,000 total publications. If the percentage of permafrost/frozen ground publications remains stable, then we should expect about 12.6% of the total number of publications or about 2500 permafrost publications to be produced.

In an attempt to locate relevant publications, all of the collaborators are trying to contact researchers through conference presentations and web sites. Instructions for reporting publications are available online at http://www.ipy.org

Conclusions

Based on the above estimates of publication rates in the permafrost literature, the CRBP would expect to add upwards of 600 new permafrost publications over the next twelve months. The data on language, country, and type of publication provide a roadmap for focusing future efforts by the CRBP. When considered from the perspective of country and language of texts, the data regarding permafrost/frozen ground publications highlight the immense contribution to the scientific literature by the Former Soviet Union/Russia. Further examination of the Russian literature is warranted to insure continued coverage and access to this information. The CRBP will focus attention on expanding its connections with relevant organizations in this region. In addition, the International Polar Year and the conferences resulting from activities of the IPY should provide a substantial pool of permafrost/frozen ground literature for future consideration for inclusion in the *Bibliography* over the next decade.

Acknowledgments

The Cold Regions Bibliography Project is supported by the U.S. National Science Foundation and the U.S. Army Cold Regions Research and Engineering Laboratory under Grant No. OPP-0440772. The assistance of AGI staff members MaryAnn Theresa Eitler and Lawrence Berg in the compilation of the data for, and the editing of, this paper is appreciated. The International Polar Year Publications Database is part of the IPY Data and Information Service (IPYDIS).

Siberian Woolly Mammoths and Studies into Permafrost in the Russian Empire in the 19th Century

Erki Tammiksaar

Ken Kalling
Centre for Science Studies, Estonian University of Life Sciences

Abstract

In 1806 an adjunct of St. Petersburg Academy of Sciences, Michael Adams, brought to the Russian capital a fully preserved skeleton of a woolly mammoth. The mammoth issue became central to research made into aspects of permafrost and of the Ice Age, started in Russia in 1837 by a member of the Academy, Karl Ernst von Baer. For the study of permafrost Baer organized in 1842–45 an expedition to Siberia, headed by Alexander Theodor von Middendorff. All the subsequent expeditions to northern Siberia in 1860–1880s (headed by Friedrich Schmidt, Gerhard von Maydell, Alexander von Bunge *jun*., Eduard von Toll) were among other areas of science aimed at the study of palaeontological remains to establish the once widespread range of the woolly mammoth. In addition, these expeditions contributed much to the study of permafrost, laying foundations for the emergence of the outstanding Soviet school of permafrost studies.

Keywords: Baer, Karl Ernst von; Ice Age; Middendorff, Alexander Theodor von; Russian Empire; woolly mammoths.

Introduction

Mammoths, the conditions in which they lived, and their extinction received much interest among the 19th century scientific community. It could even be stated that the finds of these giant mammals from the Siberian permafrost were the main impulse for studies of prehistoric animals, i.e. for the development of vertebrate palaeontology as such. As the remains of the mammoths were mainly found in the northern and Siberian territories of the Russian Empire, it was the Russian scholars (and among others those of Baltic-German origin) who contributed most to the study of mammoths. One of the topics dealt with in connection with mammoths was their preservation in Siberian permafrost. The present article discusses the importance of mammoth studies on the scholarship on permafrost in the Russian Empire.

Information on Mammoths Prior to the 19th Century

In modern times every new discovery of a well-preserved mammoth is an important event both for science and the media. In the 19th century and before that, finds of well-preserved mammoths caused much attention. But due to the low level of development of natural sciences and little public information about Siberia, superstitious theories on the matter tended to prevail. For example, it was possible to believe the legends of the indigenous people of Siberia. According to legends the mammoths lived like moles underground and died if exposed to the daylight. Ideas that mammoths still existed were found in Chinese sources (Baer 1866). Russian colonists in turn believed that mammoths became extinct during the Great Deluge which carried their bodies to Siberia.

The first confirmed information on the Siberian woolly mammoths was taken to European scholars in the 17th century by Dutch traveler Nicolas Witsen, and by a Russian ambassador to Beijing, Ysbrand Ides. The latter brought with him, to confirm his words, a skull and other bones of a mammoth (Baer 1866).

In the 18th century, the geography and nature of Siberia was studied by several foreigners at the request of the Russian authorities. One should mention Daniel Gottlieb Messerschmidt with his companion Philipp Johann Strahlenberg (Tabber), members of Vitus Bering's second Kamtchatka expedition (1734–1744), Johann Georg Gmelin and Gerhard Müller and also Peter Simon Pallas who headed an expedition group from the St. Petersburg Academy of Sciences (1768–1774). These expeditions all secured information concerning mammoths in different parts of Siberia. Gmelin reported also on the Siberian permafrost (Baer 2001), but the two topics—permafrost and mammoths—were not at this stage linked.

In the end of the 18th century, Russian merchants discovered the islands of New Siberia where a lot of mammoth tusks and teeth were found. Subsequent travels, up to the end of the 19th century, to these islands were mainly aiming at collecting this material for profit.

A Mammoth Skeleton Arrives at St. Petersburg

In 1806, the Russian diplomatic mission to China visited Yakutsk. The team included Michael Adams, an adjunct in zoology, St. Petersburg Academy of Sciences. He heard that at the mouth of the Lena River a wholly preserved mammoth had been found. Adams decided to attempt to profit from this find by going to the site, bringing the mammoth to St. Petersburg, and there placing it on sale. At the site it became evident that the soft tissues of the animal had been lost, partly eaten by scavengers (the mammoth had been discovered in 1799) (Baer 2001). The skeleton of the mammoth was placed in the Zoological Museum of the St. Petersburg Academy of Sciences. In an article published in 1807 in an obscure periodical entitled *Journal du Nord,* data concerning the conditions in which the animal was found were provided by Adams and a local chief named Ossip Schumachow, who had actually made the discovery. The data became more widely known due to a member of the St. Petersburg Academy of Sciences, Wilhelm Gottlob Tilsesius von Tilenau (1815). From him information on the mammoth spread into the works of European scholars, together with a suggestion that mammoths must have been southern animals, the carcasses of which had been carried north by the big Siberian rivers. This idea was supported by a notion that the northern pastures seemed to be too poor for such big animals to feed there. The preservation of the bodies of the animals for a long time was not a matter of concern for the scientists of the day.

The Birth of Permafrost Studies in Russia

At the end of 1837, Karl Ernst von Baer, a natural scientist and member of the St. Petersburg Academy of Sciences in the field of zoology, gave a presentation on the so-called Shergin pit in Yakutsk. This, despite its enormous depth (116 m) did not contain any water due to permafrost. In his presentation Baer analyzed data available to him on the temperature in the pit. He concluded that the observations that had produced these data had to be continued in order to secure more information on this new natural phenomenon in Siberia. Many European scholars (i.e., German geologist Leopold von Buch) were suspicious of Baer's data on the pit stating that in regions in which there was forest and bush growing, the soil could not be permanently frozen, especially if one took into account the theory of a hot core of the Earth (see: Tammiksaar 2002).

Baer in his turn proved that the geothermic observations made in the pit supported current geological theory, proving also that in those geographical regions in which the annual average temperature fell below 0°C the frost entered the soil, causing permafrost (*Boden-Eis*) (Baer 2001).

To defend his arguments, Baer started in 1838 to collect data on this topic not only from literary and archive sources but also from his colleagues who studied the Russian North. As a result he completed by the beginning of 1843 a 218-page manuscript "*Materialine zur Kenntniss des unvergänglichen Boden-Eises in Sibirien.*" This first theoretical study on permafrost remained unpublished for several reasons. In his study von Baer analyzed for the first time the physical characteristics of permafrost and its patterns on the surface and beneath it, characterizing also different formations of ice. Baer also analyzed different landscape formations created by permafrost and tried to fix the distribution of

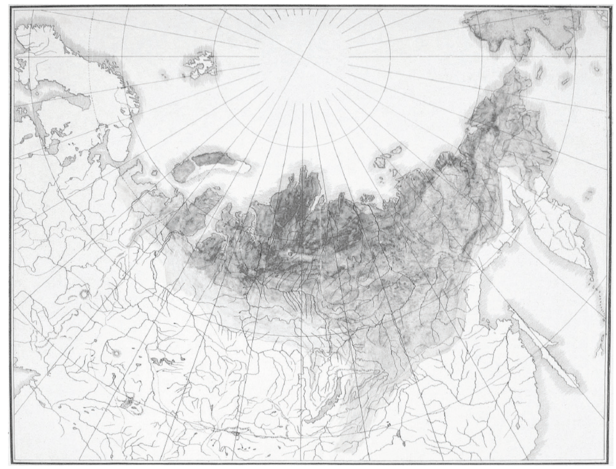

Figure 1. Map of the distribution of the permafrost area in Eurasia compiled by Karl Ernst von Baer (Tammiksaar 2002).

this phenomenon in Siberia and in the whole world (see: Tammiksaar 2001, Tammiksaar 2002). These data were used by Baer in preparing the first map in history of the permafrost areas depicting Eurasia (see Fig. 1). Von Baer also worked out a terminology concerning permafrost. Under *Boden-Eis* he meant permafrost as a physical phenomenon; that is, ice in geological layers. Under *Eis-Boden* he meant the geographic distribution of permafrost (see Baer 2001, Tammiksaar 2002).

Although Baer's manuscript remained unpublished, it was used by his disciple Alexander Theodor von Middendorff. Unfortunately there was no appropriate person in Siberia to run geothermic observations, as Baer had insisted, in the 116 m depth of the Shergin pit. To obtain the necessary data, Baer organised a special expedition with the support of the Academy to study all aspects of permafrost. The leader of the expedition was his countryman Middendorff. The expedition to North Siberia and Far East took place during 1842–1845. Baer gave his manuscript to Middendorff as instruction for the investigation, although many of the arguments set out in it (e.g., the causes of emergence of permafrost-linked surface forms, thickness of ice-cover on the rivers, etc.) still required thorough study (Tammiksaar & Stone 2007). The writings of Middendorff convinced scholars that permafrost really existed and that studies of it were needed. His studies became crucial also for the discipline in Russia, as they served as a starting point for later scholarship on the topic in the region.

Through the studies of Middendorff (Middendorff 1848, 1861) Baer's permafrost terminology spread among European scholars but, due to random and ignorant usage, became corrupted in time, so that a later scholar of permafrost, Eduard von Toll, decided to replace the term *Boden-Eis* with the term *Stein-Eis* (Toll 1895).

Adams' Mammoth, Permafrost, and Ice Age

One of the most important questions to be answered by Middendorff's expedition, according to Baer, was to fix as exactly as possible the physico-geographic and geologic conditions at the site at which Adams' mammoth had been found, Cape Bykovski in Siberia.

It was Baer's guess that mammoth corpses could survive for several thousands of years but only in permafrost. Baer thus viewed it as highly important to specify the geological and geographical circumstances in which Adams's mammoth had been found. The report by Adams on these conditions was internally contradictory, and its French was poor, leading to confusion. Baer could not understand whether the mammoth had been located on the icebergs/river ice heaped on the shore or whether it had melted out from an ice-wall covered with soil. Baer viewed this as a remnant of the Ice Age. Apparently when Adams had arrived at the site, the ice-wall had melted further and was already 30.5 m (100 ft) from the carcass.

In his manuscript Baer discussed Adams' report on the conditions of the mammoth find, and he devoted 30 pages to this. He tried to compare this data with the materials secured by members of the expedition led by Otto von Kotzebue for the search of the Northeast Passage (1815–1818). These were Johann Friedrich Eschscholtz and Adelbert von Chamisso, who had discovered a buried ice sheet in Eschscholtz-Bay (Baer 2001).

In the 1830s, Louis Agassiz and Jean de Carpentier had founded the theory of glaciation of continents. The theory caused controversy among geologists and other natural scientists. There were arguments for and against it, but only a few scholars collected empirical data to explain the theory. One of the few was Baer who was tending to support the theory. To be convinced, he needed more information on the conditions in which Adams' mammoth had been found. Until this was clear, Baer could not decide whether the carcass had survived intact due to ice surviving from the Ice Age (Tammiksaar 2002). Baer had suggested in his manuscript given to Middendorff that the mammoth must have been found on the heaped sea/river-ice (Baer 2001).

Middendorff searched for witnesses concerning the discovery of Adams' mammoth. In Barnaul he met the mining engineer, Slobin, who stated that the mammoth had not been found on the sea-ice but from the permafrost (Baer, 1866). Middendorff also discovered remnants of another mammoth at Taymyr peninsula (at Nizhnaya-Taymyr River) and described, for the first time in the history of mammoth studies, the particular site. This information suggested (at least for Middendorff) that these animals must have lived in the south, meaning that it had to be the rivers that had carried the bodies northward (Middendorff 1860a, b). Thus the information by Slobin became irrelevant for Baer, and he left the whole issue open.

During his expedition Middendorff could not prove the connections of Adams' mammoth with the Ice Age. He admitted that he could find no evidence for an Ice Age in Siberia. Thus he and Baer remained in a tentative position concerning the glacial theory (Baer 1986, Middendorff 1861).

It is not surprising that both Baer and Middendorff could not give simple answers to such a complicated matter. They were lacking hard empirical evidence upon which to draw accurate conclusions. There was also no theoretical basis for their research as permafrost studies were only in their initial stage and it was, in fact, Baer who had started them. There were also no fieldwork results or theory to distinguish ice formations of different origin (sea- and river-ice, glaciers, buried ice, etc.) as up to then a detailed approach to such phenomena had not been possible. The theory of the Ice Age was also in its initial stage.

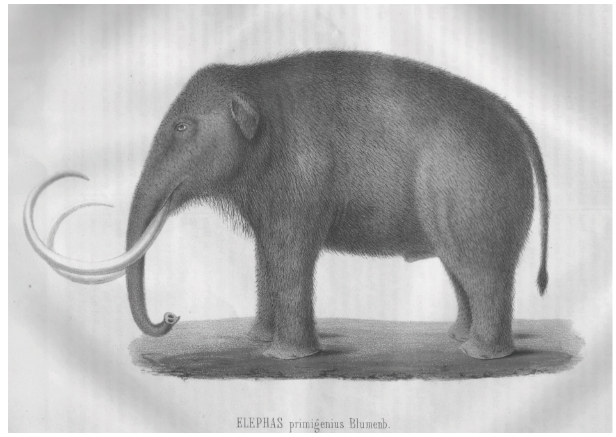

Figure 2. A mammoth drawn by Johann Friedrich Brandt (Brandt 1866a).

On the other hand, the studies of both scholars created a strong basis for future studies of mammoths and permafrost in Russia. It was just a matter of time before a new mammoth find was reported. Middendorff had created, on behalf of the St. Petersburg Academy of Sciences, a prize for those reporting mammoth finds (Middendorff 1860c, Sukhova & Tammiksaar 2005).

Woolly Mammoth as a Northern Species

At the beginning of 1866, Baer received a letter from a mining specialist in Barnaul, Stepan Guliaiev, informing him that near Tazovskaya Guba at the shore of the Arctic Ocean, a wholly preserved mammoth had been discovered. The Academy hurriedly summoned a special commission to organise an expedition to bring the carcass to St. Petersburg. Baer was the head of the commission. He hoped to solve several scientific problems that had remained open after Adams's find had been studied. For Baer it was not the preservation of the soft tissues that was particularly important but the information that might be obtainable from the surviving contents in the animal's digestive tract. He hoped to find remnants of coniferous trees and thus secure support for a theory under which mammoths had been northern animals. Such a find could also give information on the flora in historic times in Siberia (Baer 1866).

In connection with the organisation of the new expedition,Baer published an overview (based on the data of Middendorff (1859, 1860b) and of himself) on all known finds of mammoths in Siberia (Baer 1866). His colleague Johann

Friedrich Brandt, a zoologist, completed an overview on the morphology and living conditions of the extinct animal. In addition Brandt published a drawing to depict a mammoth as understood by him (see Fig. 2) (Brandt 1866a, b). Brandt also stated that mammoths could not have been southern animals but inhabitants of the north, becoming extinct due to climate change and leaving their bodies to survive in the permafrost (Brandt 1866b).

Baer took similar views, but his position was more cautious because of the lack of firm evidence. Baer did not want to rule out the possibility that the mammoths' bodies did not survive only in permafrost but also in ice formed of snow in places not reached by sun. This was possibly confirmed by Adams' case in which there had been ice covered by soil close to where the carcass had been found (Baer 1866).

Friedrich Schmidt, a geologist and later a member in palaeontology of the St. Petersburg Academy of Sciences, was appointed head of the expedition for the search of the mammoth found at Tazovskaya Bay. Arriving at the site, he discovered that the mammoth was not situated at the seashore but on the bank of the Yenissei River. Furthermore the body was badly preserved, and there was no hope of obtaining information on the contents of the digestive tract nor on the physiology of the animal. Yet Schmidt studied thoroughly the place at which the mammoth had been found and concluded that mammoths preserved in permafrost must have been northern mammals (Schmidt 1872). He reported on it to Middendorff (Sukhova & Tammiksaar 2005) and touched on the issue also in the report of his expedition (Schmidt 1869). After that, the scientific community (for example the geologist Count Alexander Keyserling) started to accept the idea that mammoths had not been inhabitants of the southern regions and that the natural conditions of Siberia must have been different in the past (cf. Taube von der Issen 1902, Toll 1895).

The Extinction of Mammoths Becomes Central in Making Broader Conclusions Concerning the Natural Conditions of Siberia

There was, therefore, no doubt that the mammoths had died out due to the chilling of the climate; but how much time the process had taken caused much argument.

In 1871, a member of the St. Petersburg Academy, the geographer Leopold von Schrenck, published a longer article on the issue of the extinction of mammoths based on field studies made by Gerhard von Maydell, a traveler of the Russian Geographical Society, in northeast Siberia studying three mammoth sites between the Indigirka and Kolyma Rivers in 1860–1870s (Schrenck 1871, Maydell 1896).

Schrenck proved that the process of slow ice formation on Siberian rivers, shallow lakes, and swamps during the chilling of the climate was the main reason preventing mammoths from leaving for areas with better conditions, and this finally caused their extinction very quickly. Schrenck also decided that only in very favourable conditions could a mammoth be preserved intact. In most cases bodies would decompose in water or in the atmosphere, and the remnants would be carried by rivers towards the sea in the area between the Indigirka and Lena Rivers. The latter process was still going on (Schrenck 1871).

According to Schrenck, mammoths could remain preserved only if their carcasses fell into the snow beneath the banks which did not melt in summer and finally turned into ice due to temperature changes (Schrenck 1871, Schrenck 1880). Agreeing with Baer in 1860, he considered that the mammoth described by Adams had been preserved in such a way. These two authorities were supported by Alexander von Bunge Jr., who participated in a Russian expedition, dedicated to the International Polar Year (1882–1883), to the delta of the Lena River, and at the request of Schrenck studied the place of Adams' mammoth find (Bunge 1884).

In 1885–1886, during an expedition arranged by the St. Petersburg Academy of Sciences, the region between the Jana and Indigirka Rivers was studied by Bunge and his companion, Eduard von Toll. The main goal of the expedition was to research the New Siberian islands, in which palaeontological finds were abundant (Bunge & Toll 1887). During this expedition the issue of the extinction of mammoths started to interest Toll, especially after seeing the high banks of the Big Lyahhov and Kotelny islands constituted mainly of buried ice/fossil ice (Toll used the term *Stein-Eis*), similar to that described by Adams at the mammoth site at Cape Bykovski. Toll was the first scholar to associate the sites in which mammoths had been found not so much with permafrost as with the occurrence of buried/fossil ice. According to him, the buried/fossil ice was a remnant of the Ice Age in Siberia.

Analysing thoroughly the slightest data on permafrost and traces of the Ice Age between the Lena River and Eschscholtz Bay (the main sources being the works of Baer, Middendorff, Bunge, Schmidt, Maydell, and writings by Erich von Drygalski on the Greenland ice sheet and the results of his two polar expeditions in 1885–1886 and 1893), Toll came to some very important conclusions. He proved that during the Ice Age, one centre of glaciation in Siberia was Cap Sviatoi Nos (east of the Lena River mouth), and this was the reason why after the Ice Age, the New Siberian islands were part of the Asian continent (Toll 1895). Toll named this "mammoth-continent," but this continent was destroyed as a result of gradual melting of the buried ice due to the transgression of the North Polar Sea and the activity of the Siberian rivers (Toll 1899).

Up to then an idea had been dominant (i.e.. Schrenck, Middendorff): the rivers had carried the bodies of the animals to their resting places from the area to the south. Similar conclusions had been made several years earlier by a Russian geologist of Polish origin, Jan Czerski, who had analysed the palaeontological finds and travel reports of Bunge (Tscherski 1893). By the analysis Toll proved that climate in northern Siberia was so warm after the Ice Age that the former continental ice sheet in the "mammoth-continent" was covered with sediments and plants (e.g., Toll found in the same layer bones of mammoth as well as stems of alder**).** This region was a suitable living place for mammoths and other mammals, but the gradual destruction of the continent and the cooling of the climate made the movement of mammoths and other mammals to the south impossible. As a result, the gradual extinction began. It was not catastrophic, for example, due to flood, a sudden fall of temperature, etc.; rather, the living conditions gradually deteriorated. Thus Toll decided correctly that the remnants of the animals had to be younger than the ice sheet in which the carcasses were preserved (Toll 1895). So, unlike his predecessors (Baer, Middendorff, Schrenck, Schmidt, Bunge), Toll came to the conclusion that the places at which extinct mammals were found in Siberia might be linked to regions with buried ice, either on riverbanks or seashore. If in rivers the buried ice submerged formations typical of the permafrost *taryn* (*Aufeis*), then the buried ice on the seashore had to be regarded as a remnant of the former ice sheet of the Ice Age (Toll 1895).

Besides generalisations made on the reasons of extinction of mammoths, Toll analysed the post Ice Age situation in the area east of the Yenissei River. He explained why Middendorff and others could not find traces supporting the glacial theory during their expeditions. According to Toll, the Arctic Ocean during the post Ice Age transgression had destroyed such traces and former glaciers on the low tundra areas and had disconnected the islands of New Siberia from the continent. Only in some regions, starting from the plateau between the Anabar and Olenyok Rivers to Eschscholtz Bay, survived former glaciers degraded into buried ice. In Toll's opinion, fossil ice was clear evidence that could not be explained differently than a remnant of the Ice Age in Siberia (Toll 1895).

Conclusion

The studies of mammoths by the members of the St. Petersburg Academy of Sciences and the expeditions organised by them in the 19th century reveal how complicated the process of scientific work can be in circumstances in which data for drawing conclusions is almost missing and the only information available is indefinite third person accounts. At the beginning of the 19th century the territory of Siberia had been not studied. In the 1830s fresh data started to emerge but initially they were contradictory. There was a need for more thorough and continual research (i.e. to discuss the relations between the mammoth sites with the essence of permafrost and relics of the Ice Age). There was no theoretical basis to link the gathered material into one entity.

That was the reason why Baer, Middendorff, Schrenck, and Bunge could not solve the question of Adams' mammoth, despite the fact that all of them (with the exception of Schrenck) had personally studied, in different parts of Siberia, both permafrost and other ice formations. Only after studies of Bunge, Maydell, and Czerski had enriched knowledge about the natural conditions in Siberia and the physiology of the extinct mammals was it possible for Toll to bind the earlier scholarship into a new entity. Thus Toll, unlike his predecessors, could explain the reasons why mammoths became extinct, as well as explaining other phenomena in Siberia, which all in turn were connected with matters of permafrost in these territories.

These studies at the end of the 19th century made Russia a leader in the theoretical and practical aspects of permafrost studies and created preconditions for the emergence of a special scientific field concerning the matter (*merzlotovedenie*) in the 20th century.

Soil Organic Carbon Stocks in the Northern Permafrost Region and Their Role in Climate Change

Charles Tarnocai
Research Branch, Agriculture and Agri-Food Canada, Ottawa, Canada

Gabriele Broll
University of Vechta, Vechta, Germany

Abstract

The soil area of the northern permafrost region is approximately $18{,}781 \times 10^3$ km^2, or approximately 14% of the global soil area. Organic soils (peatlands, total depth) and cryoturbated permafrost-affected mineral soils (100 cm) have the highest mean soil organic carbon contents (30–120 kg m^{-2}). Carbon stocks in the northern permafrost region were estimated to be 191 Gt for the 0–30 cm depth and 496 Gt for the 0–100 cm depth. Most of the soil organic carbon stocks occur in permafrost-affected soils, which contain about 70% of the stocks in the 0–100 cm depth. The values calculated here indicate that the organic carbon in soils in the northern permafrost region account for approximately 30% of the global soil organic carbon at the 0–100 cm depth, much of which will be vulnerable to release because of the large temperature increases predicted to result from climate change.

Keywords: carbon content; carbon mass (stocks); climate change; peatlands; permafrost; soils.

Introduction

The importance of permafrost-affected soils in global soil organic carbon stock estimates has been either neglected or poorly handled. This is probably due to the lack of data for these soils and the lack of understanding of the soil-forming processes in permafrost-affected soils. With recognition of the role of cryogenic processes in the genesis of these soils, came an understanding of their function in the sequestration of organic carbon (Van Vliet-Lanoe 1991, Bockheim & Tarnocai 1998, Bockheim 2007). These soils have sequestered carbon for a period of 6–8 thousand years and are still acting as carbon sinks (Tarnocai et al. 2007).

Some estimates of global soil organic carbon stocks are: 1220 Gt (Sombroek et al. 1993), 1395 Gt (Post et al. 1982), 1462 to 1548 Gt (Batjes 1996), and 1576 Gt (Eswaran et al. 1993). Although all of these estimates were based on the 0–100 cm depth, Batjes (1996) did report carbon stocks of 2376–2456 Gt for the 0–200 cm depth.

Post et al. (1982) estimated that the soils in the tundra zone contained, globally, approximately 191.8 Gt of organic carbon. This estimate, however, was based on only 30 samples. Using the, at that time, newly-developed Northern and Mid Latitudes Soil Database, Tarnocai et al. (2003) estimated that the carbon stocks in the 0–100 cm depth of Cryosols (Soil Classification Working Group 1998) in the northern circumpolar region were approximately 268 Gt of organic carbon. In this database, however, coverage of permafrost-affected soils in Eurasia was greatly underestimated.

This paper provides estimates of the organic carbon stocks in both permafrost-affected and nonpermafrost soils in the northern circumpolar permafrost region. The effect of climate change on this carbon is also discussed.

Materials and Methods

Terminology

The U.S. terminology for permafrost-affected (Gelisols) and nonpermafrost soils is used in this paper (Soil Survey Staff 1999).

SOCC (soil organic carbon content) refers to the content of organic carbon in a one meter square soil column. It is expressed as kilograms per square meter (kg m^{-2}).

SOCM refers to the soil organic carbon mass and is expressed as kilograms (kg) or gigatons (Gt).

The northern permafrost region refers to the northern circumpolar permafrost region as outlined by Brown et al. (1997).

The Northern Circumpolar Soil Carbon Database (NCSCD)

This database (Tarnocai et al. 2007) provides the spatial framework and the data needed to determine the organic carbon stocks for soils of the northern permafrost region. The NCSCD contains many thousands of polygons, with each polygon containing one or more named soil or soil taxa that form the basis for determining the carbon stocks.

The North American portion of the NCSCD was compiled from existing soil maps. For remote areas in North America, where more detailed survey maps were unavailable, data from other sources, such as pedon, climate and vegetation data, together with high quality LANDSAT imagery, were used to delineate polygons. The Greenland and Eurasian portion (Russia, Kazakhstan, Mongolia, Scandinavia, Svalbard, and Iceland) was also compiled from small-scale soil maps that had been digitized.

During this process, especially in the case of the Russian maps, the map symbols and classification terms had to be translated into English, and the soil classification terms had to be converted to the US Soil Taxonomy. A special effort was made to harmonize the data and to ensure that no information loss occurred during translation and data conversion, especially for permafrost-affected soils.

Pedon and peatland databases

Data used to calculate soil organic carbon content (kg m^{-2}) were derived from various pedon (soil profile) databases containing numerous pedons and their associated soil attribute data. The Canadian portion of the NCSCD was built up using 3530 pedons. No figures are available for the number of pedons used for the Alaskan portion of the database, but it relies, proportionally, on approximately the same level of supporting data as was used for Canada. Soil data used for the Eurasian portion of the NCSCD is drawn from a number of databases. A pedon database containing information for 253 pedons was developed for the Russian part of the NCSCD. In addition, the West Siberian Lowland Peatland GIS Data Collection, containing data for 90 peat cores (Smith et al. 2000, 2004, Sheng et al. 2004), was also used. Information from Batjes (1996) was also used for Eurasian soils, including Russia, especially where no pedon information was available.

Calculating SOCC and SOCM

Pedons for each soil taxa (Eurasia) or named soil (North America) are selected. These pedons contain all of the data needed to calculate the SOCC. The data for each named soil (North America) are entered into the database and are used to calculate the carbon content of each named soil in the polygon, while data from pedons of each soil taxa (Eurasia) are used to calculate their carbon contents, which are then entered into the database.

The SOCC (kg m^{-2}) was calculated for each named soil (North America) and for the representative pedons for each soil taxa (Eurasia) using the formula:

$$\mathrm{SOCC} = \mathrm{C} \times \mathrm{BD} \times \mathrm{T} \times \mathrm{CF} \tag{1}$$

where C = organic carbon (% weight), BD = bulk density (g cm^{-3}), T = depth of soil layer (0–30 cm and 0–100 cm), including the surface organic layer, and CF = coarse fragments and/or ice content (% weight). The SOCC data are then stored in the database to be used for further calculations or to generate carbon content maps.

The SOCM was then determined by multiplying the SOCC of the specific soil by the area of each such soil component in the polygon.

Results

Soil area

The total soil area of the northern permafrost region is 18,782 × 10^3 km^2 (Table 1). The Eurasian portion covers approximately 65% of the soil area and the North American portion 35%. Gelisols are the dominant soils in the area, covering approximately 54% of the permafrost region with the remainder of the area (46%) being covered by unfrozen soils. The Continuous Permafrost Zone, the largest of the four permafrost zones, covers 54% of the northern permafrost area while the Discontinuous, Sporadic, and Isolated Patches zones cover the remaining 46% of the area. The distribution of the major soil groups for frozen mineral soils (Turbels and Orthels), peat (Histels and Histosols), and unfrozen mineral soils are shown in Figure 1. Perennially frozen and unfrozen mineral soils cover approximately the same areas (40% frozen, 41% unfrozen). Peat soils cover the remaining 19% of the soil area.

Table 1. Areas of all soils in the various permafrost zones.

Permafrost zones	Area (10^3 km^2)		
	North America*	Eurasia	Total
Continuous	2868	7255	10,123
Discontinuous	1443	1649	3092
Sporadic	1149	1444	2593
Isolated patches	1186	1788	2974
Total	6646	12,136	18,782

* Greenland included in the North America calculation.

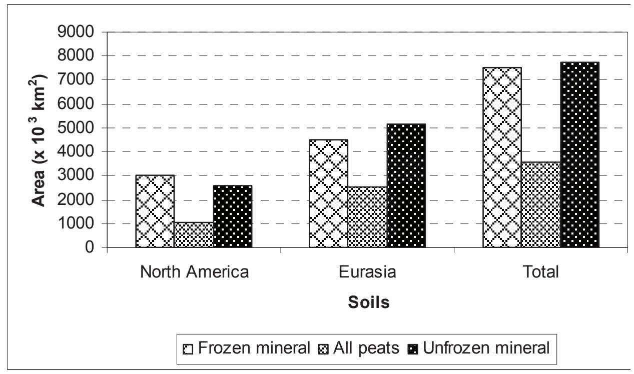

Figure 1. Distribution of major soil groups in the northern permafrost region.

Soil organic carbon content

The mean SOCC values calculated for the northern permafrost region are given in Table 2. Histels (perennially frozen soils) and Histosols (unfrozen peatland soils) have the highest SOCC with average values ranging from 67 to 69 kg m^{-2}. Maximum SOCC values slightly above 100 kg m^{-2} are not uncommon for these soils. The SOCC values for mineral Gelisols (Turbels and Orthels) range from 23 to 32 kg m^{-2}. Turbels have the highest SOCC values, in some cases as much as three times those for unfrozen mineral soils (Table 2).

The standard deviation was greatest (>50) for Histels and Histosols (Table 2). This is probably due to the variability of peat materials, the degree of decomposition, and the mineral (ash) content. Turbels, Orthels, and Spodosols had the second greatest standard deviations (20–27). Their large values were probably due to the various thicknesses of surface organic material associated with these soils and, for Turbels, also to the variability of amounts of cryoturbated organic materials they contained.

Soil organic carbon mass

In the northern permafrost region, the SOCM is approximately 191 Gt in the 0–30 cm depth and 496 Gt in the 0–100 cm depth (Table 3). Approximately 67% of this mass occurs in Eurasia and 33% in North America. The

Table 2. Average carbon contents for soils in the northern permafrost region.

US Taxonomy	Soil organic carbon content ($kg\ m^{-2}$)		
	Mean	SD	No. of pedons
Gelisols			
Histels	66.6	53.3	87
Turbels	32.2	27.4	256
Orthels	22.6	21.4	131
Histosols	69.6	56.9	417
Andisols	25.4*	=	unknown
Spodosols	24.7	20.2	6
Aqu-suborders	20.1	9.7	531
Inceptisols	15.3	9.4	871
Vertisol	13.5	7.3	11
Entisols	9.9	15.8	198
Mollisols	9.6	8.3	422
Natric-suborders	9.1	7.6	67
Alfisols	8.9	6.9	533
Aridisols	3.0*	=	unknown

* SOCC data from Batjes (1996)

Continuous Permafrost zone contains approximately 60% of the carbon mass; the remaining three zones each contain approximately 13%.

The SOCM for all major soil orders is shown in Figure 2. Gelisols are the major SOCM contributors in the permafrost area. They contain approximately 71% of the SOCM at depths of 0–100 cm in the region. Within the Gelisol soil group, the Turbels contain the largest amount (64%) of SOCM in both the 0–30 cm and 0–100 cm depths (Fig. 3).

Peatlands (Histosols and Histels) contain approximately 48% of the SOCM in the northern permafrost region, with the Histosols containing the second largest soil carbon pool (13% of the SOCM).

When the SOCMs of the major soil groups are compared (Fig. 4), the peat soils and frozen mineral soils are the major contributors of SOCM in both North America and Eurasia. The SOCM in the 0–100 cm depth (for both frozen and unfrozen organic and mineral soils) is approximately 239 Gt for organic soils (peatlands) and approximately 256 Gt for mineral soils. It should be pointed out that, although the SOCM values for these soil groups are similar, peatlands cover only 19% of the soil area of the region.

When soil areas and SOCM values of major soil groups were compared, it was found that, although unfrozen and frozen mineral soils cover about the same area, the SOCM values of frozen mineral soils are approximately twice those of unfrozen mineral soils (Fig. 5). Peat soils (unfrozen and frozen) cover about half as much area as the frozen and unfrozen mineral soils, but they contain about 13% more SOCM than the frozen mineral soils and nearly three times more than the unfrozen mineral soils (Fig. 5).

Discussion

Carbon dynamics

The total SOCM at the 0–100 cm depth for soils in the

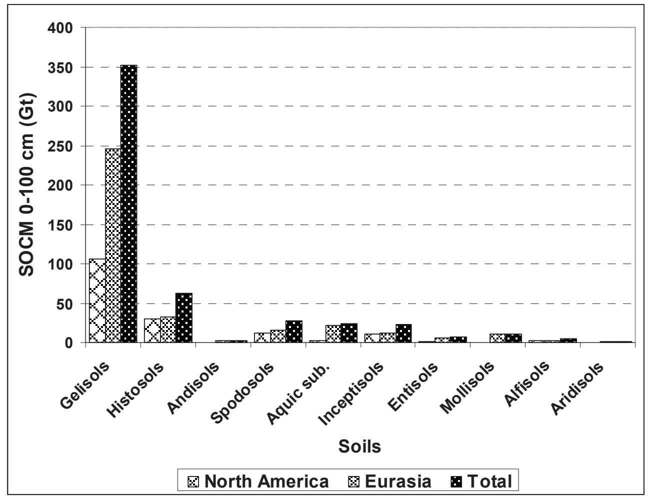

Figure 2. SOCM for the 0–100 cm depth in all soils in the northern permafrost region (SOCM in Vertisols and Natric-suborders is <0.5 Gt).

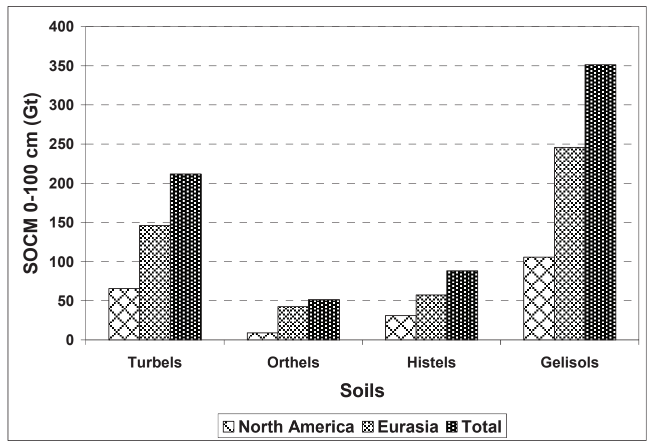

Figure 3. SOCM for the 0–100 cm depth in the three Gelisol suborders and in all Gelisols in the northern permafrost region.

northern permafrost region is approximately 496 Gt, which is about 30% of the global SOCM. The large amount of soil organic carbon in this region is due to the large areas and high carbon content of the peat (organic) soils and cryoturbated mineral soils (Turbels).

Peat soils are composed of organic materials with a high concentration of carbon that has accumulated over a long period of time. Robinson & Moore (1999) found that, in the Sporadic Permafrost Zone, mean carbon accumulation rates in unfrozen bogs (Histosols) and frozen peat mounds (Histels) over the past 100 years were 88.6±4.4 and 78.5±8.8 $g\ m^{-2}$ per year, respectively. They also found that, in the Discontinuous Permafrost Zone, the mean carbon accumulation rate in peat plateaus (Histels) during the past 1200 years was 13.31±2.20 $g\ m^{-2}$ per year, while in unfrozen fens and bogs (Histosols) the comparable rates were 20.34±2.86 $g\ m^{-2}$ and 21.81±3.25 $g\ m^{-2}$ per year, respectively. Radiocarbon dates from the basal peat (the base of the peat deposit, indicating the beginning of peat deposition) suggest that, in North America, the average basal peat date is 7200 ^{14}Cyr BP in the Arctic, 6200 ^{14}Cyr BP in the Subarctic and 6000 ^{14}Cyr BP in the Boreal (Tarnocai

Table 3. Organic carbon mass in all soils in the permafrost zones.

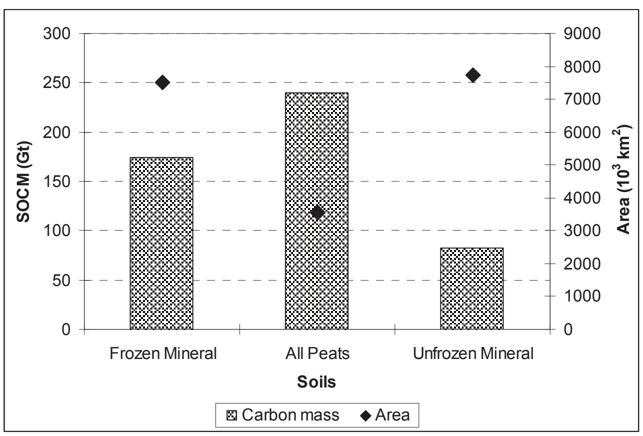

Figure 5. Comparison of the area covered and SOCM in the 0–100 cm depth for the major soil groups.

& Stolbovoy 2006). In Russia, the basal peat dates for the Tundra zone are 2000–3000 ^{14}Cyr BP and for the Taiga zone are 5000–8000 ^{14}Cyr BP (Tarnocai & Stolbovoy 2006).

In mineral soils, Turbels had the highest SOCM, containing approximately 43% of the organic carbon mass occurring in all soils in the northern permafrost region. Cryoturbation, a unique process operating in these soils, is responsible for the high SOCM values. Although the ecosystems in the permafrost region produce much less biomass than do temperate ecosystems, permafrost-affected soils that are subject to cryoturbation (Turbels) have the ability to sequester a portion of this annually-produced biomass and store it for thousands of years. Bockheim (2007) estimated that 55% of the soil organic carbon in the active layer and near-surface permafrost could have resulted from translocation by cryoturbation.

Radiocarbon dates for 50 cryoturbated organic samples from earth hummocks presented by Zoltai et al. (1978) indicate that the dates ranged from 500–11,200 ^{14}Cyr BP. The frequency of dates indicates that the number of samples was constant in the 500–5000 ^{14}Cyr BP range, with a peak occurring in the 3000–3500 ^{14}Cyr BP range. The number of samples decreased in the 5000–11,500 ^{14}Cyr BP range and showed no pattern.

Soluble organic materials also move downward within the soils because of the effects of gravity and the movement of water along the thermal gradient towards the freezing front (Tarnocai 1972, Kokelj & Burn 2005). When these organic materials reach the cold, deep soil layers where very little or no biological decomposition takes place, they may be preserved for many thousands of years.

The SOCC and SOCM values for unfrozen mineral soils in the permafrost region are low because these soils lack a mechanism to move insoluble carbon from the surface into the deeper soil layers. Soluble organic materials, however, may move downward and roots do contribute organic carbon to the subsoil. Trumbore & Harden (1997) reported carbon accumulations of 60–100 g C m^{-2} per year for these soils, but the turnover time, especially because of wildfires, is 500–1000 years. The turnover time for deep carbon, originating mainly from roots, is 100–1600 years (Trumbore & Harden 1997).

Land-use change also has significant effects on soil carbon stocks, especially in northern Europe where large areas are used as pasture (Smith et al. 2005). More research is needed to determine the effect that land-use change will have on northern soils, especially in view of the changing climate and such properties as cryoturbation.

Reliability and uncertainties of carbon data

It is difficult to determine the accuracy of the carbon stocks presented in this paper since no such information has been published for the northern permafrost region.

The North American soil organic carbon estimates were tested by Bhatti et al. (2002), who compared the carbon values generated by both the Carbon Budget Model of the Canadian Forest Sector (CBM-CFS2) and the Boreal Forest Transect Case Study (BFTCS) with the Canadian Soil Organic Carbon Database (CSOCD) (Soil Carbon Database Working Group 1993). They found that the CSOCD generated slightly lower carbon values than the CBM-CFS2 carbon model, but that there was good agreement between the CSOCD- and BFTCS-generated values.

No SOCM data are available for the permafrost region in Eurasia, but Stolbovoi (2000) estimates that the area of permafrost-affected soils in Russia is 307 million ha. He did point out, however, that this value is much less than the total area of the permafrost zone in Russia, which is more than 1,000 million ha. Stolbovoi (2002) reported that the SOCM in Russia is approximately 297 Gt C for the 0–1 m depth and 373 Gt C for the 0–2 m depth. Estimates of Russian peatland areas and the organic carbon stocks they contain are 1162–2730 × 10^3 km^2 and 94–215 Gt, respectively (Botch et al. 1995, Efremov et al. 1998). Although the peatland area (2730 × 10^3 km^2) given by Efremov et al. (1998) is close to that given in this paper, the carbon mass value (118 Gt) is only half that given here. These large variations occur because of the poor inventory and limited amount of reliable pedon data available for these soils. This supports the statement of Efremov et al. (1998) that: "The accuracy of estimates of peat carbon is ± 10 to 15 percent for the European part of Russia and ± 20 to 30 percent for the Asian part of the country."

Climate warming

It is predicted that the average annual air temperature in the permafrost region of Canada will increase 3–4°C by 2020 and 5–10°C by 2050. Such increases have already been observed at seven northern circumpolar climate stations that tracked temperature changes in winter and spring (NOAA 2007)

Various predictions have been made about the effect this large temperature increase will have on soil carbon. The most commonly predicted effects are melting of ice-rich frozen soil materials, higher frequency of wildfires and shoreline erosion.

It is also predicted that the greatest effects of climate warming on Canadian peatlands will occur in the Subarctic and Boreal zones (Tarnocai 2006). Major concerns are the drying of peatlands and an increase in frequency and extent of wildfires. Richie (1987) found that boreal forests in western Canada have a fire return interval of 50–100 years while Kuhry (1994) indicated that, for Sphagnum bogs, the interval is 400–1700 years.

A study similar to that of Tarnocai (2006) was carried out on mineral soils in the permafrost region of Canada (Tarnocai 1999). This study suggests that 12 Gt of organic carbon in Canadian Cryosols could be severely to extremely severely affected by climate warming. This study also suggests that permafrost-affected soils will cease to exist in the southern part of the permafrost region in Canada, and that cryogenic processes will diminish or disappear in southern regions. In these areas, the mechanism for sequestering carbon would cease to operate and a portion of the soil carbon would be released as carbon dioxide and/or methane.

Bockheim (2007), however, suggests that continued warming of the Arctic could accelerate cryoturbation and, thus, enable the soil to store more soil organic carbon than it can at present. Zoltai et al. (1978) suggest that, based on the higher frequency of carbon dates between 3000 ^{14}Cyr BP and 3500 ^{14}Cyr BP, this period coincided with a time of higher soil moisture and lower temperatures with increased cryoturbation. Relict earth hummocks found in the Mackenzie Valley (Zoltai & Tarnocai 1974) suggest that these hummocks were active during the Little Ice Age, but became dormant and cryoturbation ceased when the climate warmed. The soil horizons in these dormant hummocks showed no signs of cryoturbation, although some fossil cryoturbation features remain in the lower part of the soil.

These contradictory findings indicate that we know very little about the complex interactions between soils and climate in these northern regions.

Acknowledgments

We would like to thank Drs. Peter Kuhry, Galina Mazhitova, and Sergey Goryachkin for providing the Russian pedon data. Special thanks are also due to Dr. David Swanson for translating and digitizing the Russian soil maps, which also included Kazakhstan and Mongolia.

Abstract

Canada's Mackenzie Delta has experienced Holocene lake development on a permafrost landscape, exerting significant influence on the sub-lake geothermal regime. Two-dimensional finite element geothermal modeling is used to simulate talik formation beneath lakes of various diameters in sand, clayey-silt, and clay. Forward modeling was initiated from a simplifying assumption of thermal steady state at the end of the Wisconsin, and subsequently incorporated the transient effects of Holocene warming and mid-Holocene lake formation, to the present-day. Thermal taliks (>0°C) quickly developed beneath all lakes. In sands, sediments beneath the taliks remained almost entirely ice-bonded to the present time. In contrast, in fine-grained clayey silt, sediments beneath the taliks developed elevated unfrozen water content that eventually extended to the base of permafrost, thus forming chimney-like structures of partially ice-bonded soils that penetrate thick permafrost beneath larger lakes. This characteristic arises from the strong temperature dependence of unfrozen water content in finer-grained sediments.

Keywords: geothermal; lakes; modeling; permafrost; seeps; talik.

Introduction

Lakes and river channels represent dramatic thermal anomalies in terrestrial permafrost environments. In the arctic, the impact of water bodies on permafrost is accentuated because of the large contrast in mean annual ground surface temperature beneath lakes and rivers (if they do not freeze completely in winter) compared to that of the adjacent sub-aerial terrain. The classic study is the analytic model of Lachenbruch (1957), which demonstrates the steady-state (or equilibrium) impact and simple transient effects of lakes on permafrost. Over 30% of the land area of the Mackenzie Delta is occupied by lakes, and large variations in the subsurface geothermal regime are expected from the contrast of warm lakes (mean annual lakebed temperature about +2°C) superimposed on a cold (-6°C or colder) permafrost landscape. Mackay (1963, sect. 76) calculated the thermal disturbance beneath such lakes and W. Brown et al. (1964) presented early field evidence for the presence of a talik beneath a lake in the Mackenzie region. Numerical studies of talik formation beneath lakes have been made by Ling & Zhang (2003) in northern Alaska, and Burn (2002) in the Mackenzie Delta.

In this paper, we use a two-dimensional finite element model to predict the thermal impact of lake formation (during the Holocene) on thick Pleistocene permafrost typical of the Mackenzie Delta, northwestern Canada. The study focuses on the thermal sensitivity of two typical lithologies (sand and clayey silt) to lake diameter (20 m to 4 km), and to time of lake formation (10 kaBP and 6 kaBP). Model outputs are two-dimensional (horizontal and depth) depictions of ground temperatures and unfrozen water contents through the permafrost, and are presented as contours and summary graphs. The model is not calibrated to observed permafrost temperatures or thicknesses at a particular location. Rather, the intent of the paper is to demonstrate the gross impact of the development of hypothetical lakes on permafrost terrain in terms of changes to the local geothermal regime, subsequent development of taliks, and modification of the properties of underlying sediments. Thermal taliks are unfrozen sediments (temperature >0°C) in association with permafrost, and "geophysical taliks" are defined here as frozen sediments (temperature <0°C) which contain sufficient un-crystallized pore water (herein referred to as unfrozen water) so as to be discriminated by geophysical methods.

Extensive permafrost developed in Quaternary sediments of the Pleistocene Mackenzie Delta (principally the Tuktoyaktuk Peninsula and Richards Island) and today is typically 400–700 m in thickness (Judge 1973, Taylor et al. 1982), consistent with late Wisconsinan and Holocene surface temperatures (Taylor et al. 1996). The glacial history is controversial, but the region was mostly unglaciated during the late Wisconsinan (Dyke & Prest 1987). Maximum development of thermokarst lakes occurred in the early Holocene and most lakes have undergone one or more partial drainage events, attaining their present size by ~6 kaBP (Mackay 1992), and lacustrine sediments bordering many present-day lakes reflect this earlier, more extensive lake cover (Rampton 1988). Numerous tundra polygons and pingos are characteristic of poorly drained areas comprising former lake bottoms (Mackay 1963, §64).

Model Description

The TEMP/W geothermal modeling software (Geo-Slope International Ltd. 2004) was employed in this work. This two-dimensional finite-element numeric model combines conductive heat transfer and phase-change enthalpies, and accommodates the explicit specification of appropriate geologic properties and temporal boundary conditions. The model has been verified extensively against analytic solutions as well as the pioneering numerical permafrost model of Hwang et al. (1972) and has been used in the permafrost community (e.g., Mottaghy & Rath 2006).

Our problem space extends to a depth of 1000 m along a 14 km hypothetical transect. Lakes of diameter 20 m, 50 m, 100 m, 200 m, 500 m, 1 km, 2 km and 4 km are situated at a spacing that ensures minimal thermal disturbance of adjacent lakes but which is, however, not untypical of the spacing of lakes on Richards Island and the Tuktoyaktuk Peninsula. The goal was to develop, without the advantage of a full 3-dimensional code but with the flexibility of applying quasi-continuous surface boundary conditions, a model that could be applied easily to an actual transect across this region (see Discussion). Water depth in Mackenzie Delta lakes is typically a few meters (Mackay 1963) and is not explicitly considered in the model, except that our results apply only to the central basins of sufficient depth that water does not freeze to the bottom in the winter.

Physical properties

Unfrozen water content as a function of sub-0°C temperature (Smith & Tice 1988) is a primary physical property for permafrost modeling, and refers to pore water that remains in the liquid phase even though its temperature is below 0°C. The Geological Survey of Canada has measured unfrozen water content, porosity, salinity, and grain-size distributions for a suite of some 30 subsurface soils from the Mackenzie-Beaufort area (Dallimore & Matthews 1997). Curves of unfrozen water content as a function of sub-0°,C temperature were chosen that are typical of sand, clayey silt and clay (Fig. 1a). Nowhere does clay fully constitute the entire permafrost section in the Delta, but clay was chosen to compare with sand as geologic "end members" of typical Delta soils. Averages of ~ 2000 measured thermal conductivity values (needle probe method), and unfrozen water content curves from previous field programs (Dallimore 1991, 1992) were used to calculate conductivity-temperature profiles for these three lithologies (Fig. 1b). Thermal heat capacity was calculated from the constituent fractions of soil particles, frozen (ice), and unfrozen water. The phase change temperature assumed for pore water is 0°C. Note that as fine-grained sediments freeze or thaw, the latent heat is distributed over a range of temperatures, according to the unfrozen water content curve (Fig. 1a). TEMP/W fully accommodates such a "distributed" latent heat budget of freeze/thaw. The latent heat of the water is 3.38 x $10^8 J\cdot m^{-3}$; hence for soil volumetric latent heat is less, depending on the porosity.

Boundary conditions

Steady state condition. A geothermal heat flux of 69 $mW\cdot m^{-2}$ (Judge 1973, Majorowicz 1996, Fig. 16) was applied at 1 km depth for all models and times.

Initial and transient surface boundary conditions provide the basic constraints under which the geothermal regime is modeled in the forward sense, from ~13 kaBP through the

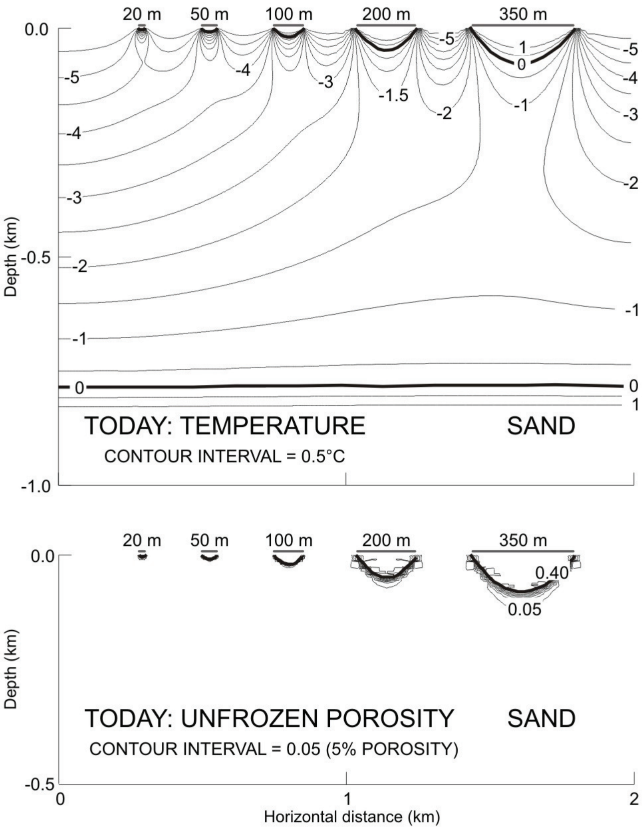

Figure 3a. Modeled present-day temperature vs. depth (upper; contours in °C) and fractional unfrozen volumetric water content (lower) beneath lakes of various sizes (20–350 m diameter) for a sand lithology with volumetric porosity 40%; thus 0.4 designates a totally thawed sand.

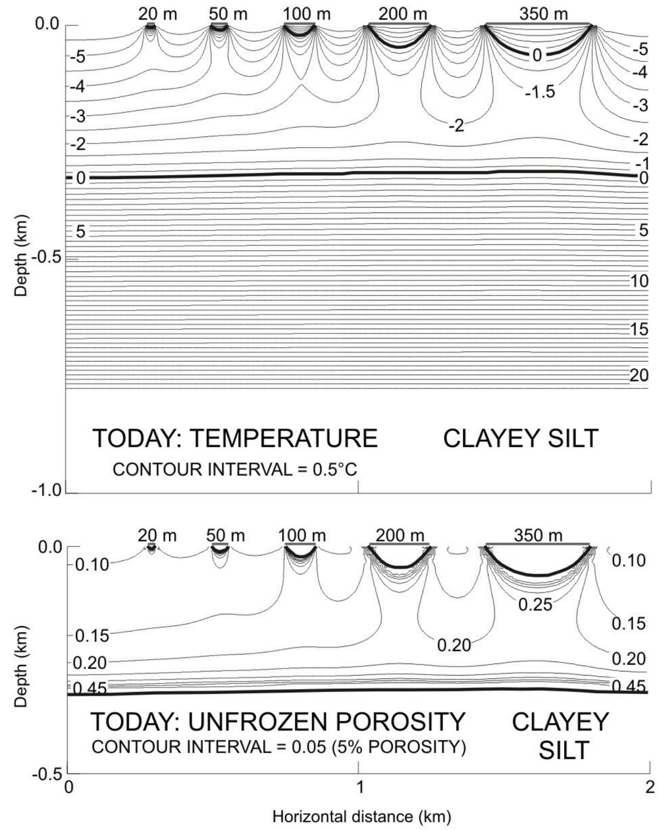

Figure 3b. As above, for a clayey-silt lithology; volumetric porosity 48%; thus, 0.25 indicates sediment in which about half the pore space is unfrozen water.

present to ~13 kaAP (after present). Boundary conditions were developed from the literature for earlier work and were verified through their successful prediction of temperatures measured today (see Taylor et al. 1996 for citations).

Initial conditions provide the geothermal structure at the end of the Wisconsinan from which forward modeling is initiated. Permafrost temperatures at ~13 kaBP were assumed to be in quasi-equilibrium with surface temperatures of -15°C (typical of severe arctic conditions for unglaciated areas) and with the steady state geothermal heat flux.

Transient boundary conditions specify the variation of ground surface temperature through time, forward from the steady state and initial boundary condition at 13 kaBP and at different points along the hypothetical 14-km transect through lakes. Two surface boundary conditions are considered: land that is always subaerial (temperatures variable), and lakes. See Taylor et al. (1996, 63-65) for discussion of subaerial temperatures assumed throughout the Holocene. Lake bottom temperatures were assumed +2.3°C (cf. Burn 2002, +2 to 4°C, 1290). Geological evidence suggests that lakes formed as early as 10,000 to about 6000 years ago (e.g., Mackay 1992); the numerical model applies the subaerial boundary condition prior to those times, and a combination of the subaerial and the lake boundary conditions following lake formation; lakes are assumed to form to full size, a simple "step change" ramped over ~100 years (Fig. 2). The Little Ice Age is not considered. Finally, we invoke a scenario of contemporary climate warming, at 2°C per 100 years for land and half that value for water temperatures for 300 years following the present, thus reaching +0.1°C (land) and +5.3°C (lakes) by 300 aAP. At that time, the transient boundary conditions represent a non-sustainable permafrost environment. Modeling results are saved at frequent time intervals, allowing a depiction of the gross evolution of the two-dimensional ground thermal state.

Model Results

Time slice – present

Figure 3 presents contours of the present transient geothermal regime for lakes formed 6 kaBP in (a) sand, and (b) in clayey silt lithology. The base of permafrost is more than twice as deep in sand due to the effect of higher thermal conductivity (Fig. 1b). Thermal taliks beneath lakes are defined by the upper 0°C isotherm and the base of permafrost is defined by the lower 0°C isotherm. There are two critical observations: (1) Temperature contours are very similar in character for both sand and clayey silt; but (2) the unfrozen water content contours are very different, with <5% volumetric unfrozen water content in sand beneath all lakes regardless of size, whereas >15% unfrozen water content in clayey silt beneath lakes >100 m diameter. The through-

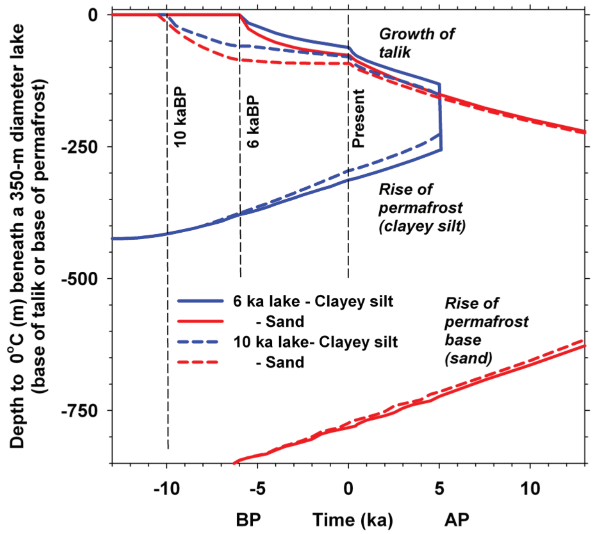

Figure 4. Growth of a talik and rise of permafrost base beneath a 350 m diameter lake, following lake formation at 10 kaBP or 6 kaBP on a permafrost landscape of sand or clayey silt.

going "hourglass" of partially unfrozen soils beneath lakes is absent in sand. These contrasting regimes are directly related to the contrast in unfrozen water content curves in the two lithologies, such that at sub-zero temperatures within a few degrees of 0°C, a comparatively large fraction of pore water remains in the liquid phase in clayey silt compared to sand (Fig. 1a). As a direct result, geophysical taliks (soils having high unfrozen water contents) completely penetrate the permafrost in a clayey silt substrate, while sands underlying lakes of comparable size are almost completely frozen.

Growth of taliks after mid-Holocene lake formation

Figure 4 shows thermal talik development and evolution of permafrost during the Holocene. Today, thermal taliks extend possibly 20 m deeper beneath lakes formed at 10 kaBP than at 6 kaBP. In our model, the 0°C isotherm fully penetrates the permafrost within several hundred years of lake formation on a hypothetical clay lithology (not shown), within ~5 kaAP in clayey silt under contemporary climate warming, and apparently only after several tens of thousand years in sand. The permafrost base rises throughout the Holocene. Many lakes forming ~10 kaBP contracted in size by the mid-Holocene, leaving lacustrine "halos" surrounding some present-day lakes (unit L in Rampton 1988); modeling showed that the geothermal effect at the present time is very small.

Regime beneath lakes and intervening land

Figure 5 depicts the present thermal regime beneath adjacent 100 m and 200 m lakes and the 150 m of land separating them as predicted by the transient model (clayey silt). The expected regime if ground thermal conditions were in equilibrium with today's climate is also shown (lighter

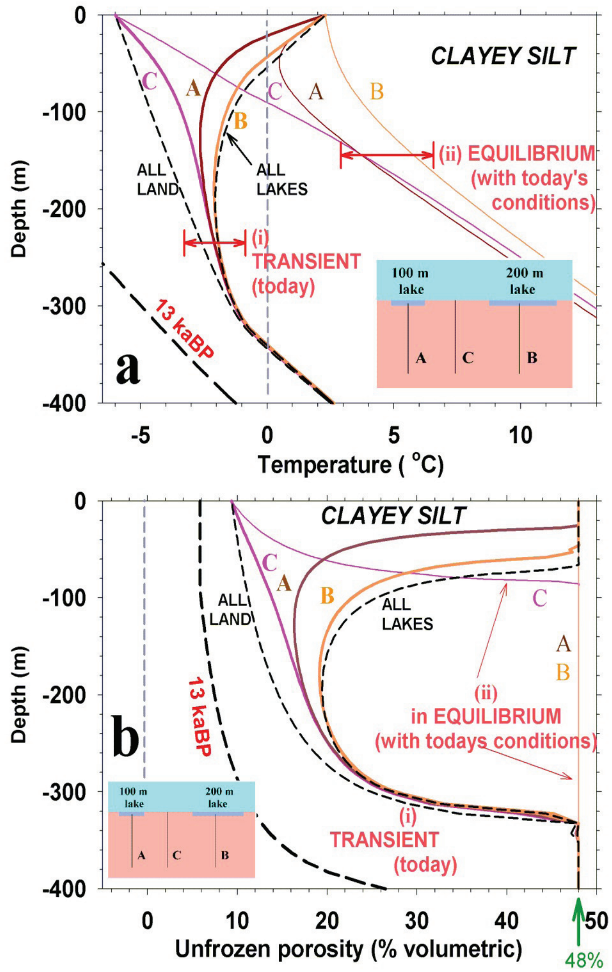

Figure 5. Thermal regime predicted in a clayey silt lithology for today beneath two adjacent lakes (A and B in the insets) and the land separating them (C). (a) transient temperature profiles (i), and equilibrium temperature profiles (ii) for today's surface conditions. (b) volumetric unfrozen water content. Transient profiles labeled "all land" and "all lakes" are bracketing "end member" cases of a landscape that is lake-free or fully inundated.

curves) to demonstrate the fallacy of such an assumption (see "Discussion" for field evidence). Profiles labeled "all land" and "all lake" are the end-member scenarios of the extent of lake coverage and bracket the profiles predicted for a lake-dominated landscape. The temperature profiles beneath lakes 100 m and 200 m in diameter ("A" and "B") contrast to the profile ("C") beneath their shared inter-lake area. Both temperatures and unfrozen water contents deeper than ~300 m appear largely independent of surface conditions (i.e., lakes or land, or Holocene climate change) while at depths less than ~300 m, temperatures reflect the surface environment and Holocene warming. The depth to the base of the sub-lake thermal talik increases from ~ 21 m (100 m diameter lake) to ~40 m (200-m lake, Fig. 5a).

Permafrost with low volumetric unfrozen water content (~6%) underlies all land at 13 kaBP, as predicted by the unfrozen water curve at –15°C for clayey silt (Fig. 1a) and a soil porosity of 48%. The impact of lakes on the modern landscape is to raise the minimum unfrozen water content to ~10% beneath the intervening land between lakes, and to ~16%–20% beneath lakes >100 m in diameter. Hence, almost half the pore space is unfrozen beneath larger lakes situated on clayey-silt sediments, although ground temperatures remain <0°C. Unfrozen water content, and hence sediment permeability within these geophysical taliks, may be sufficiently high to facilitate vertical transport of water and/or gas from deeper horizons to the surface in these environments (e.g., Williams & Smith 1989, §7.5).

The depth to the base of the thermal talik increases with lake diameter, to a maximum of ~50 m under the largest lakes or an "all lake" landscape (clayey silt) and ~85 m (sand), and at present continues to increases at ~4 m/1000 years at present. In contrast, the permafrost base is rising at ~10 m/1000 years (Fig. 4). The depth to the minimum of the unfrozen water content profile is about 4 to 5 times deeper than the depth to 0°C in clayey silt; and the value of the minimum unfrozen porosity is ~20% in clayey silt and <3% in sand. There is little indication of a "geophysical talik" in sand (Fig. 3a, lower).

Discussion and Conclusions

Our finite element geothermal model demonstrates that the present permafrost geothermal regime is in disequilibrium following the onset of the Holocene, and that for lithologies typical of the Mackenzie Delta, the continuous permafrost is not perforated by through-going thermal taliks (i.e., temperatures >0°C) beneath Holocene lakes of any size. However, '"geophysical taliks"' do penetrate the permafrost beneath lakes due to the substantial unfrozen water content of clayey silts at negative temperatures to about -7°C (Fig. 1a). There is some field evidence in support of our interpretation of modeling results and for the presence of both thermal and geophysical taliks beneath lakes. Pre-drainage temperatures beneath the centre of Illisarvik Lake reach -3°C at 84 m with the sub-lake talik extending to ~32 m (Burgess et al. 1982). Temperatures to ~350 m below seabed in the Amauligak geotechnical hole some 80 km offshore in 32 m of water on the Beaufort Shelf are near isothermal at -2.3°C, a good analogy to the "all lakes" model of Figure 5 (Taylor et al. 1989). Beneath a small island in Parsons Lake, permafrost is >300 m deep, similar to depths at several wells surrounding the lake (Judge et al. 1981). Electromagnetic soundings provide some field evidence of the unfrozen water content of sub-talik sediments (Geophysicon 1983, Todd & Dallimore 1998).

Interpretation of 3-dimensional seismic data by Riedel et al. (2006) provides evidence of seismic blanking beneath shallow lakes in the vicinity of Mallik Bay, Richards Island, possibly due to lower seismic velocities in sub-lake sediments containing significant unfrozen water.

The geology of the Pleistocene Mackenzie Delta is largely sands, silts, and clayey silts, at least through permafrost (Dallimore 1992). Where lithology tends towards finer-grained sediments, our model suggests that geophysical taliks may perforate the permafrost beneath lakes, and the elevated unfrozen water content may have implications for the migration of ground water and/or hydrocarbon gases from below permafrost to the surface. In the case of natural gases such as methane, these conduits may provide physical pathways for the transport of greenhouse gases from deep geological sources (conventional hydrocarbon reservoirs and/or gas hydrate deposits) into the atmosphere.

Our model is meant to be a gross prediction of the thermal regime evolving from the initial formation of lakes in the early to mid-Holocene. The gradual *ab initio* enlargement of lakes (e.g., ~1 m/a at 10 ka or 6 kaBP) is not modeled and may be a negligible effect on the subsurface thermal regime today. An inherent assumption in the 2-D model is the "'third dimension" that extends to infinity. Hence, our model more correctly represents a transverse section across a river. For our model, the result is a moderately enhanced talik development arising from the unconstrained third dimension, especially under smaller lakes. An alternative quasi-3D model could be developed in cylindrical symmetry (e.g., Ling & Zhang 2003), better to model details of the thermal impact of an isolated lake but less appropriate to model transects of the closely-spaced lakes of the Mackenzie Delta where we might expect substantial thermal effect of one lake on another (e.g., Figure 3 predicts permafrost temperature between the lakes is higher than away from the lakes).

To the authors' knowledge, there are no "through-permafrost" temperature profiles with which to constrain our model. The intent here is to present a simple model constrained by the literature and reasonable geological assumptions. Current numerical methods enable almost any detail of lake evolution to be modeled; however, the most significant limitation remains the lack of relevant field measurements to constrain the models.

Abstract

Retrogressive thaw slumping can transport ion-rich meltwater and thawing sediment from terrestrial to aquatic systems. Tundra lakes affected by shoreline slumping have elevated ionic concentrations, low dissolved organic matter concentrations, and colour compared to unaffected lakes. To investigate the potential photochemical implications, an in situ microcosm experiment was performed involving the incubation of water from an undisturbed lake with thawed slump sediment. Sediment treatments were 10, 25, and 50% of the total container volume, and containers were incubated in the lake for 52 days during the summer of 2007. Water colour decreased successively with sediment volume, and was highest in the control. Specific conductivity was more than 8 times higher in the 50% sediment treatment water than in the control. Sedimentation of organic matter may explain the low colour in the treatment water. The transportation of thawing permafrost sediment into tundra lakes may rapidly increase water clarity and alter carbon supply.

Keywords: climate change; coloured dissolved organic matter; Mackenzie Delta region; microcosm experiment; retrogressive thaw slumping; tundra lakes.

Introduction

In the uplands east of the Mackenzie Delta, NWT, Canada, thousands of small lakes and ponds are surrounded by terrain underlain by ice-rich permafrost (Mackay 1992, Kokelj et al. 2005). In this region, thawing of the near-surface permafrost commonly leads to the formation of large retrogressive slumps on slopes adjacent to lake shores (Lantz & Kokelj 2008). Solute concentrations in permafrost may be enriched with respect to the overlying active layer (Kokelj & Burn 2003, 2005). The geochemical contrast between the active layer and permafrost is attributed to progressive leaching of soluble materials from seasonally thawed soils and preservation of solutes in underlying frozen sediments, and due to thermally induced migration of water and soluble materials from the base of the active layer into the top of permafrost (Kokelj & Burn 2005). Thaw slumping may release these solutes in the permafrost, with implications for sediment and runoff chemistry (Kokelj & Lewkowicz 1999).

A survey of 298 lakes on five 49 km^2 study plots between Inuvik and the Beaufort Sea indicated that 6 to 17% of the lakes were affected by shoreline slumping (Kokelj et al. 2005). Thaw slumps can be relatively large compared to the size of adjacent lakes. In a sample of 11 first-order upland lakes affected by slumping in the Delta region, the median disturbance area: lake area ratio was 0.48 (Kokelj et al. 2005). The median disturbance size was 1.9 ha, and the median lake size was 4.0 ha. In many cases, disturbance area was almost equivalent to lake area.

Lake chemistry interactions

The water chemistry of small tundra lakes is strongly influenced by lake catchment characteristics, including surficial geology, sediment development, peatland extent, and terrestrial vegetation (Pienitz et al. 1997, Duff et al. 1999, Frey & Smith 2005, Gregory-Eaves et al. 2000, Rühland et al. 2003). In the Mackenzie Delta region, a survey of 22 lakes indicated that those adjacent to retrogressive thaw slumps had elevated ionic concentrations, lower concentrations of dissolved organic carbon (DOC), and were less coloured compared to lake waters in undisturbed areas (Kokelj et al. 2005). Organic carbon supply and related changes in visible and UV light penetration influence the productivity of pelagic algal and bacterial communities (Jones 1992, Teichreb 1999).

Base cations can increase the adsorption and flocculation of coloured dissolved organic matter (CDOM), or humic matter, from the water column (reviewed in Jones 1992, Thomas 1997). Mineral soils, especially clays, that may enter lakes can adsorb humic matter leading to sedimentation (reviewed in Jones 1992, Thomas 1997). This raises the possibility

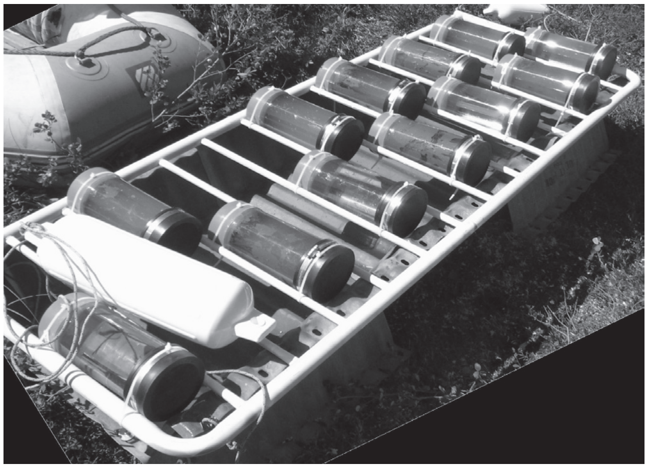

Figure 1. Experimental incubation containers positioned on rack prior to deployment in the lake.

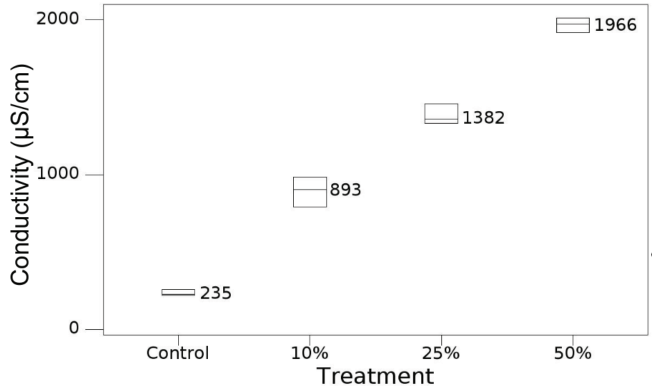

Figure 2. Mean specific conductivity of the incubated lake water in each of the permafrost sediment treatment and control containers (with 95% confidence intervals, mean value provided).

that sediment and soluble ions delivered from terrestrial to aquatic systems by the process of thaw slumping may affect CDOM concentrations and optical properties of water in small tundra lakes.

Here we examine the effects of ion and sediment additions on the colour of lake water by undertaking an incubation experiment. The goal was to test whether exposure of humic lake water to thawed permafrost sediment and associated runoff could produce similar water chemistry conditions characteristic of a "disturbed" lake affected by lake shore thaw slumping.

Methods

Incubation experiment

Recently-thawed sediments and pooled surface runoff were collected on 24 June 2007 from a thaw slump scar located on the shore of a small lake 60 km north of Inuvik. The sediments, comprised of silty clay, were homogenized by mixing with surface water collected from the slump (specific conductivity 2345 µS/cm) to form a saturated slurry. The gravimetric water content of the runoff-sediment mixture was 33% by weight.

The sediment mixture was added to containers constructed from sections of clear acrylic pipe (approximately 10 cm diameter) with a total volume of 2 L. The pipe sections were sealed on one end with a silicone-sealed cap and on the other with a removable rubber "test cap". A spectral scan of the acrylic pipe material indicated that it blocked most UV-B (absorbance at 320 nm = 1.027) and much of the UV-A (absorbance at 380 nm = 0.096) wavelength range. This desirable property of the pipe materials minimized the breakdown of coloured humic substances in lake water by incoming UV radiation (photolysis). The proportion of saturated sediment in each of three replicated container sets was 50, 25 and 10% of the container volume (1.0, 0.5, and 0.2 L respectively).

The incubation containers were installed in a shallow (estimated Z_{max}: 2 m), humic lake within 15 minutes road access of Inuvik, which is unaffected by thaw slumping. Before installation, surface lake water from the same incubation lake site was collected and added to each of these containers, along with a set of replicate control containers, to a total volume of 2 L. The sediment slurry in each container was purposefully not mixed homogeneously with the lake water, since slump materials often enter the lakes as intact blocks. The containers were sealed immediately after the lake water addition, and were attached to a rack apparatus which kept the containers horizontally aligned, approximately 0.75 m below the water surface and elevated approximately 0.75 m above the lake benthos (Fig 1). The containers were installed on 6 July 2007 and were retrieved on 28 August 2007 for a total incubation period of 52 days.

An additional container was filled with distilled and deionized water in order to test the water-tightness of the container seals. Initial specific conductivity of the distilled water was 2 µS/cm; —after incubation it was 20 µS/cm. Specific conductivity in the lake was 219 µS/cm just prior to deployment of the incubation containers.

Analysis

Following retrieval, the containers were removed from the support rack, immediately transported and refrigerated at the Aurora Research Institute lab. Within 3 hours of arrival at the lab, the incubated water was removed from the containers without disturbing the sediment settled at the bottom of each container. Specific conductivity, pH, dissolved oxygen (DO) and oxidation-reduction potential (ORP) of the water was measured using a YSI 556 multiprobe meter (Yellow Springs Instruments, Idaho, USA).

In preparation for measurement of water colour as spectral absorbance, a 125 ml volume of the incubated water was filtered through a 0.45 µm Supor membrane syringe filter (Pall Corporation, NY, USA). Samples were placed in glass containers and kept in a dark refrigerated area until absorbance could be measured. Absorbance was measured across the range 190–900 nm using an Ultrospec 3100 pro spectrophotometer equipped with a 1 cm cuvette (Biochrom, Cambridge, UK). Absorbance measurements at 320 nm (UV-B), 380 nm (UV-A) and 440 nm (PAR, photosynthetically active radiation) were corrected for

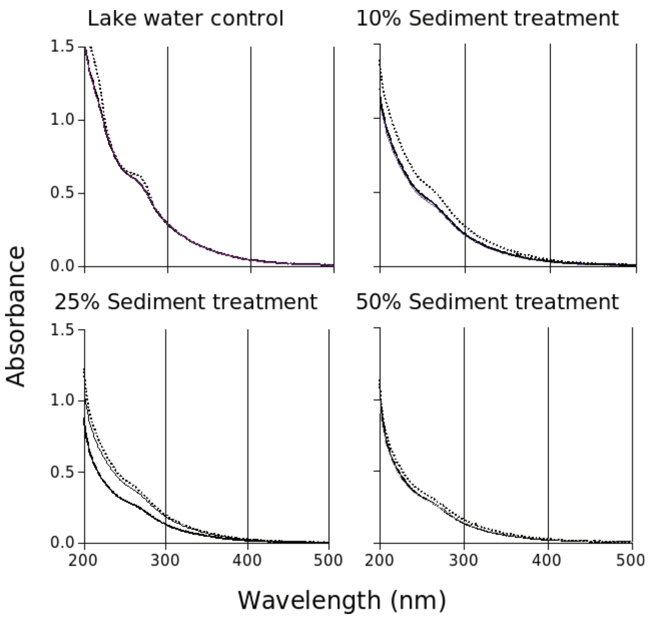

Figure 3. Replicate spectral scans of incubated lake water from the control and each sediment treatment container. For each treatment graph, $n = 3$.

turbidity-related light scattering by subtracting absorbance values at 740 nm. These corrected values were used in statistical analyses.

A one-way analysis of variance (ANOVA) was used to assess the response of the lake water specific conductivity to the sediment treatments. The effect of the sediment treatments on the spectral absorbance of the incubated lake water was tested using a repeated measures ANOVA, including absorbance values at wavelengths in the UV-B (320 nm), UV-A (380 nm) and photosynthetically active radiation (PAR, 440 nm) ranges. Post hoc Tukey tests were used to distinguish between significantly different treatment level. Finally, conductivity and all absorbance measurements were tested for significant Pearson correlations across treatments, with Bonferroni adjusted significance levels. All analyses were completed using SPSS 13.0 (SPSS Inc., Illinois, USA).

Results

Specific conductivity

The measured specific conductivity of the incubated lake water in each of the treatment and control containers are shown in Figure 2. The water at each sediment treatment level and in the control had significantly different mean specific conductivity, with relatively little variation within treatments (one-way ANOVA, $F = 396.23$, $df = 3$, $p < 0.000$). The control and treatment mean specific conductivities were all significantly different from each other (Tukey HSD test).

Water colour

The spectral scan absorbance values for each treatment replicate are shown in Figure 3. Absorbance is generally higher in the control than in all sediment treatments. The greatest difference in the absorbance values between the control and all sediment treatments is apparent in the UV-B and UV-A range (280–320 nm and 320–400 nm, respectively). Differences between the control and treatments in the photosynthetically active radiation range (PAR, 400–700 nm) were lower than observed for the UV range. Relative change in absorbance between the control and treatments for representative wavelengths are provided in Table 1. The change in absorbance across wavelengths in the 25% sediment treatment is somewhat obscured by one low-absorbance replicate (Fig. 3).

There was a highly significant effect of sediment treatment on corrected absorbance at all three representative wavelengths (UV-B, UV-A, PAR) (repeated measures ANOVA, $F = 15.156$, $df = 3$, $p = 0.001$). Error variance between treatments for the 320 nm measurements was not homogeneous and could not be remedied via transformation however, and this must be considered when interpreting the ANOVA results. Post hoc tests found no significant difference ($p > 0.05$) between the control, the 10% and 25% sediment treatment, but did indicate a significant difference between the control and 50% treatment (Tukey's HSD test).

Negative correlations (Pearson's r) between incubated lake water specific conductivity and absorbance values in the UV and PAR range were statistically significant with the exception of the correlation with PAR (corrected $p > 0.05$).

Table 1. Relative decrease in mean spectral absorbance at representative wavelengths of lake water after incubation with thaw slump sediment. Change is relative to the untreated control mean. *PAR* is photosynthetically active radiation. *aX* is absorbance at wavelength X.

Sediment treatment	UV-B (a320)	UV-A (a380)	PAR (a440)
50%	49%	43%	27%
25%	43%	44%	44%
10%	20%	22%	13%

The highest correlation occurred with UV-B absorbance ($r = -0.91$), followed by UV-A ($r = -0.85$) and PAR ($r = -0.64$). Absorbance was strongly positively correlated between the three wavelengths ($r > 0.85$).

Discussion

In the Mackenzie Delta uplands, lakes affected by shoreline thaw slumping contain elevated concentrations of major ions in contrast with lower concentrations in undisturbed lakes (Kokelj et al. 2005). The soluble materials that enrich the lakes are derived from the thawing ion-rich permafrost (Kokelj & Burn 2005). The effect of sediment slurry treatments had a similar effect on lake water specific conductivity in this experiment, as soluble ions were released into solution from the solute-rich slump sediment mixture.

In the natural setting, lakes affected by slumping have clear water in comparison with more coloured water in undisturbed lakes. The experimental response of lake water colour to the sediment treatments suggests that sediment slurry treatments caused the removal of coloured organic materials from the lake water. This is indicated by the lower spectral absorbance in sediment-incubated lake water compared to the lake water control. High-molecular weight CDOM absorbs UV radiation very effectively (Scully & Lean 1994, Laurion et al. 1997), and the relatively high change in absorbance in the 50% and 10% sediment treatments at the UV-B and UV-A wavelengths compared to the PAR wavelength suggests that it is this type of DOM which has been removed from solution in the incubated water.

The within-treatment variability between replicates was relatively large in the 25% and the 10% sediment treatments. This contributed to the heteroscedasticity in the 320 nm absorbance range and the nonsignificant Tukey test between these treatments. Presence of a slight biofilm on a few of the containers walls, variation in sediment-water interface surface area, and variations in possible photolysis rates may contribute to observed within-treatment differences.

Allochtonous (origin outside the lake, terrestrial) DOM content in lake water is linked to catchment conditions, especially the supply (related to catchment vegetation) and the delivery (related to catchment morphology) of carbon (Rasmussen et al. 1989, Pienitz et al. 1997). Subarctic lakes with catchments underlain by permafrost are typically high in DOM because waters are derived from surface runoff through a thin, often organic-rich active layer (Pienitz et al. 1997). Allochtonous DOM usually has a higher molecular weight and is more highly coloured than autochtonous (origin inside the lake) DOM (Lean 1998, Perdue 1998). Catchment-derived carbon is also generally more reactive with metals and base cations due to its more aromatic structure (Perdue 1998). Adsorption of this humic material to fine-grained clay particles readily occurs. Each of these processes can lead to dissolution and sedimentation of the allochtonous DOM. Field observations in conjunction with our experimental results indicate that degradation of permafrost within the catchment can influence the biological and geochemical availability of DOM within lakes (Kokelj et al. 2005).

Organic matter delivered from the lake catchment may be an important source of energy within the lake. For example, bacteria are known to utilize allochtonous sources of carbon as an energy supply (Jones 1992). DOM may also contain phosphorous, often a limiting nutrient for algal and bacterial production (Jones et al. 1988, Klug 2005). Indeed, uptake of DOM by algae and/or bacteria in the experimental containers used here may have contributed to the observed decrease in absorbance, especially if the slump sediment enhanced biological production by providing limiting nutrients (Hobbie et al. 1999). However, the habitat conditions within the incubation containers were likely not representative of *in situ* conditions, so that conclusions concerning biological activity cannot be made here. In addition to the role of DOM as an energy and nutrient source, allochtonous humic material is generally coloured, and capable of attenuating radiation within the water column. This can limit phytoplankton photosynthesis (Jones 1992, Klug 2002), but can also limit the penetration of damaging UV radiation through the water column (Laurion et al. 1997, Lean 1998).

Humic materials in lakes, therefore, can be involved in many interactions between planktonic biota through their effects on nutrient and light quality and supply. The fact that several of these interactions may be competitive or mutually beneficial, makes the ecological outcome of changes in tundra lake conductivity and DOM concentration difficult to predict. However, such shifts have been linked to the overall heterotrophic or autotrophic nature of lakes in northern/cold regions (Jansson et al. 2000). Certainly a reduction in humic matter content due to addition of ion-rich runoff and sediments derived from slumping permafrost appears to be capable of changing the physical and chemical conditions in the pelagic habitat of tundra lakes.

Identification of Permafrost Landscape Changes Caused by Climate Variability in Central Siberia

Marina Tishkova
Institute of Environmental Geoscience, Russian Academy of Sciences
Sergey Gorshkov
Moscow State University named after M.V. Lomonosov

Abstract

The functioning of natural and natural/man-made ecosystems is impacted by changes in the duration of seasons more than by rising temperatures. Modeling changes in permafrost conditions caused by climate variability requires identifying the types of permafrost landscapes in terms of their sensitivity to climate changes, as well, as studying transformation rules for specific natural complexes. A large amount of data on changes occurring in the lower reaches of the Stony Tunguska River was gathered during field work of 1999–2007. For further analysis, active processes were classified as short-period and long-period, and as local and regional. Landscapes were classified by sensitivity level. Degradation of permafrost landscapes will occur in the order of sensitivity classes. Study of the most sensitive landscapes will be the most interesting for further research and yield the greatest value for monitoring.

Keywords: permafrost; Central Siberia; climate change; permafrost degradation; sensitivity.

Introduction

Woodwell and Mackenzie (1995) suggest that the Earth's climate is not just changing from one equilibrium to another, but probably is moving towards an unbalanced state, which we may already observe each year in the form of catastrophic climate events (Tchebakova 2006). The area of study (Fig. 1) is the low western edge of the Central Siberian Plateau in the lower reaches of the Podkamennaya Tunguska River. It is located in the periphery of discontinuous permafrost in the middle taiga subzone and thus is in an area vulnerable to climate change. The area presents a prime example of landscape ecotone diversity. Changes in many climate and landscape characteristics are evident, and we have been monitoring them in the course of our multi-year observations. In this paper, we discuss instability while recognizing that it is difficult to predict the patterns and rates of change. In order to predict changes in permafrost conditions in the current climate, it is necessary to identify types of permafrost landscapes in terms of sensitivity to climate change. It also is important to study the rules or mechanisms of transformation, patterns of landscape and climate change, and the individual and collective processes for specific natural complexes.

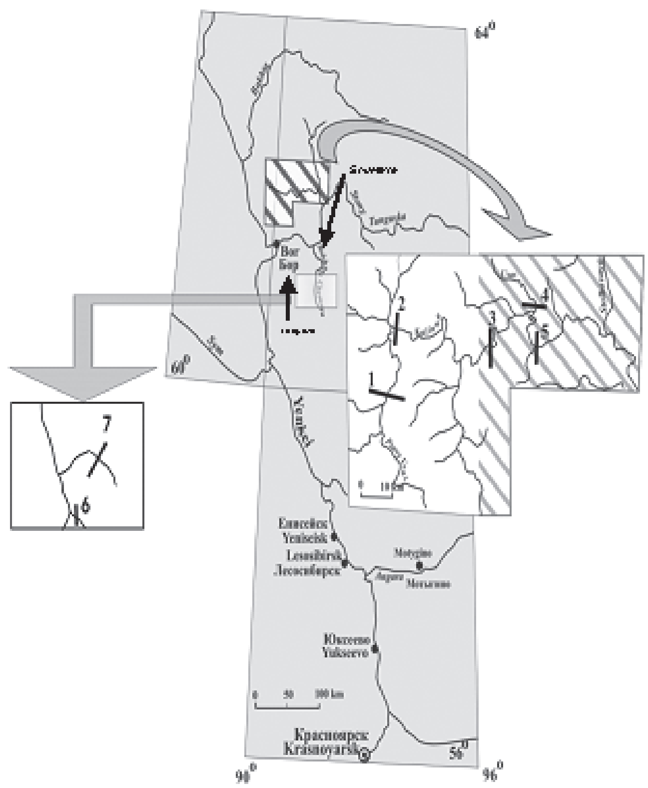

Figure 1. Key areas and transect locations on rivers: (1) Pravy Usas; (2–4) Kulinna; (5) Usas; (6) Bol'shaya Kolonka; (7) Malaya Kolonka; and (8) Bol'shaya Chernaya.

Methods

The methods that we used can be divided into two main categories: evaluation of meteorological data and collection of field data on terrain characteristics.

Meteorological data were evaluated using a range of applied methods. We used air temperature, precipitation, and snow cover data from the weather stations Bor, Vorogovo, Baikit, Yartsevo, and Bakhta. Data are available mainly from the 1980s on, and in some cases from the late 1960s onward. All these locations have high-quality meteorological stations operated by trained personnel. Annual, monthly, and daily data were analyzed using standard statistics tools, such as differential-integral curves, probability/frequency curves, correlation coefficients, etc.

To evaluate the changes in temperature and precipitation over the last 60 years, their time series were approximated by a linear function of $y = ax + b$ type, where y was the value of temperature (precipitation); *a* and *b* were empirical coefficients calculated using the least square method; and *x* was the year. The statistical confidence level was calculated by student criterion. A trend was considered to be statistically significant if the significance level (*P*) was equal to or greater than 0.95.

Landscape responses to the changing climate were evaluated through three main stages. First, we performed a preliminary analysis of satellite images for key areas overlaid with geological, forestry, geomorphology, topography, and fire distribution maps. Second, based on the above, we made our prognosis about the sensitivity of particular landscapes. Third, we confirmed our assumptions by actual field observations. This work was performed using ArcGIS software and GPS instrumentation in the field.

An important element of this combinational method was sampling along landscape transects. The sampling included terrain-unit descriptions, identification of reference soil catenas, detailed descriptions of soil, and measurement of active layer thickness and depth to the top of permafrost using a ground auger. Permafrost and non-permafrost landscapes were differentiated through direct observation using various indicators. Special attention was given to studying rock streams (kurums) and blockfields due to their high information value. In active rock streams we counted the abundance of blocks in an unstable position; in inactive blockfields, we studied forest/vegetation covers and the characteristics of tree stands (percentage of trees in non-vertical positions, the character of tree stand abnormalities, etc). Ground-auger measurements sometimes were of reduced quality, because not all of them were made in survey pits (used as control points for building transects) and many were made from the surface, and thus, liable to some error. Most of our survey pits were dug to the top of permafrost. During the latest field season, we also used temperature loggers but they provided clearly wrong data due to installation mistakes, so we did not use any of those data in our analysis.

Results

Climatic changes

As shown in the Synthesis Report on Climate Change 2001 (Watson et al. 2003), 1980 was an inflection point for positive temperature anomalies in relation to the average temperatures for the period of 1961–1990. Analysis of winter and summer temperatures and precipitation in the northern part of the Central Siberian Plateau shows that during 1980–2000, winters became 1°C warmer in comparison to the period prior to 1980. South of latitude 56°N, especially in the mountains, warming was even more significant, up 2–4°C. Summer warming proved to be as significant as the winter warming (1°C) with a high confidence level and the same scale on the south and on the north (Tchebakova 2006).

The linear trend of air temperatures in the area studied is positive for the past 60 years (data from the Bor village, latitude 61°35′N) (Fig. 2). A considerable increase in annual temperatures started in 1980, and in 1995 the anomaly exceeded a record 3°C. The most significant changes

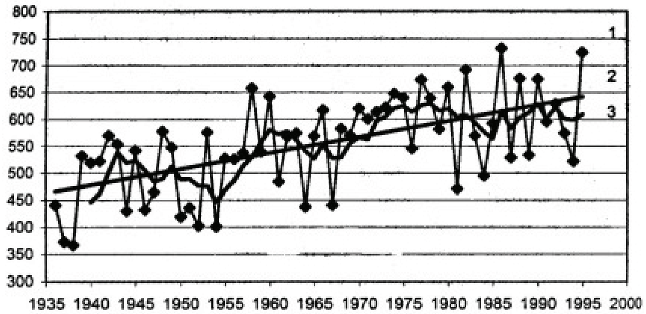

Figure 2. Precipitation at Bor meteorological station: 1 – annual precipitation, 2 – linear trend, 3 – 5-year moving average.

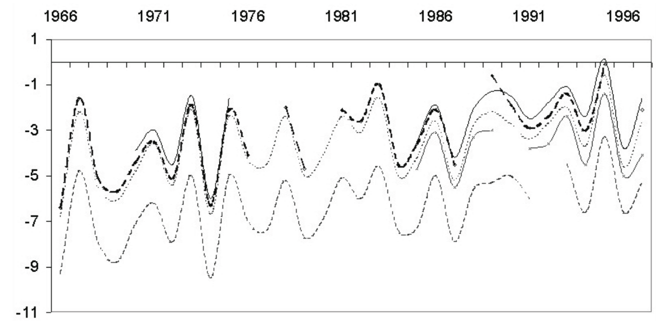

Figure 3. Annual average air temperatures (°C) at Vorogovo, Bor, Bakhta, Baikit, Yartsevo stations.

have occurred during the past 15 years. Analysis of winter (December to March) temperature changes over the past 60 years shows that December temperatures have risen by 3.5°C, and March temperatures have risen by 2.6°C, indicating that winters have become shorter and warmer. Analysis of summer temperature changes also reveals an increase in July and August temperatures. The trend is statistically significant (*P*=0.997 and 0.995 for July and August, respectively). On average, for the time period under consideration, July temperatures rose by 1.9°C, and August temperatures, by 1.1°C. No tendency was observable for June, and May temperatures became somewhat lower. Therefore, winter warming has been more significant than summer warming. A similar situation occurred in the latter half of the 19th century, when contemporaries observed winters becoming essentially less severe, and thawing happened more often (Fedorov 1991).

Annual precipitation for the last 60 years also showed a positive, statistically significant (*P*=0.999) trend, which was even more pronounced than the temperature trend (Fig. 3). The average increase in precipitation was 141 mm. It can be inferred, that this increase was caused by a rise of cyclone activity, especially in the last 20 years of the 20th century. The same process leads to air temperature rises. It should be noted that similar changes of general atmospheric circulation have been traced for the middle latitudes in the European part of Russia (Klimenko 1994). Thus, these changes can be considered global.

Snow accounts for only about 40 per cent of the total annual precipitation (which is 580 mm). There are no apparent trends for changes in snow cover depths.

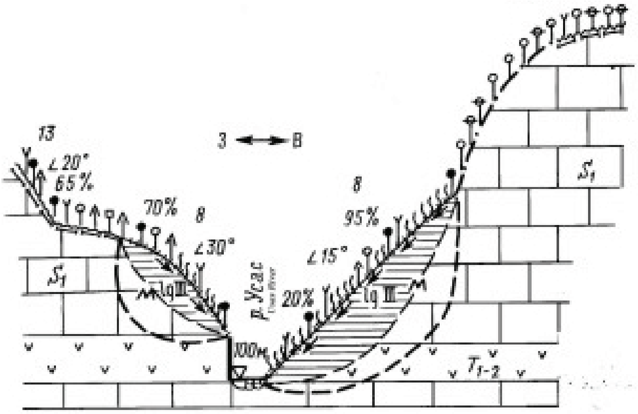

Figure 4. Transect on the Usas River near its mouth.

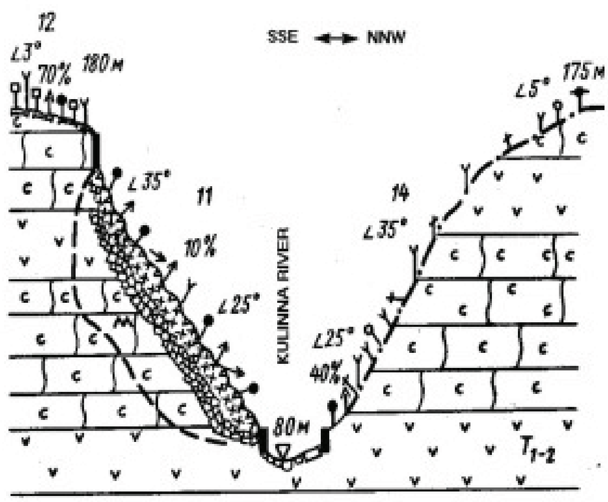

Figure 5. Transect on the Kulinna River near its third line of rapids.

Landscape responses

A large amount of data on changes in Siberian ecosystems was gathered during our field trips between 1999 and 2007. Two representative transects across the valley of the Usas and Kulinna rivers (tributaries of the Bol'shaya Chernaya River), which were sampled during 1999–2003, are shown in Figures 4 and 5.

The Bol'shaya Chernaya River transect crossed the valley with a strongly pronounced hummock swamp under stunted fir-birch taiga with sporadic larch. Hummocks were up to 50 cm in height and covered with true mosses. The depth to the top of permafrost reached 1.05 m under hummocks, and 80 cm under pits, measured from the water surface. This is abnormally deep for such conditions. Evidence of solifluction was abundant on this transect, including at a site by a small creek where soil was probed to a depth of 1.5 m without reaching the top of permafrost.

Observations in rock streams (kurums) on the left bank of the Bol'shaya Lebyazhy'a River about 50 m down from the mouth of the Malaya Lebyazh'a River showed that large rock streams were extremely warm and low in moisture content. At the same time, bi-valley frozen gentle slope deposits (along a zone of a river accumulation that are flooded during the spring floods, and where slope deposits are overlaid with alluvial silts and sands) and hanging bogs kept their permafrost even though it was found at different depths: from the normal depth (0.5–0.7 m) to 1.5 m or deeper. On the whole, data from this and other transects indicate that the top of permafrost has been moving down quite rapidly almost everywhere. Only small areas of bi-valley slope deposits, and hanging peat bogs do not show any signs of permafrost degradation.

During the last observation period, especially recently (in 2006–2007), degradation of cryogenic processes has been clearly tracked in rock streams (kurums). They have been drying out and losing ground ice. In the valley of the Kul'emka River, rock streams have been moving and joining with bottom boulder perluvium, which has a paragenetic connection with rock streams. A similar situation has been observed on the Shumikha River, where a semi-closed rock stream in a birch forest has been joining with an open rock stream on the left cold slope of the river valley.

Systematization of long-term field data shows that with further climate changes, the processes that are already active will only intensify. For further analysis of these processes, we classified them as short-period (fast processes) and long-period (slow), and as local-scale and regional-scale (Table 1).

All these processes manifest an initial response of landscape to climate changes. These primary responses, in turn, will cause secondary changes. For example, the number and the area of forest fires will noticeably increase, vegetation will reorganize, forest/steppe border will shift, the phenological environment will change (which, according to Tchebakova, will affect seed-bearing cycles, cause explosive increases in the numbers of some insects, etc). If the speed of climate change exceeds the adaptive capacity of ecosystems, it will cause a restructuring of all forest hierarchic levels from zonal forests and forest ecosystems to forest forming tree species and populations (Tchebakova et al. 1995, Tchebakova & Parfenova 2003, Tchebakova et al. 2005).

Next Steps

The next steps in our research will include the following:

1) Analyze river run-off data from weather stations and river stations in Bratsk, Boguchany, Motygino, Yeniseisk, Yartsevo, Severoyeniseisk, Vorogovo, Bor, Baikit, Vanavara, Bakhta, Verkhneimbatskoye, Turukhansk, and Tura. These data will be compared with extreme event data, which will make it possible to identify a general rhythmicity of the aggravation and weakening of adverse and catastrophic natural events that reduce the ecological potential of Central Siberia.
2) Evaluate the lowering of the top of the permafrost table and of the process's dependence on particular characteristics of specific terrain units.
3) Select geologic cross-sections with dated syngenetic permafrost structures for detailed documentation and testing. It is necessary to determine the age of permafrost

Table 1. Primary landscape responses to climate warming.

	Short-period	Long-period
Local-Scale	Rock streams (kurums): increase in number of unstable blocks, and increase in number and area of reindeer moss patches left by irrecoverable loss of ice; Rock streams: significant warming of deposit after its water content decreases; Abnormally frequent falls of trees that have creeping root system. Usually it occurs in over-wetted clay soils of visco-plastic consistence and thicknesses of 1.5 m or more; Replacement of solifluction material movements in the lower part of accumulative glacial deposits with local landslide-land creep.	Rock streams : the top of permafrost is going deeper; Rock streams advance towards valley floor as a result of landslide shifts; Solifluction intensifies, especially in areas where slope deposits are in a frozen state and where the thickness of the active layer increases; Drainage improvement on top surfaces and on adjacent gentle slopes (water has disappeared in many pit-ruptures and is often absent in crack-ruptures); General landscape changes with a prevalence of depressive forms which leads to formation of thermokarst lakes; Depletion of underground watercourses under rock streams; Appearance of young fir forests on completely or partially burned out taiga that previously consisted of other tree species.
Regional-Scale	Drying of rock streams. To some degree, drying is also seen in swamped cryogenic-taiga terrain units (e.g., stows, or homogeneous geological and hydrogeological condition).	Thermokarst processes intensify; Wide development of long-frozen rocks which can be evidence of recent permafrost degradation; Solifluction intensifies; The active layer goes down deeper.

(Holocene or Pleistocene) in Central Siberia. This will drive forecasting events resulting from permafrost thawing.

4) Revisit sampling sites.
5) Create a map of permafrost landscapes ranked by sensitivity to climate changes, showing the increased depths to the top of permafrost. This map should also show the estimated times when permafrost will thaw down dozens of meters and cease to impact surface landscapes.
6) Integrate with SEARCH (monitoring of landscape and biological changes as a result of climate change) and TSP (temperature data gathering and evaluation) programs.

Conclusions

Based on the data gathered, landscapes of the region studied can be classified by sensitivity level, where sensitivity is a function of the rate at which landscapes respond to climate change. A slower response indicates a lower sensitivity of the landscape to change.

The *most sensitive* landscapes are terrain units (natural complexes) of "warm" gentle slopes (2–3°) and glacial-related deposits, and low (200–250 m) apical plains, including rock streams. These landscapes are mainly located north of the Podkamennaya Tunguska River. It is an area of Pleistocene moraine and glacio-lacustrine deposits (fine sands, aleurites, loams, and clays). Solifluction in this area is well pronounced. At the end of the summer (1995–1997), the thickness of the active layer did not exceed 0.9–1.0 m; however, during the same period of 2001, the active layer became more than 1.2–1.3 m thick. Thus, there has been a noticeable growth in the depth of the active layer over a few years.

Less sensitive are landscapes of "cold" slopes and slope-related deposits, glacial floodplains, and open rock streams of warm slopes. Mountain and headwater floodplains consisting of slope wash-off material and floodplain alluvial deposits are often swampy, sometimes hummocky, and support dwarf-birch and meadow-bog vegetation growing on alluvial-colluvial bog and meadow-bog cryogenic soils. They are modeled by solifluction and fluvial processes (valley solifluction, alluvial fragment accumulation, bank fragment shifts, and subsiding channel erosion).

The *least sensitive* are multi-factorial permafrost terrain units of cold slopes, including "hanging" peat bogs and forested floodplains of major rivers. "Hanging" bogs are located on moderately steep to steep (25–35°) slopes on hummocky traps and skarns, covered by rock streams and permafrost bogs. Vegetation there consists of scattered trees, alternating with thin cedar pine-spruce-larch forest ("drunken forest"). Our measurements of permafrost depths in "hanging" bogs and floodplains did not show any changes of active layer thickness during the past few years.

We predict that the degradation of permafrost landscapes will occur in the order of the sensitivity classes. The most sensitive landscapes will be the most interesting to study in the course of further research, as they are changing the most rapidly, and their changes will enable us to characterize climate dynamics. The most sensitive landscapes will also yield the highest monitoring value.

Our research showed that it is not annual temperature increases as such, but rather a modification in season durations (changes in intra-annual climate patterns), as well as sharp intra-season fluctuations of temperature and precipitation regimes, which have the greatest impact on the functioning of natural and natural/human-made ecosystems. A rapid downward movement of the permafrost table (5–15 cm/yr) has been occurring since the late 1990s. Permafrost has been moving deeper in most permafrost landscapes. With the depth of the active layer increasing, both solifluction and thermokarst formation have been activated. “Warm” permafrost degrades and rock streams undergo transformation.

Dry and hot weather during the spring season, and followed by severe frosts and different weather fluctuations, which that are not typical for the region with its continental climate, can cause chronic crop setbacks. These in turn influence animal populations. Progressive permafrost degradation can also cause additional emissions of greenhouse gases into the atmosphere and impair biodiversity.

Some of the least sensitive terrain units have not shown any response to climate change yet. However, the processes mentioned, especially solifluction, appear to be a large-scale response to global climate change. It can be considered as a trigger for other natural processes.

If climate change continues at the current rate, it is possible that low-productivity permafrost landscapes will be replaced with highly productive non-permafrost landscapes. With regard to the area of permafrost transition in the zone we studied, this will not cause an ecological disaster, although impacts of such landscape reformation throughout the permafrost zone has not been studied yet.

The work performed is necessary for a comprehensive evaluation of the current and future situation and for the scientifically proven management of natural and natural/man-made systems, consistent with the concept of sustainable development. For the full-fledged and full-scale implementation of what we have intended to do, it is necessary to integrate our research with similar international programs, such as SEARCH and TSP.

Aknowledgments

The research has been performed as part of RFBR Project No. 07-05-00815.

Permafrost in Low Mountains of the Western Chukotka Peninsula

Sergey Titkov

Vladimir Chernyadyev
Geological Research Institute for Construction, Moscow, Russia
Maria Tsvetkova
Geological Research Institute for Construction, Moscow, Russia

Abstract

The study region is located in the northwest part of the Chukotka Peninsula in the zone of continuous permafrost. Permafrost thickness is from 120–250 m in river valleys and up to 300–350 m on slopes and watersheds. Mean annual ground temperatures are between -4°C and -6.5°C. The ice content of Late Pleistocene-Holocene syncryogenic alluvial, deluvial, eluvial, or solifluction deposits covering the river valleys and slopes is 50%–60%. These types of deposits are characterized by massive fossil ice layers with a typical thickness of 0.5–3.0 m and total area of a separate ice massif up to 30,000 m^2. Thermokarst hollows up to 30 m in diameter are located on sites where the ice surface is less than 1.5 m beneath the ground surface, thus indicating the disposition of the ice body. Frost cracking and frost sorting results in the formation of kurums and patterned ground, such as stone rings and stone stripes that move slowly down slope.

Keywords: continuous mountain permafrost; frozen dam; massive ice layers; patterned grounds; thermal regime of permafrost; thermokarst.

Introduction

A problem of safety in the exploitation of water-engineering systems is especially important in the permafrost zone. The reliability of constructions strongly depends on the consideration of engineering-geological conditions (Biyanov 1983, *Water-Engineering Systems* 2005). Engineering-geocryological investigations in 2007 were carried out in the vicinity of the gold deposit "Mayskoe" at the site of the projected dam for a future water reservoir in order to obtain sufficient data for projecting and construction of the ground dam, pump station, and water pipeline in the zone of continuous permafrost. The study region is widely exploited as a stanniferous and gold-bearing province. Numerous geological expeditions carried out geological exploration in different points of the region (*Engineering Geology of the USSR* 1977, *Geological map of the USSR* 1979, *Chukotka…* 1995.*)*, but it is very poorly investigated by geocryologists. Permafrost researches under similar conditions of low mountains were held in Northern Yakutia (Shur 1988, Kanevskiy 2003).

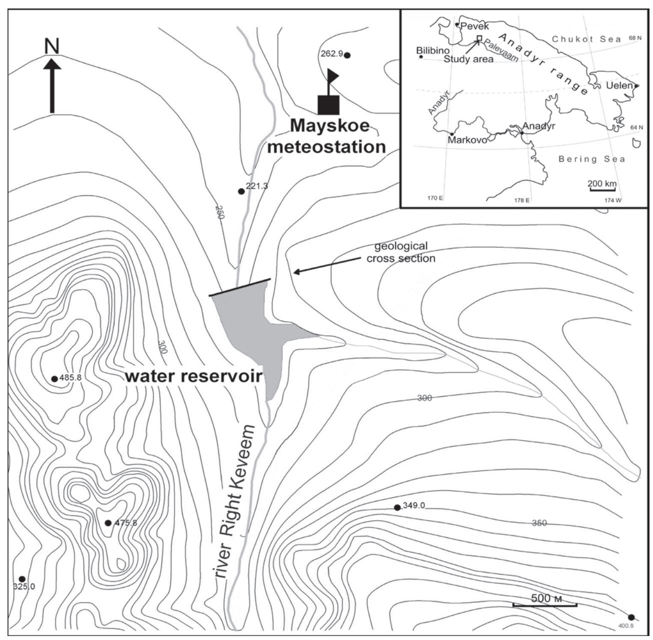

Figure 1. Sketch map of the study area.

Study Area and Methods

The gold ore deposit is located within the Chukotka uplands in the northwest part of the Chukotka Peninsula (68°50′N, 173°40′E) in the northern part of the Anadyr Range, 187 km southeast of the regional center Pevek (Fig. 1).

The study area is situated on a local divide between the rivers Keveem, Pegtymel, and Palevaam, and is characterized by low-mountain relief with gentle slopes and flat watersheds of absolute elevations up to 600 m. Mountain tops rise about 150–250 m above river valley bottoms.

The river valley network is young and has a poorly developed structure. Traces of Late Pleistocene glacial erosion and accumulation are expressed in the presence of exaration and fluvioglacial landforms. The study area is located near the source of the river Right Keveem. The river and its tributaries have fast flow; channels abound with bars and are frequently meandering. The mode of water-flow is extremely changeable in time and depends, basically, on the precipitation regime. The nearest large waterway is the river Palevaam 20 km south of the deposit. During the winter period, it freezes completely as well as other streams and keeps underground runoff along talik zones.

During the engineering-geocryological research, 57 bore holes 20 and 30 m deep along 6 profiles covering the dam and contour of the future water reservoir were drilled. Geophysical investigations revealed linear zones of fractured bedrock located in the vicinity of the projected dam. Laboratory tests of frozen core samples were held to determine physical, mechanical, and thermal physical properties of loose material and solid rocks. The forecast evaluation of the dam and bed of the reservoir has been carried out. The engineering-geocryological map at a scale of 1:2000 has been compiled based on the results of investigations.

Results

Climate

The climate of the area is determined by its location in the northeast of Asia, in the zone of influence of two oceans with the complex atmospheric circulation differing in cold and warm season. The climate is Arctic, transitive from moderately continental to continental. Mean annual air temperature according to the data of the meteorological station "Mayskoe" (~1,5 km north of the site) for the period of 1982–1991 is -13.7°C. The air temperature absolute maximum is 29.5°C in July, and absolute minimum is -45°C in February. Average temperature of July is 9.3°C, that of January -27.8°C. The annual amplitude of average monthly air temperatures is 37.1°C. Winter is long and cold, with strong snow storms, summer is short and cool, but warmer by 7°C than at the coast of the East-Siberian Sea. The positive average monthly air temperature lasts no more than 3.5 months. The duration of the warm period, both in the air and on the ground surface, is less than 30 days in more than 50% of the years.

The annual precipitation is 262 mm and about 60% of this amount is snow. The average thickness of the snow cover depends on surface relief and does not exceed 0.7 m on flat sites. In the rear parts of cryoplanation terraces, in river valley bottoms, and on leeward slopes the snow cover thickness is 2–3 m and more. The snow cover is established in the middle of September and disappears in the end of May. Snow cover density reaches 0.35 g/cm^3. The wind regime is rigid; the average annual wind speed is 3.5 m/s, with maxima in squalls reaching 40 m/s; the annual number of days with a wind speed higher than 15 m/s is 46.

Geological structure

Loose deposits of interstream areas are comprised of eluvial-deluvial and deluvial-solifluction formations, overlapping slopes, and tops of watersheds with a continuous cover. Loose deposit thickness varies from tens of centimeters on narrow watersheds to up to 15–20 m in places where slopes merge into river valleys. The petrographic structure of these sediments is similar to the bedrock. Gradual transitions of one genetic type to another are marked. All types of deposits were formed during the Holocene period (Q_{IV}), except for the bottom layers of eluvial and alluvial sediments, which are of Late Pleistocene age (Q_{III}). According to the analysis of spores and pollen, the most ancient horizons of deposits were generated in the Late Pleistocene interglacial.

Holocene fluvial sediments (aQ_{IV}) are comprised of alluvium of river beds, flood plains, and the first terraces in rivers and brook valleys of 2–3 orders and consist mainly of blocks of a different degree of roundness (up to boulders), gravel and pebble of different size, sand and a sandy-loam material with lenses of peat and ice. The thickness of alluvial layers is 1.5–3.5 m.

Holocene eluvial-deluvial sediments (edQ_{IV}) are developed most widely on gentle spaces of watersheds and flat (1°–3°) slopes. They consist of rubble from 5% up to 30%-40%, or gruss with a sandy-loamy fill (up to 50%-80%). In the direction towards the central part of valleys, the abundance of rubble is reduced up to 5%–10%. The thickness of eluvial-deluvial deposits is 10–15 m in valley boards and 1–2 m in river bed parts of valleys.

Deluvial (dQ_{IV}) and deluvial-solifluction (dsQ_{IV}) deposits are developed on slopes of watersheds with gradient more than 3°. They are presented by blocks, rubble, or gruss with a sandy-loamy fill. The thickness of deluvial deposits is 1–5 m.

Deluvial-colluvial deposits (dcQ_{IV}) are located on slopes of river terraces and erosive benches having a gradient of more than 10° and comprised of sandy loam and loam with a proportion of rubble and gruss of about 30%–50%. The thickness of deluvial-colluvial deposits is up to 2.5 m.

Eluvial deposits (eQ_{III-IV}) underlay the above listed genetic types everywhere and overlay Triassic sandstones and aleurolites. The thickness of continuous cover eluvial deposits is between 1.5 and 7 m. They are comprised of coarse ground with loam and sandy loam; the rubble content is about 30%–40%, and the gruss content about 10%–20%.

Geocryological conditions

The study area is located in northern geocryological zone and characterized by continuous permafrost. The thickness of permafrost is 120–250 m in river valleys; at transition to slopes it increases up to 300–350 m and more, and reaches the greatest values on watersheds (Geocryology of the USSR 1989). The mean annual ground temperature (MAGT) at the depth of 10–12 m is between -4°C in valley bottoms down to -6.5°C on surrounding slopes. The ground temperature on ridges naturally goes down to 7.5°C–8.0°C. Highest temperatures are characteristic for slopes of a southern exposition and the bottoms of valleys. Outside of talik zones, the snow cover is the most essential influence on MAGT; a thick snow cover results in a rise of ground surface temperature by 5°C–6°C in comparison to snowless sites.

Measurements of temperatures in boreholes 3 and 10 in an axial part of the future dam have demonstrated that the

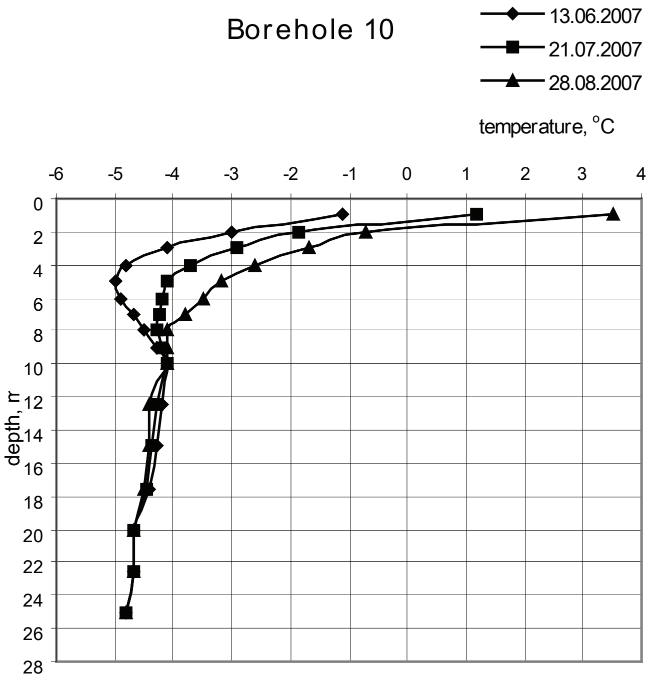

Figure 2. Ground temperature in Borehole 10.

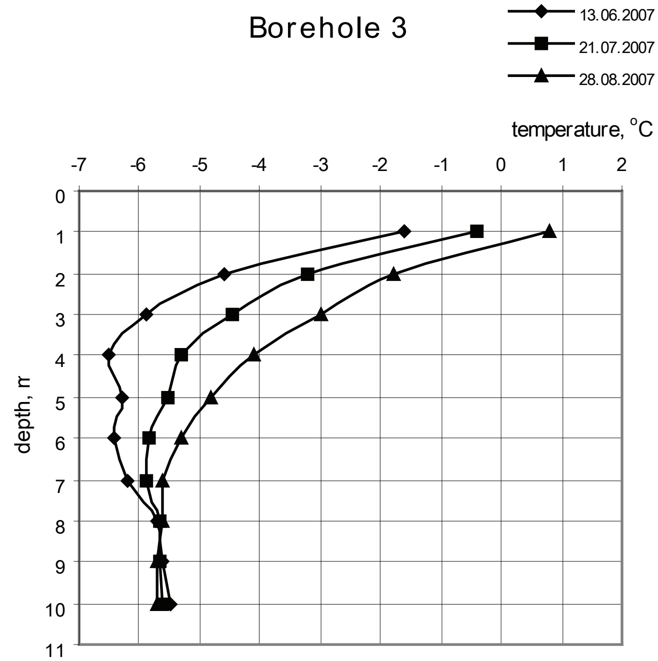

Figure 3. Ground temperature in Borehole 3.

highest MAGT at the depth of 10 m (-4.1°C) is found in the bottom of the river Right Keveem valley in Borehole 10 (Fig. 2).

The ground temperature on the left side of the valley slope was -5.5°C in Borehole 3 (Fig. 3) and -6.5°C on the right side of the valley.

Active layer depth varies from 10–15 cm on sites with thick moss and peat cover to 70–80 cm under swampy areas. At foots of slopes composed of coarse deposits as well as under streamlet beds, active layer thickness is 2–3 m and more.

In a vertical section of frozen ground epigenetic deposits prevail. The characteristic feature of weathered bedrock is its low ice content not exceeding 15%. The average ice content of fissured aleurolites is 5%–6%, decreasing to 1% in monolithic, low-fissured sandstones. The ice content increases up to 10% in strongly fractured aleurolites and argillites where cracks are filled with ice and in sandy-loamy ice-rich ground. Cryogenic structures of the bedrock are massive and crack-like.

Fine-grained deposits contain usually coarse material (up to 30%–40%), and have massive and massive-crust-like cryogenic structures. The ice content does not exceed 10%–15%. Rocks are completely frozen except in separate, localized, fractured, water-saturated zones along tectonic faults.

Late Pleistocene and Holocene deposits are a syncryogenic type of frozen ground formation. These are alluvial, lacustrine, fluvioglacial, swamp, eluvial, deluvial-solifluction and other formations. The ice content often exceeds 50%–60%, and cryogenic structures are lenticular, layered, and recticular.

Loose surface deposits often contain massive ice sheets in the sub-surface. In 2004, drilling in solifluction deposits intersected ice layers that were 1.8–2.0 m thick and had no mineral impurities. The ice sheet was of a layered structure with alternating layers of transparent firm ice and white loose ice 1–2 cm thick. Drilling in 2007 has shown massive ice sheets between 20 cm and 3 m thick occur in an area of about 30,000 m^2 on the left slope of the river Right Keveem valley oriented directly along the axis of a projected dam for a water reservoir (Fig. 4). Ice structure is layered, and the ice contains about 3%–5% fine mineral material.

Massive ice sheets represent, apparently, primary interground ice of segregation-intrusive genesis. They were generated in freezing, water-saturated deposits with constant additional charging by underground water.

Within the limits of the region, permafrost in river valleys has a two-layered structure. In the top part of the section there are friable epigenetic and syngenetic ice-rich and very ice-rich disperse deposits, and in the bottom there is Triassic bedrock frozen epigenetically and having a characteristic, low ice content . The single-layer structure of frozen rock mass is characteristic for epicryogenic bedrock in a mountain part of the region. Cryogenic structures of crack-like type are common for this type of deposit. On highly fissured sites corresponding to zones of constant water saturation before freezing, rocks are characteristic by a high ice content and have crack-vein cryogenic structures. Near the surface, the elevated ice content due to goletz (crust-infiltrated) and segregated ice occurs in most weathered rocks. Crack-like, crust-like, and basal cryogenic structures are most common for this type of deposit.

Numerous cryogenic processes are widely spread in the study area. Frost weathering developed on slopes and watersheds where the snow cover is negligible results in rock destruction and moving of the loose material down slope due

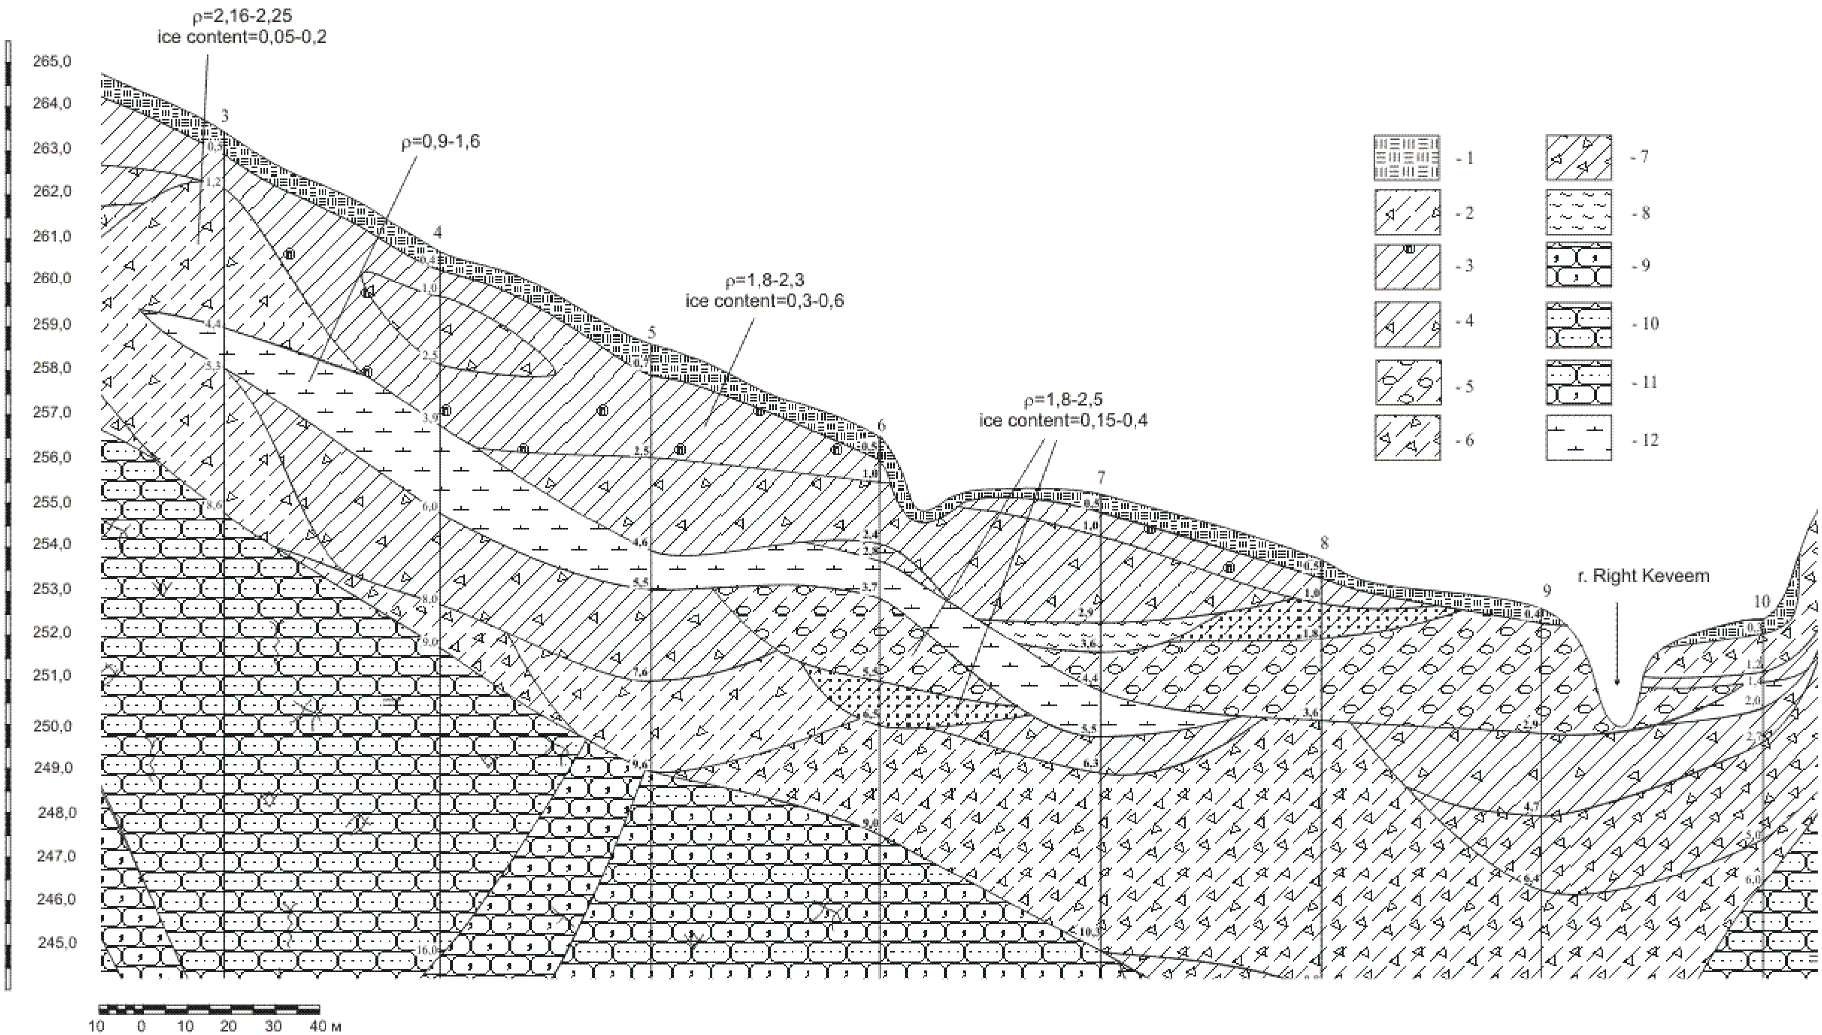

Figure 4. Part of cross section through the left side of the river Right Keveem's valley along the axis of the projected dam. Horizontal and vertical scales in meters. 3… 10 – number of borehole. Lithology: 1 – peat; 2 – sandy-loam with breakstone; 3 – loam; 4 - loam with breakstone; 5 – pebble with sandy-loam; 6 - breakstone with sandy-loam; 7 - breakstone with loam; 8 – silt; 9 – aleurolite; 10 – sandstone; 11 – interleaving of sandstones and aleurolites; 12 – massive ice layer. Ground is frozen from the surface (May 2007).

Figure 6. Thermokarst depression – a result of massive ice layer melting.

to active gravitational and deluvial processes. Fine-grained products of the frost weathering accumulate in lower parts of slopes thus forming deluvial and deluvial-solifluction aprons. The surface of slopes is complicated by dells, mud circles, solifluction terraces, and lobes. Dells are the linear hollows 10–12 m wide with flat, swamped bottoms.

On gradual (less than 10°) slopes, solifluction, and deluvial-solifluction slopes, processes of plastic-viscous flow develop. Solifluction occurs in sandy loams and dust-like loams containing sometimes a significant amount of coarse material. The rate of solifluction movement depends on the slope degree, active layer thickness, deposit grain size, etc. Coveral solifluction is a kind of solifluction without surface disturbances when the ground flow is rather uniform and slow. It develops on slopes of 3°–10° and is accompanied by material sorting resulting in the formation of layers of fine and coarse material in longitudinal section.

Frost cracking develops in the active layer and is well defined on the surface in the form of numerous sorted and non-sorted polygons and circles with flat or convex surfaces free of vegetation, 1–3 m in diameter, limited by frost fissures and banks of jacked debris. In non-homogenous friable grounds with a high content of debris (gravel, gruss, pebble), multiple cycles of freezing-thawing result in the frost jacking of coarse material towards the ground surface and its displacement to the fissures located in hollows, thus forming stone rings and polygons. On the slopes, stone rings transform into stone stripes 1.5–2 m wide and 0.4–0.6 m high, divided by convex-plane surfaces covered with turf (Fig. 5).

Thermokarst processes develop by melting out underground ice and ice-rich ground and result in ground subsidence, shallow depressions, and the formation of thermokarst lakes. Thermokarst features are usually closed or semi-closed round-shaped hollows up to several tens of meters in diameter, located predominantly on flat surfaces or gentle slopes. Thermokarst is often caused by the disturbance of natural heat-exchange conditions as a result of technogenic impact or active layer thickness increasing. Thermokarst hollows on the left side of the river Right Keveem valley are connected to the massive ice sheet melting where the ice surface is at a depth of 0.7–1.2 m below the surface (Fig. 6).

The formation of kurums in the study area is a result of a combination of a number of processes. The main factors are cryogenic and gravitational ones. Kurums usually form on deluvial-colluvial slopes of 5°–10° gradient in good conditions of fine-grained material outwash. The thickness of kurums is 1.5–2.5 m, and they consist of clumpy-debris material with sandy-loam fill in the base of the section. This layer is of high ice content, and sometimes lenses of goletz (crust-infiltrated) ice up to 0.5 m thick exist. Kurums move predominantly due to cryogenic creep in the active layer, partly because of plastic deformations of goletz ice in the basal layer.

Discussion

According to the computer modeling, at a constant maximum water level in the future water reservoir, the depth of ground thawing in the upper prism scarp of the dam after one year of operation will be 3.3 m, and by 15 years it will reach 9.9 m. In the seasonal changes of water level in the reservoir assumed by the project, the depth of thawing in the top part of the upper prism scarp will be 1.5 m and should not change during the period of operation while in the bottom part, the depth of thawing will be up to 5.5 m. On the slopes of the lower prism of the dam, the depth of ground thawing during period of operation should remain stable at 1.1–1.5 m.

The depth of frozen ground thawing in the bed of the water basin for 15 years of operation will change from 1.1 m up to 4.9 m. With the presence of ice-rich frozen ground of the relative subsidence 0.2–0.3 (according to engineering-geological researches and laboratory test of frozen ground compressibility in thawing) the total ground subsidence in the water basin bed may be 1.0–1.5 m. It will result in the slipping of the ground of an upper prism and to the infringement of the dam stability. Therefore, replacement of the ice-rich ground to a depth of 1.5–2.0 m is necessary.

During the process of dam and water reservoir construction, the activation of thermokarst, thermal erosion, cryogenic landslides, frost heaving, and frost cracking should be expected.

The most dangerous process in water basin operation is thermokarst. The tendency of global climate warming may lead to the increase of the active layer thickness and, as a result, to the acceleration of massive ice bodies melting (Fig. 6). Thermal subsidence of ice-rich deposits of the water reservoir bed can be up to 1.0–1.5 m.

The activation of frost heaving and frost cracking on the dam surface with low snow cover is possible. It should promote the development of thermal erosion processes during the warm period. To avoid the activation of these processes, predominantly coarse material should be used in the dam construction.

The thermal effect of water filtration through the dam body should be reduced by using a synthetic diaphragm within the dam. It is preferable to erect the dam in the winter time. Additional ground cooling during dam operation should be provided by the application of two-phase hybrid thermosyphons designed so that the dam can be cooled actively as well as passively. As practice shows, installation of air cooling is less effective. Cooling units should be installed on the crest of the dam close to the head race at a distance of 3 m to a depth of at least 15 m. If the dam will be erected in the summer time, freezing thawed ground in the body of the dam using thermosyphons will take one winter season.

For dam stability maintenance, monitoring of the ground thermal regime should be established.

Conclusions

The projected dam for the water reservoir is located in the zone of continuous permafrost. The presence of ice-rich coarse deposits, massive ice sheets, and numerous cryogenic processes significantly complicate conditions of dam construction. The activation of thermokarst, thermal erosion, cryogenic landslides, frost heaving, and frost cracking should be expected in dam and water basin operation.

The dam should be erected in the winter time and supported in the frozen state by two-phase hybrid thermosyphons installed on the surface of the dam near the head race. The complex monitoring of the ground thermal regime should be carried out to provide for the reliable operation of the dam and water reservoir.

Acknowledgments

The authors are grateful to G.P. Pustovoit (Moscow State University) who carried out the computer modeling of the future frozen dam thermal regime dynamics. We also sincerely thank reviewers for editorial assistance and additional language improvement.

Abstract

The present work focuses on the analyses of glacial ice from thermokarst in relict glacial and degraded Andean permafrost environments (4200 m a.s.l.) in order to reconstruct its environmental or paleoenvironmental history and to understand the processes that generated the Andean rock glaciers. The study area belongs to the Morenas Coloradas rock glacier, situated in the Cordón del Plata (at 33°S approximately), Central Andes, Mendoza, Argentina. An interpretation of the ice samples and an analysis of their internal and crystallographic characteristics is carried out in order to explain the geomorphological and cryogenic history of the landforms. The area of periglaciation—where cryogenic forms are generated—is studied thoroughly. Due to climatic oscillations, these periglacial areas may be identified by thermokarst. The degradation phenomenon helps to build new cryogenic forms like rock glaciers. Different possible environmental scenarios for the genesis of protoperiglacial landforms may be imagined.

Keywords: Central Andes of Mendoza; glacial ice; global warming; periglaciation zone; permafrost; rock glaciers.

Introduction

Rock glaciers, the typical Andean cryogenic mesoforms which characterize creeping mountain permafrost, contain different types of ice that interact with frozen cryosediments, that is to say with sediments of cryogenic origin. From a structural point of view, the types of constitutional ice generally observed are interstitial and segregation ice, but buried massive ice of sedimentary origin is also to be found (Shumskiy 1964, Haeberli & Vonder Mühl 1996). Areas with over 80% of ice (supersaturated permafrost) appear in the structure of the few drillings that have been carried out (Haeberli et al. 1988).

Interstitial ice is a superficial ice found in the first meters of depth in the rock glacier. This kind of ice depends on the diameter of the sedimentary pores which allow for an optimum nucleation of the ice (Van Vliet-Lanoë 1998) and correlates with the size of the particles which induce nucleation (Hobbs' ice, see Anderson et al. 1978), while segregation ice is the kind of ice that creates lenses or layers of few centimeters inside the frozen body (Shumskiy 1964, Trombotto et al. 1999).

But concerning the origin of the ice, periglacial ice is closely linked to different processes (e.g. percolation or regelation), various contributors (e.g. snow, graupel, harsch, or firn) or to other natural manifestations such as glaciers or nivodetritic avalanches. Sedimentary ice in periglacial domain is created mainly by the transformation of snow and graupel which percolate into the open structure of the cryosediments, although snow, harsch, and firn from Andean avalanches also play a decisive role in its creation. This material also incorporates to the frozen sedimentary body of the rock glacier by percolation and burying of the latter under cryosediments. Another origin of the ice is the regelation of glacial ice, after a previous process of melting, which incorporates into the body of rock glaciers as periglacial ice, although the mechanism is fairly unknown.

A parallel process has been observed in the Andes of Mendoza for example, expressed by the fluxion of isolated ice bodies of glacial origin which, favoured by the slope, directly incorporate to the periglacial sedimentary bodies. This is the type of ice we are mostly concerned with in the present work and which shall be analysed and identified, because it contributes to the origin of periglacial landforms.

In general, macroscopical or large scale phenomena may be scientifically interpreted in function of microscopical parameters. In the case of the ice, and as has been shown

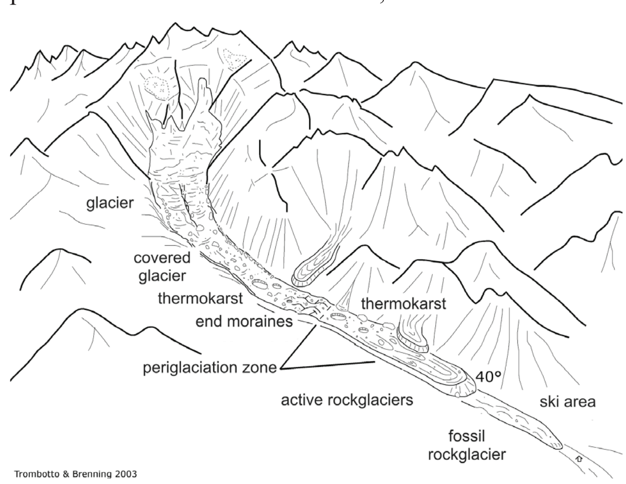

Figure 1. Periglaciation zone.

for glacial ice in thermokarst areas (Arena et al. 2005) microcrystallographical characteristics can be correlated with geomorphological characteristics of the environment in which the ice originated.

This work analyzes ice of a periglaciation zone (Fig. 1), that is to say, an area that used to be glacial and in which periglacial or cryogenic landforms are being generated.

As glaciers retreat to higher altitudes, they leave a large quantity of still frozen morainic or cryogenic sediments behind. At the same time, islands of covered ice may remain. These types of ice, considered 'dead ice' by many authors, are key contributors or perfect natural cryogenic environments for the 'roots' or the genesis of debris rock glaciers. These processes indicate that at the Cordón del Plata, Mendoza, the periglacial level reaches down to 3600 m a.s.l. approximately (Fig. 1). This is a relatively low height considering that 'quasi continuous permafrost' at the same latitude exists only above a height of 4200 m a.s.l. (Trombotto 2000).

The present work also analyzes experimental samples in order to certify natural processes. In particular, microcrystallographical parameters are set up, which allow one to determine whether an ice sample belongs either to regenerated ice of the region close to the active layer, to thermokarst of cryogenic origin (degraded permafrost), or to ancient glacial ice. Moreover, correlations between the mentioned microscopical characteristics and the stress, directions samples underwent in thermokarst, are analyzed. Finally microscopical ice characteristics are linked with environmental and palaeoenvironmental processes.

Study Area

The study area is located in the Cordón del Plata, a mountain range of the Andes of Mendoza. The area is situated between 32°24′S and 33°39′S and 70°14′W and 70°46′W (Fig. 2). The area is glacierized. The Landsat 2000 image reveals glaciers, perennial snow patches, and also snow patches which are mostly considered to be temporary. The entire surface was figured to be 148 km², 119 km² of which correspond to rock glaciers (Trombotto 2003).

Geologically the Cordón del Plata is part of the Cordillera Frontal, limited in the W by the Argentine geological region called Cordillera Principal. In the Cordón del Plata graywacke prevails, sandstone conglomerates from the lower Carboniferous and volcanic rocks of the volcanic Variscian Association of Permian Age. A very important granitico-granodiorhyte batolite as intrusive is associated to the more recent Variscian tectogenesis. The Andean tectonic movement reactivated the entire area during the Tertiary, and it was particularly during that period that sedimentary rocks were deposited as sandstones and conglomerates (Fm Mariño and Mogotes). Three mountain chains may be distinguished in this area: La Jaula in the W, the Cordón del Plata in the central part, to the N and E after which the entire area is named, with El Plata as its highest peak (6310 m a.s.l.), and finally the Cordón Santa Clara in the SW. Taking into account the topographical line of 2000, the study area comprises a surface of approximately 2830 km².

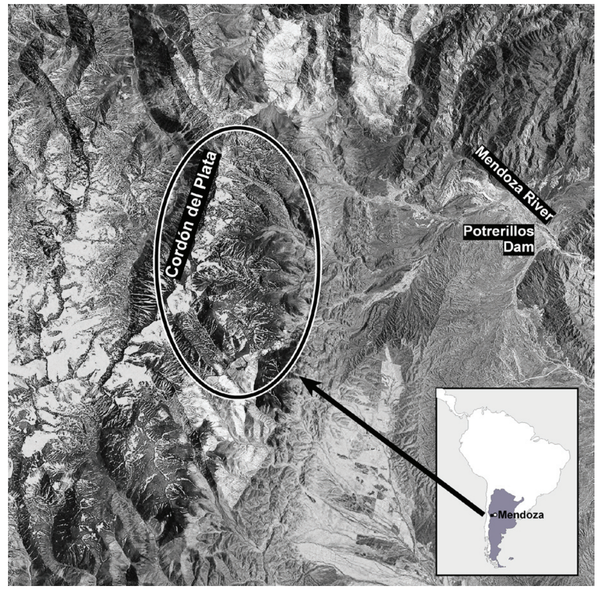

Figure 2. Study area.

The MAAT of the meteorological stations of Aguaditas (1972–1983) at a height of 2225 m a.s.l. and Vallecitos (1976–1985) at a height of 2500 m a.s.l. at its eastern flank are 7.7°C and 6°C respectively. The meteorological station Balcón I at 3560 m a.s.l. on the tongue of a rock glacier at Morenas Coloradas indicates a MAAT of 1.6°C and an annual precipitation between 500 mm (warm period April 2001–April 2002) and 630 mm (1991–1993). The vegetation ranges from shrubs to Andean tundra until 3600 m. Above this height and on rock glaciers vegetation is extremely scarce.

The analyzed ice samples come from a periglaciation zone of the composed rock glacier Morenas Coloradas (with different superposed frozen cryoforms), an area with thermokarst and a detritic cover that varies in thickness between 60 and almost 150 cm. The samples were taken at a height of approximately 4200 m a.s.l. in a tributary valley which unites with the main valley, and where cryosediments meet with the main valley of the composed rock glacier.

Methodology

The natural samples were taken at a glacial valley and rock glacier which are being monitored and investigated at the IANIGLA (Institute of Snow and Ice Research and Environmental Studies) in Mendoza, Argentina, since the 1980s. The extraction of the samples is done by a simple procedure of cutting ice blocks in areas with visible ice. The samples were extracted from two different profiles taken from thermokarst walls perpendicular to each other, according to the imaginary axis of an ovoid (Fig. 3). Before cutting out ice blocks, surfaces were cleaned to a depth of 5 cm. For extraction, blocks or ice monoliths were confectioned in the ice wall. These blocks were carefully oriented according to two fundamental criteria. One is the zenith of the sample itself, in order to identify its positioning within the body of ice, and the other one is the magnetic N of the site, in

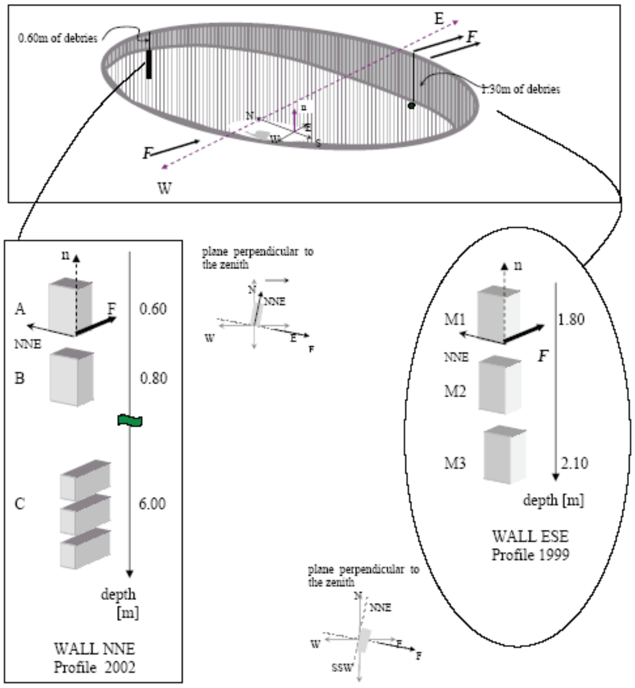

Figure 3. Sketch of thermokarst. F: principal stress, n: zenith.

order to be able to position the entire ice body sampled in the area. The samples were transported to the cold chamber of the LEGAN in Mendoza, where they were classified and preserved at -13°C.

Then thincuts were made of the ice samples, and plastic replicas were created at the University of Córdoba, Argentina. This technique complements the studies of the thincuts and helps to determine size and orientation of the ice crystals, dislocations as well as concentration, orientation and distribution of the bubbles inside the crystals. The method of plastic replication allows the detection of dislocations on the surface of the ice.

Thincuts were made using a xylotome Leitz, model 1400, adapted for ice cuts in the cold chamber. Thincuts were made in the cold chamber of the LEGAN Institute in Mendoza as well as at the University of Córdoba in Argentina. At the same time, laboratory tests of uniaxial statical isothermical compression of the ice core samples extracted from ice from below the base of the active layer of the thermokarst were carried out. These samples, treated in the laboratory, and those extracted from the ice cores and left in natural condition were crystallographically analyzed and compared to each other. It is the aim of these studies to establish a correlation between microcrystallographical and geomorphologically determined characteristics.

Analyzed Ice Characteristics

The most important components of the ice described in the present work are: (1) ice crystals: size and orientation of their C axis, (2) bubbles: areas with bubbles and areas without bubbles. Bubbles are classified into bubbles >50 µm and bubbles <50 µm and microbubbles, (3) defects and dislocations, and (4) presence of particles.

While for the study of the ice crystals (Table I) the size and orientation of their C axis were the important factors, in the case of the bubbles three different types were found and classified as follows:

- Two types of bubbles belong to microbubbles, with a diameter smaller than 0.1 mm
- Another type are macrobubbles with a diameter larger than 0.5 mm

In the first group, bubbles are distinguished according to whether their mean diameter is smaller than 50 µm or larger than 50 µm. This distinction is important because size may influence the migration of the ice crystal edges. If the mean diameter of the bubbles is larger than 50 µm, it was observed that they do not impede or anchor the migration of the grain limit (Arena et al. 1997). The analysis of the bubbles (Table II) in the ice is very important because although some of them may abandon the edge of the grain without producing a remarkable effect, others, if they are small enough, anchor growth of the ice grain. In other cases bubbles of intermediate size may simply slow down their growth. Only at low temperatures and under the phenomenon of isothermic warming in the laboratory, for a long time (over one year), could it be observed that bubbles do not stop the growth of ice crystals.

There are two types of areas considered in the thincuts sections; one was called CB when it contained microbubbles and the other was called SB when it did not contain microbubbles (Table II).

In general (Nassello et al. 1992, Arena 1995) the mean size of ice crystals in areas with microbubbles is smaller, because these anchor the limits of the ice grains. This also occurs in areas with bubbles >50 µm and macrobubbles. It strikes the eye that the bubbles <50 µm are almost spherical while those >50 µm and macrobubbles are not, and thata they can give clues about the main stress directions.

Regarding defects, the density of traces of dislocations holds information for us, for example about the forces of residual stress. The defects were classified into prismatical (P) and hexagonal (H) (Table III). The particles are mainly of mineral and cryogenic origin. They are the product of cryoweathering of cryosediments of glacial or periglacial origin.

Results

The microscopical characterization of glacial ice buried in a thermokarst at a height of 4200 m a.s.l. which displayed ice visible to the naked eye, based on two ice profiles, is shown in the following tables. They summarize the most important results found in crystals, bubbles, and defects of the different analyzed ice samples.

Crystals

The mean size of the grains in an SB area generally increases with depth, except for the case of sample A. On the other hand, polycrystalline samples are more textured, that is to say they have a defined or particular texture which is more pronounced with growing depth of the profile.

Table 1. Crystals.

Sample		Characteristics	D [mm]		Orientation
			SB	CB	
Profile I	M1	Top of profile, sedimentary ice	4.2	0.4	Random
	M2	naturally degraded ice zone (collapse)	5.8	nd	crystallographic axis C perpendicular to n
	M3	glacial ice, stress parallel to F	20	2.6	Crystallographic axis C parallel to F
Profile II	A	Top of the profile, naturally degraded ice zone (collapse)	4	0.4	Crystallographic axis C quasi perpendicular to n
	B	Top of the profile, naturally degraded ice zone (collapse)	2	0.3	Crystallographic axis C is 45° from n and NNE
	C	glacial ice	6	nd	Crystallographic axis C parallel to F

See Figure 1; D= mean diameter; SB= area without microbubbles; CB = area with microbubbles; nd = no data.

Table 2. Bubbles.

Sample		Bubbles				
		d [μm]		N_v [mm^{-3}]	Shape	Orientation
		MBA	MBNA			
Profile I	M1	Nd	500	840	Spherical	Random
	M2	50	Nd	58	Spherical an d elongated	25% elongated parallel to F
	M3	10	Nd	23	Elongated	parallel to n
Profile II	A	20	1250	52	Elongated	parallel to n
	B	20	60	1080	Spherical	45° from n and NNE
					Elongated	45° from n and F
	C	6	<50	465	Spherical	parallel to n
					Elongated	parallel to n

N_v = volumetric bubble density; d = mean bubble diameter; nd = no data; MBA = bubble <50 μm; MBNA = bubble >50 μm.

In M3 and C the crystals take a preferential orientation with the crystallographical axis C parallel to the direction of the flow, while at the top of the permafrost the bubbles appear coincidentally. Those crystals with a size of ≥0.5 cm suggest older age and a glacial origin. The latter are observed in samples taken at greater depth of the profiles.

Bubbles

For the understanding of Table 2 it is helpful to consider that:

- The mean size of the microbubbles which anchor the growth of grains (bubbles <50 μm) decrease with growing depth by a factor of 3 or more, except for sample A.
- The mean size of bubbles which do not anchor the growth of grains (bubbles >50 μm, macrobubbles) changes their shape from spherical to elongated with growing depth, except in the case of sample A.
- In profile I, elongated bubbles have their C axis parallel to “F”, which is the flow direction, in sample M2 (Fig. 4). This is not the case in sample M3 where the prevailing direction is parallel to n.
- In profile II, microbubbles are aligned with the zenith of the samples A and C, but they build an angle of 45° with the zenith of sample B.
- In the samples taken at greater depth, volumetrical density of the bubbles is greater in sample C (profile II) than in M3 (profile I).

Table 3. Defects and dislocations.

Sample		Defect density [x 10^6 mm^{-2}]	
		Hexagonal plane	Prismatic plane
Profile I	M1	2.1 ± 0.5	3.0 ± 1.4
	M2	1.5 ± 0.4	2.6 ± 0.8
	M3	1.5 ± 0.6	2.0 ± 0.1
Profile II	A	2.4 ± 0.7	5 ± 1
	B	0.7 ± 0.2	3 ± 1
	C	0.5 ± 0.2	3 ± 1

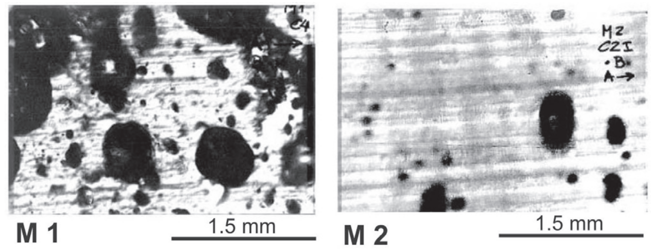

Figure 4. Ice thincuts of profile I (M1 and M2).

Defects, dislocations, and particles

From Table 3 we may deduce that the samples indicate, in the sections analyzed with plastic replicas, that the density of patterns of chemical attack, expressing defects and dislocations, decreases with depth. As to the obtained particles, a lithological study has yet to be made, but it may be supposed that their origin is the local parental rock. In profile II, a majority of a diameter >20 μm prevails. It is assumed that this abundance must have had an important influence in slowing down the growth of the crystals.

Discussion

For reasons of climatic oscillations, ice covered areas express a degradation of glacial ice and formation of thermokarst. Thermokarst are holes or pits and when they are active they are usually filled with melting water, building tiny lakes, unfrozen only in summer. They are a typical characteristic of the irregular landscape of covered glaciers in the Andes of Mendoza. They are also found, less frequently though, on the surface of composed rock glaciers. This phenomenon of degradation of glacial ice contributes to a transformation of the area, making it part of a periglacial landscape. The ice partly melts and then freezes again in the matrix of the structures of periglacial forms.

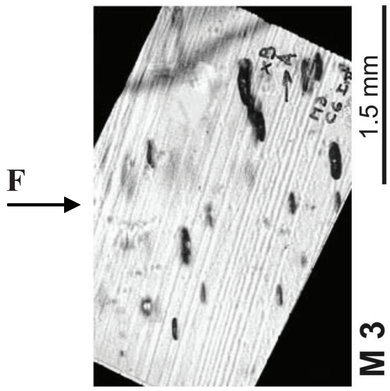

Figure 5. Ice thincut of profile I (M3).

Another important mechanism is the slow movement of small bodies of ice in the form of an "injection." This process is associated with the existence of so-called "dead ice," that is to say, bodies of ice without a connection with the glacier which generated them and which may continue to exist but withdrawn to much higher altitudes. The ice that remains locked in parallel, smaller, and colder valleys with less solar radiation, tends to flow or end up in main valleys with important rock glaciers or composed rock glaciers. In other words it favours periglacial genesis.

Comparing the two ice profiles made in 1999 (profile I) and 2002 (profile II) in a chosen thermokarst, it is easy to observe that M3 of profile I and C of profile II indicate the presence of glacial ice by analyzing the characteristics of their texture. Grains increase in size at growing depth, and their orientation follows the relict flow of the glacier, and the bubbles are elongated perpendicularly to F. In this sense, the C axes of the samples testify to the past glacial flow following the main direction of the stress (F). This way it is possible to prove that the samples taken at depth are correlated and have the pattern that corresponds to the stress of the main direction denominated F (Figs. 3, 5), and that they are of glacial origin.

On the other hand the decrease in the density of the defects indicates that the age of the samples increases with depth. The mean diameter of the bubbles also decreases with depth, following the same principle. Apparently the bubbles try to escape or move upwards, in the direction of n that is, responding to a temperature gradient in a direction normal to the site at the permafrost table. This would also explain the parallel alignment regarding n.

While sample M1 is not textured, M2 shows a texture. The first is indicating a genesis that is different from the second, possibly associated to the thick detritic cover of the profile which acts as an active layer. This ice is mainly of sedimentary origin, generated by solid precipitations which infilter and recrystallize, partly undergoing a liquid state in summer. The textured sample M2, with crystallographical axis C parallel to n, suggests an intervention of a different type of stress with an orientation that is perpendicular to the main stress and which may be due to the collapse phenomenon in connection with thermokarst formation. The shape and the orientation of the bubbles support this idea (Fig. 4). On the other hand in the 2002 profile, sample A is textured, surprisingly with a diameter of grains superior to that of sample B which follows below, indicating most likely that the first sample has been exposed to a higher temperature than the samples of the rest of the thermokarst. This would be a case of degraded ice, a possible effect of local or global warming, and different from the characteristics mentioned above. The size, shape and orientation of the bubbles would also indicate a possible phenomenon of freezing. In addition a remarkable difference between samples A and M1 has to be pointed out, also reaffirmed by the low density of bubbles in sample A which was taken in 2002 and is interpreted as an increase of the mean temperature that affects and creates thermokarst. The special texture of sample B indicates a stress phenomenon geomorphologically observed in a thermokarst environment, which is growing at profile II. But what would be the origin of the ice of profile II? Is it glacial? This question arises when the proper characteristics of the different ice samples are defined. What existed before the ice suffered the variations described? The hypothesis is that it was glacial ice that grew with a sedimentary contribution on top, but that is being transformed and adapted to the present environmental conditions with warming. It would be interesting to reconsider the classification by Shumskiy (1964) according to the processes involved in ice formation.

Conclusions

The microscopical characterization presented in this work helps to classify three different types of ice in an area of periglaciation, or cryogenic processes, which interact with the rock glaciers and may be resumed as follows:

1. Massive ice of glacial origin, indicated by larger ice crystals with a preferential orientation, that is to say with the crystallographic C axis parallel to the flow direction; by elongated or ovoideal bubbles, with low density, also oriented towards the flow direction in some cases and by dislocations in the thincuts or plastic replicas which also indicate the flow direction; in some cases however, like C in profile II, the particles may limit the size of the crystals and influence the interpretation;
2. Sedimentary ice represented by small crystals and by almost spherical bubbles; like in the typical case of M1 and M2, with a high volumetrical density of bubbles and a larger mean diameter; and
3. Regenerated or degraded ice, which is monocrystalline, with bubbles of a large mean diameter but with low volumetrical density of bubbles. This ice is associated with the degradation of permafrost like in A and B of profile II.

On the other hand, as presumed, the layer of sediments has an important role in relation to the penetration of the external caloric wave which interacts with different types of subterranean ice. The phenomena are expressed microscopically and macroscopically.

In profile I, the external caloric wave is impeded and stopped by the thick layer of cryosediments accumulated perpendicularly to the F axis of the main flow and at lower height which interacts with the solid precipitation that falls throughout the year and supports the agradation of ice. However, this is not the case in profile II, where a much thinner layer of a thickness less than 1 m, allows much more external heat to enter and causes a regeneration or transformation of subterranean ice. In addition there are clear signals of collapse processes that preferably affect certain parts (profile II) of the thermokarst perimeter.

Evidently the chosen periglacial area is not in equilibrium, as inferred by the presence of active or reactivated thermokarst. These forms are supposed to be much older, probably from the Middle Holocene when a worldwide warming and a glacial inactivity were produced. This was also registered in South America (Röthlisberger 1986).

The changes caused by present warming, and which affect the structures of the ice, are also clearly observed in the microcrystalline results of the samples. The area of periglaciation extends altitudinally, but also affects lower heights for the contribution of more regenerated ice. It is an area with abundant "dead ice" that is integrating into periglacial forms such as rock glaciers. The "glacial flow" is kept up, hidden, discontinuous and slow, favoured by the inclinaton of the slopes of small colateral valleys.

The periglacial environment is growing or expanding upwards as glaciers disappear, are covered by sediments or are transformed into relict ice. Downwards, that means descending in height and slope downwards, the ice integrates into morainic or cryogenic sediments that fill up valleys and contributes to the formation of new rock glaciers or helps to maintain the existing rock glaciers in activity.

Different environmental situations may be analyzed on the basis of the conclusions. If the environment is considered as continually changing, the "dead ice," as if it were relict ice of glacial origin, does not persist in situ; it keeps flowing as has been pointed out above. This movement is proven by the microscopical characteristics of ice samples taken at great depth of the studied profiles. Sedimentary ice also incorporates into the massive ice in a process of agradation. These types of ice merge from a periglacial environment in the existing periglacial forms that have been observed. The erroneously called "dead ice" partly disappears by degradation and sublimation, but partly plays an essential role for the evolution of periglacial forms at lower altitudes.

The phenomenon of ice agradation would cease if the sedimentary or active layer was very thin and if the mean temperature of the thermokarst increased. These processes, the asymmetry and the deformation of the thermokarst, are represented in the landscape and are expressed in the microcrystallography of the ice, and they may be used as environmental indicators.

These studies allow the reconstruction of three environmental or paleoenvironmental scenarios: (1) old ice expressing its paleoenvironmental background, (2) ice indicating agradation or degradation of the present permafrost environment, and (3) ice expressing geomorphological processes to be expected in the near future.

Acknowledgments

This work was carried out with the financing of project 4664 (PIP 1078/98) by CONICET: "Argentine General and Applied Geocriology." We would especially like to thank José Hernández (IANIGLA) for his permanent cooperation during fieldwork and his logistical support, and Sabine Herfert and Silvina Pereyra for their help with the English version.

Abstract

Three case studies are presented to demonstrate the effect of *InterHeatPipes,* which are small-diameter thermostabilizers, under different permafrost conditions. The installation of the *InterHeatPipes* increases the bearing capacity of piled foundations and therefore provides increased building stability. Thermal disturbances caused by the installation of piles in warm saline permafrost required a quick heat extraction from the ground to provide the required bearing capacity of a multistory business centre in Yakutsk during construction. A series of thermostabilizers were installed that provided very fast ground cooling. Thermostabilizers were also installed to freeze unfrozen soil in the foundation of a nine-story residential building. The third example presents results of a power line tower foundation using thermostabilizers. Supports for power lines are critical because frost heave in warm permafrost often results in uneven lifts of the pile foundation resulting in tilted masts. Ground temperature measurements from the three examples demonstrate how thermostabilizers can be utilized to increase the bearing capacity of the soil.

Keywords: bearing capacity; permafrost; pile foundations; stability; thermostabilizer.

Introduction

Widespread saline and warm frozen grounds, and natural or human-induced taliks cause major problems in the construction of multistory buildings and engineered structures in permafrost environments. Pile foundations are affected by vertical frost heave and pull out forces. Such problems are recorded in Yakutsk, the oldest city among those with a population of more than 50,000 people built on permafrost. The geocryological conditions differ significantly from natural ones. Ground temperature regimes are extremely non-uniform within one construction site and talik zones are common under old buildings promoting permafrost thaw.

Future development of modern northern cities requires the construction of multistory buildings with increased foundation loads, both vertically and horizontally. Seasonal cooling devices in combination with local thermal insulation of the ground surface are efficient in increasing the bearing capacity of the ground for pile installation, freezing talik zones and providing stability of foundations against pull out forces, including frost heave forces. This paper presents the usage of *InterHeatPipe* thermostabilizers as cooling devices on two multistory buildings and a power line foundation.

Site Description

Business centre office building: Block B

The construction site for a new business centre is located in the centre of Yakutsk where previously one-story wooden houses and public buildings were situated. The office building (block B) is 33.0 m x 40.5 m and is located in the centre of the new complex. It is a 13-story building capped by a two-story dome. Structurally, it represents a monolith reinforced concrete framework with a maximum pillar grid distance of 6.0 m x 7.5 m. During site investigations geocryological conditions were identified, characterized by low temperatures, which are typical for the centre of the city of Yakutsk, and high salinity of shallow soil layers. At the depth of zero annual amplitudes (10 m) the ground temperature varied between -3.4 and -5.2ºC, with the lower temperatures measured in places with maximum ground salinity (D_{sal} = 0.58%), and warm temperatures (-3.4ºC) in places with minimum ground salinity (D_{sal} = 0.13%).

According to the Russian construction code (1988) the calculations of the bearing capacity for pile foundations have to consider less favorable conditions: higher ground temperatures (-3.4ºC) at a depth of 10 m, and the maximum depth of saline ground (5.5 m).

The geological section is represented by the following types of soils:

- 0–0.8 m: fill (medium and silty sand, construction waste);
- 0.8–5.5 m: silty sand with the some organic remains, saline;
- below 5.5 m: fine and silty sand of massive cryogenic texture, hard frozen.

Pile clusters of three or four piles combined were designed

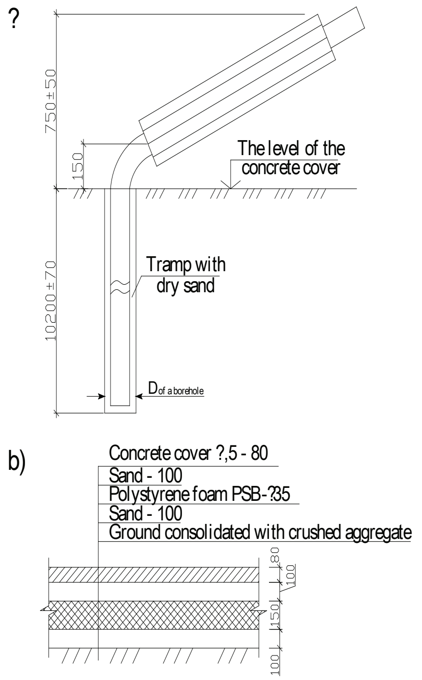

Figure 1. Schematics of the thermostabilizers (a) and the thermal insulation of the ground surface (b) for the business centre.

for the foundations depending on the loads. Square reinforced concrete piles measuring 40 cm x 40 cm were 10 m and 12 m long, and embedded into permafrost to depths between 8.8 m and 10.8 m. The piles were installed into boreholes with diameters larger than the piles. According to the design, borehole pockets should have been filled with cement and sand slurry. The calculated bearing capacities for the pile installation was 1620 kN and 2380 kN, for the 10 m and 12 m long piles, respectively. The calculated pile loads were 1300 kN and 1930 kN.

During the pile installation, water from the thawed layers close to the surface penetrated into the boreholes warming the ground so that the temperatures at 10 m depth increased -2.1 to -2.7ºC. Inspections of the borehole grout showed that piles froze to the saline drilling mud but not to the cement and sand slurry. In addition, the temperatures were significantly higher than calculated. New calculations that considered in situ ground temperatures and salinity increase along the entire length of the piles showed that the bearing capacity of the installed piles was only 610 kN and 856 kN for the 10 m and 12 m long piles, respectively.

Nine-story residential building in the 29th city block in Yakutsk

Until late 1970s there was a lumber-processing plant located on the bank of the Zavodskaya river canal. Later the river canal was filled with lumber-processing waste. A zone of unfrozen ground with high content of organic material formed.

The site mainly consists of upper quaternary alluvial sediments represented by sandy and clayey deposits to a study depth of 26.3 m. Between a depth of 23.5 m and 25.7 m the top of Jurassic sediments formed by siltstones

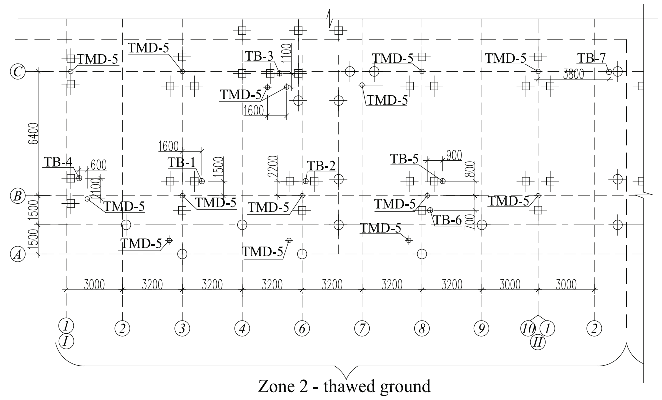

Figure 2. A section of the founda tion scheme of the area with taliks of the 9-story residential building and the scheme of the thermostabilizers (TMD-5) and the location of boreholes (TB-1, 7).

were penetrated. The natural ground is overlain with a fill of sand, sandy loam and loam mixed with chip, bark, board chippings, logs; that is, all sorts of sawing wastes. The inclusions vary from rare to thick and are non-uniform in both horizontal and vertical direction. The thickness of the fill within the site is between 3.9 m and 9.4 m. Some loam sand lenses were also found. These layers are usually saline with organic inclusions. Below the fill the geological section is represented by sands of various ranges; that is, fine, silty, medium, and gravel sands.

Drilling in July/August 2006 revealed both frozen and thawed ground on the site. Thawed ground was penetrated in the active layer as well as at greater depths within the permafrost. Later are inter-permafrost taliks of different thicknesses and distribution. Thawed ground occupies about a third of the site. The origin of the inter-permafrost taliks is initially connected to a former river canal that formed a talik. The river canal was later filled with lumber processing wastes and the surface was leveled with fill, consisting of dry ground that resulted in deep freezing from the surface and a formation of shallow short-term frozen ground. Cast-in-place piles of 650 mm diameter and different lengths are designed for the foundations. The design also suggests that the lower part of the pile to be embedded in permafrost, as well as preconstruction ground freezing.

Power line supports

The site with supports for a power line is situated in the southwestern part of Yakutsk. According to the site investigations the active layer is represented by sandy loams and loams. The ground becomes liquid when it thaws. According to a frost heave parameter the sandy loam is referred to as a highly frost susceptible soil and the loam to an extremely frost susceptible soil.

The frozen ground is represented by silty, fine and medium sands. Ground temperatures measurements carried out in 2001 showed warm temperatures that are not typical for Yakutsk (-0.3 to -0.9ºC at a depth of 10 m). The inclination of the support exceeded the maximum allowable values. The power line supports are sunk-drill piles (two piles under each foot)

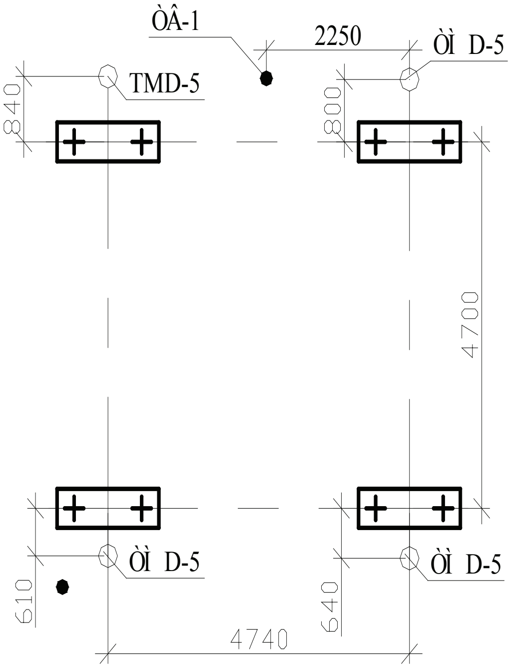

Figure 3. The scheme of the TMD-5 and location of temperature borehole TB-1 near the power line support No. 44.

with a 30 cm x 30 cm cross section and a length of 8 m.

Calculations of foundations showed their instability under vertical forces due to frost heave when the active layer refreezes. The power line supports are subjected to both compressing and pull out forces, therefore, the combination of pull out and vertical forces due to frost heave control heave and tilt of the foundations.

Techniques of Pile Bearing Capacity Increase

To provide the bearing capacity and stability of piles for engineering structures under the above-mentioned permafrost conditions ground temperature control was necessary. Seasonally cooling devices were widely used for heat extraction and to cool down ground temperatures. Thermopiles (Long 1963) and kerosene devices (Gapeyev 1969) are well known. Liquid seasonally cooling devices were used to refreeze thawed ground and to cool plastic frozen grounds (Biyanov et al. 1973), refrigerated piles were installed for multistory buildings in Mirny (Makarov et al. 1978), different types of thermosyphons and thermopiles were further used for numerous constructions in Alaska (Borjesson et al. 2007). In recent years *InterHeatPipe* thermostabilizers of small diameter are widely used for constructions in the Russian north (Lyazghin & Pustovoit 2001, Bayasan et al. 2002). Aluminum thermostabilizers, type TMD-5, with an equivalent diameter of 54 mm have the following advantages compared to other well-known seasonally cooling devices:

- low internal and external thermal resistance where the evaporator and the condenser are located;
- low temperature gradient along the length of the seasonally cooling device;

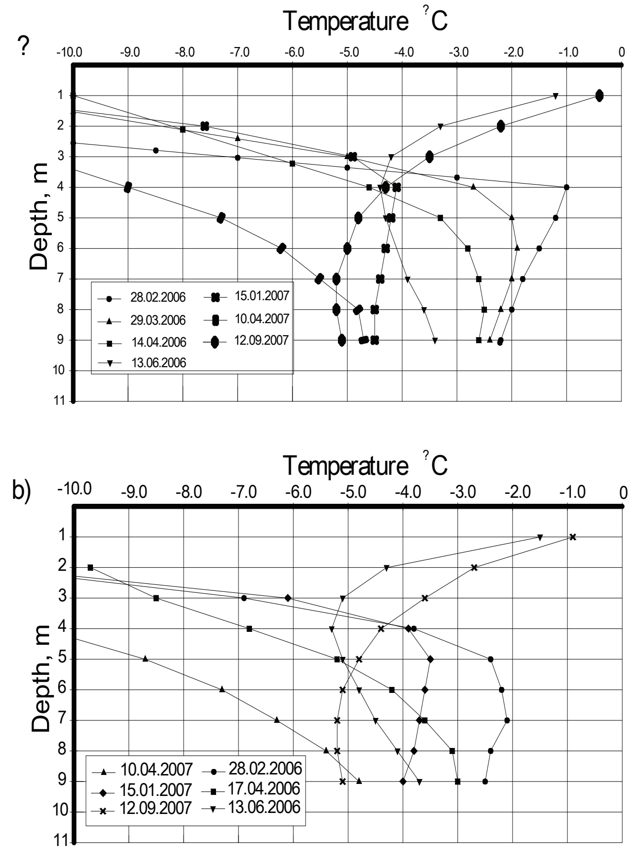

Figure 4. The ground temperatures near piles No. 52 (a) and No. 77 (b) of the business centre building after the installation of the thermostabilizers.

- high rate of freezing and effective cooling;
- short response time, which increases the period of active work of TMD-5 (1.0–1.5 months per season).

In addition to the seasonally cooling devices, the engineering design for ground thermal control includes the use of a thermal insulation. This was recommended and applied in all of the above-mentioned examples.

For the business centre office building, where the ground temperatures increase was recorded and the pile bearing capacity was exceeded, it was designed to install additional piles and to place thermostabilizers TMD-5. The condensators were tilted under the grid, in the centre of pile cluster. To decrease the depth of thawing and, consequently, to expand the adfreezing surface of the piles with the frozen ground the surface was protected with a thermal insulation foam (Fig.1).

Thermostabilizers for the 9-story residential building foundation were designed preliminary to refreeze the thawed ground. Piles will be loaded after the ground around them is frozen. The bearing capacity of the cast-in-place piles in a thawed zone was calculated considering the thawed state of the ground. An air space under the building allows cold air circulation, hence a gradual freezing of thawed ground and the maintenance of the frozen state.

Figure 2 shows a section of the foundation scheme for the area with inter-permafrost taliks where thermostabilizers were installed.

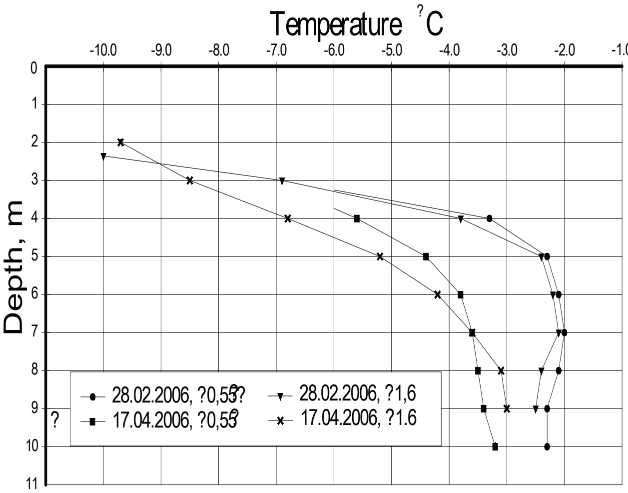

Figure 5. Ground temperature change after the installation of thermostabilizers located at different distances.

To prevent the failure of the power line supports, ground cooling by installing seasonally cooling devices was recommended. Thermostabilizers together with surface thermal insulation are provided to cool down the ground temperatures and to reduce the depth of seasonal thawing. This measure increases the adfreezing surface of the piles with the ground and decreases the surface of piles under the effect of vertical forces due to frost heave. The scheme of the TMD-5 installation is shown in Figure 3.

To measure the performance of the thermostabilizer and monitor ground temperatures boreholes were instrumented with thermistors. In addition, survey points were installed to measure support and foundation deformation.

The thermostabilizers for the business centre office building were installed in March 2006, those for a 9-story residential building in March 2007 and those near the power line supports in December 2006.

Results and Discussion

Figure 4 shows a set of ground temperatures beneath the business centre office building in two representative boreholes. TB-1 (near pile No. 52) is placed at the distance of 1.2 m, TB-2 (near pile No. 77) at the distance of 1.6 m from the TMD-5. Prior to the installation of the thermostabilizers (February 28, 2006) the temperatures at the tip of the pile (at the depth of 9 m) were between -2.2 and -2.5ºC. At the same level the natural ground temperatures reached values between -3.4 and -4.2ºC. Thermostabilizers were installed near pile No. 52 on March 15, 2006, and near pile No. 77 on March 26, 2006. The temperatures decrease as soon as the thermostabilizers had been installed. At the same time in upper permafrost layers (4–7 m) the temperature decrease was even more intensive and continued during the warm season (June 13, 2006)

Some temperature increase was recorded on January 15, 2007, but by the end of the cold season (April 10, 2007) the ground temperatures became much colder than on April 14, 2006 (after thermostabilizers worked for 20–30 days).

The end of a warm period (September for Yakutsk) is typical for the ground temperature regime. According to the temperature distribution on September 12, 2007, permafrost temperatures in both boreholes were low and nearly identical. As it has been stated above, thermistors were installed at a different distances from the thermostabilizers. Figure 5 shows the ground temperature decrease in two boreholes located at the distance of 0.55 m and 1.6 m from the thermostabilizers. Initial temperatures were almost similar and the thermostabilizers were installed on the same day. The figure further shows the intensive decrease in temperature where thermostabilizers were placed close (0.55 m) to the boreholes. However, such a tendency is not typical for the middle layers, which is probably affected by other factors, such as the composition, moisture content and salinity. These factors were not the subject of this investigation.

The data demonstrate that the proposed engineering design allowed the increase of considerably colder ground temperatures and a decrease in depth of seasonal thaw beneath the business centre office building. Ground temperatures lower than the calculated ones allowed the required bearing capacity of the soils and the transfer of calculated loads to piles.

Figure 6 shows typical diagrams of ground temperature changes for the 9-story residential building. As it was stated above, talik zones of different thickness were found below the building; thus ground temperatures were non-uniform. Figure 6a shows the temperature changes in borehole TB-1.

Ground temperatures along the entire depth of the borehole were positive at the end of a warm season (September 10, 2007), but by November 29, 2007, zero degree was recorded at depths below 3 m, and they stayed until January 24, 2008. Similar temperatures were observed in boreholes TB-2 and TB-4. Figure 6b presents the change in ground temperatures in borehole TB-5, where a talik was present at a depth of 7.5–9.5 m. According to the figure, ground cooling with the use of thermostabilizers resulted in subzero temperatures by December 5, 2007, and they continued to decrease (e.g., January 28, 2008). The figure further shows the peculiarities of refreezing thawed ground. Freezing of moist ground is characterized by the latent heat during phase change from water to ice. Therefore, the temperatures remain at about 0ºC (the temperature of water freezing) before ground cooling continuous, which was observed in borehole TB-5. The data obtained demonstrate the efficiency of thermostabilizers when thawed soils are frozen under buildings.

The calculations for made-in-place piles of this building were made with consideration of thawed ground conditions. The purpose of installing thermostabilizers was to reach uniform ground temperatures and to avoid uneven settlements of the foundation. The design also requires the establishment of subzero temperatures before loading of the foundation may begin.

Thermostabilizers were installed near the foundations of each foot of power line supports, subjected to heave deformation. Figure 7 illustrates the change in ground temperatures after the thermostabilizers were installed in the ground under one of the supports.

Thermistors were installed in a borehole located at a

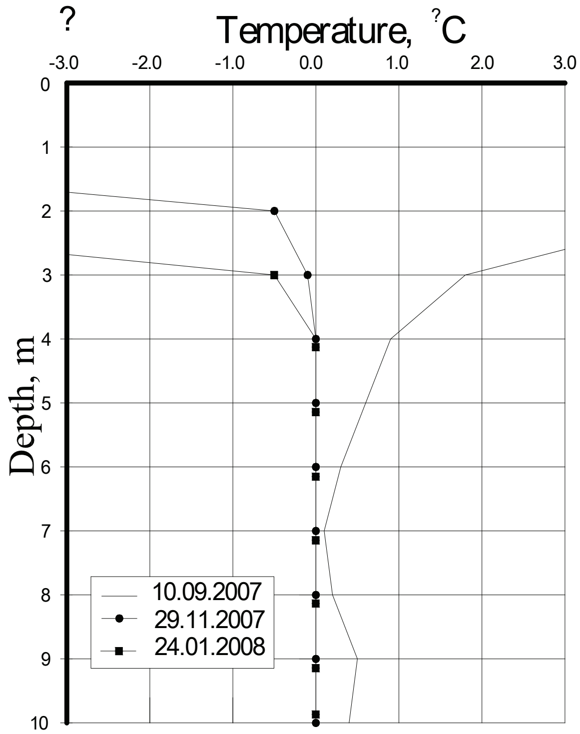

Figure 6. Ground temperature changes in boreholes TB-1 (a) and TB-5 (b) for the 9-story residential building.

rather large distance from the thermostabilizers (2.25 m). Nevertheless, the figure shows the decrease in temperature compared to the initial conditions. In addition to the temperature measurements, foundation deformations were monitored during the winter of 2006–2007, and no vertical deformations were noted for the two supports; that is, the reduction in ground temperature provided the necessary resistance of the foundations against the vertical forces of frost heave.

Conclusions

Small diameter *InterHeatPipe* thermostabilizers were installed under different structures in the city of Yakutsk to improve the ground-bearing capacity. In situ measurements of the temperature regimes of the ground cooled by the thermostabilizers allow for the following conclusions.

- Problems during the installation of the piles for a business centre office building resulted in warming ground temperatures and insufficient bearing capacity. Thermostabilizers and thermal insulation on the ground surface allowed the obtainment of calculated ground temperatures to decrease the depth of seasonal thaw and increase the bearing capacity of the pile foundation.
- Thermostabilizers used to freeze talik zones below a 9-story residential building showed their suitability and the dependency of the talik thickness on the period of temperature decrease.
- Thermostabilizers used to decrease ground temperatures and increase the resistance against vertical forces due to frost heave also eliminated uplift deformation of the pile foundations for a power line support.

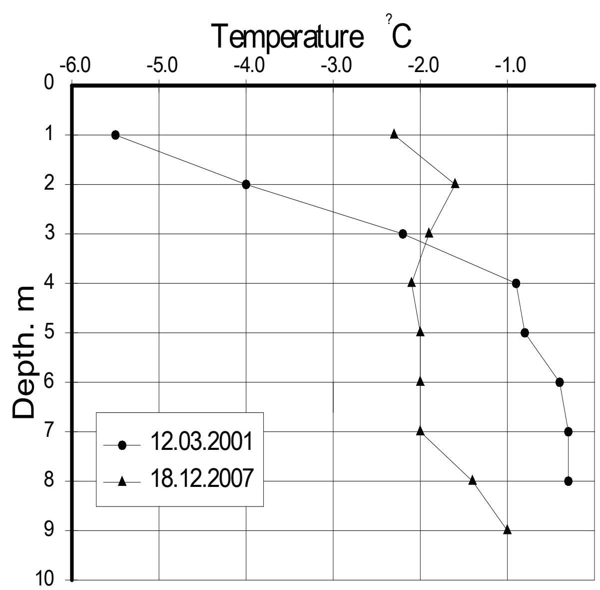

Figure 7. Ground temperatures before (2001) and after (2007) the installation of thermostabilizers the near power line support No. 44.

- The effectiveness of thermostabilizers depends on the initial ground conditions, properties, composition, and temperatures.
- The data obtained confirm the validity of engineering solutions by the use of seasonal cooling devices to increase the bearing capacity and stability of piles in permafrost.

Vegetation Response to Landslide Spreading and Climate Change in the West Siberian Tundra

N.G. Ukraintseva
Institute VNIIST (Institute of the Engineering and Construction of the Oil-Gas Pipeline), Russia

Abstract

Cryogene landslides are widespread and well investigated in the sub-arctic tundra. On the Upper Pleistocene marine plains, active landslide process brings to the surface marine saline deposits saved by permafrost. The landslide-affected slopes present a system of morphologically expressed and often overlapping landslides of different age. Patterns of re-vegetation and "self-stabilization" of landslides as indicators of landslide age have been studied. Natural enrichment of the soil, water, and vegetation in many nutrients leads to anomalous productivity on landslide-affected slopes and to the expansion of high willow shrub to the north. Areas of near-surface distribution of marine saline deposits and old landslides are correlated to the area of high willow shrub tundra. Estimation of cryogenic landslide distribution north of Western Siberia has been studied using methods of landscape indications. Spreading of cryogenic landslides further to the north may be an indication of a warming tendency in the Aarctic climate.

Keywords: cryogenic landslides; marine deposits; willow shrub.

Introduction

Special interest in studying the process of cryogenic sliding has arisen after a mass descent of landslides in many areas of the Russian and North American Arctic regions in 1988–1991. Landslide processes affect the surface of marine plains and terraces. The permafrost table serves as a "mirror" for sliding masses; therefore, the majority of researchers name them "cryogenic landslides" or "active-layer detachments" (Levkovicz 1990, Harry & Dallimore 1989, Leibman 1995, Poznanin 2001). The cryogenic landslides are developing on surfaces built of fine-grained marine sediments with high salinity. Outcropping of frozen salty marine sediments took place due to seasonal sliding of the thawed water-saturated ground over the permafrost table. This process leads to sediment desalinization and enrichment of the active layer with salts (Dubikov 2002, Leibman 1995, Ukraintseva et al. 2003).

The purpose of the present study is to estimate the distribution of cryogenic landslides in the north of the Western Siberia using methods of landscape indication.

Study Area and Methods

The basic area of research is the region of the Bovanenkovsky gas refinery (between the Mordyjaha and Naduyaha Rivers) and projected gas pipeline "Yamal Center" in western and central Yamal. The author's research materials from the Peljatkinsky gas refinery (Lake Pelyatka, southern Gudan) and the coast of the Yenisey Gulf (Shajtansky, western Taimyr) are used also.

The research station of "Vaskiny Dachi" is located in typical tundra of central Yamal. Since 1991, field groups from the Earth Cryosphere Institute of the Russian Academy of Sciences (Tyumen) have been studying cryogenic landslides (with participation of the author). The technique of field sampling and laboratory analysis of samples is described in the paper by Ukraintseva et al. (2003).

Figure 1. Study area: research station Vaskiny Dachi in central Yamal Peninsula is marked by the star.

In the area of the Bovanenkovsky gas field, 10 key sites within landscapes of IV, III, and II marine plains and terraces in the valleys of Nadujjaha, Seyaha, and Mordiyaha Rivers were explored. The large-scale landscape map of the Bovanenkovsky area was made using GIS-Technologies (Drozdov & Ukraintseva 2000). A method of landscape indication was applied to determine the relative age of landslides slopes (young and ancient) in each landscape.

The landscapes map of the north of Western Siberia published in 1991 (with scale 1:1,000,000) was used for extrapolation of the obtained data to all typical tundra. The legend of the landscape map of the Bovanenkovsky gas field was generalized and made consistent with the legend of the published map. This allowed the extrapolation of calculation results according to the principle of landscape analogies and estimation of a fraction of landslide slopes in landscape areas of typical (sub-arctic) tundra.

Spatial distribution various vegetation communities was evaluated using an analysis of the distribution of Nenets'

names (toponyms) on topographic maps of northwestern Siberia with a scale of 1:1,000,000 (with insertion of several larger scale pieces).

Landslides in the Subarctric Tundra

Biogeochemical features of landslide-affected slopes

In the region of typical tundra where salted marine loams and clays lie close to a surface, cryogenic landslides of sliding are widespread on the Upper Pleistocene marine plains and terraces and have been studied in detail. Extended landslide slopes represent a system of morphologically expressed landslides of different ages quite often overlap each other. In comparison with background conditions, biogeochemical features of ecosystems of landslide slopes vary significantly. The main features of landslide processes in the regions of interest were described earlier:

- Mechanical displacement of land, mixing, and increase of heterogeneity (vertical and lateral) of granulometric structure of the active layer (Ukraintseva & Leibman 2007);
- Periodic activation and recurrence of landslide descent, leading to change of a longitudinal profile of a slope and position of the permafrost table (Ukraintseva et al. 2003);
- Destruction of topsoil layer and vegetation cover along the sliding surfaces, and burial of organic soils on the landslide bodies (Ukraintseva & Leibman 2007);
- Desalination of the marine premafrost and enrichment of the soil-vegetation cover with dissolvable salts (mineral nutrients), accelerating "self-stabilization" process of the landslide-affected slopes (Ukraintseva et al. 2003);
- Age of the landslides defined by the radiocarbon dating of buried organic matter, varies from 0–30 till 1500–2000 (Leibman et al. 2000).
- Increase of fertility of the soils enriched by nitrogen, potassium and organic matter: peat soils prevail in ancient landslide slopes with thickness of organic layer 20 cm or more (Ukraintseva & Leibman 2007);
- Change of structure and increase of the phyto-mass storage on the surface of the landslide slopes represented by high willow shrubs (Ukraintseva & Leibman 2000, Ukraintseva 2004).

The rich microelement structure of the substratum promotes zinc accumulation in leaves and trunks (Fig. 2), and raises the frost resistance of willow. Due to this, willows form steady communities in unusually high latitudes (up to 70°N, –72°N). This is confirmed by conclusions of other researchers who refer to willow bushes as pioneer plants which spread out into natural or human-caused bare soil tundra (Andreev 1970, Burn & Friele 1989, Geertsema & Pojar 2007, Matsuda et al. 1988, McKendrick 1987, Pospelova & Pospelov 2000, Rebristaya et al. 1995, Sturm et al. 2001, Ukraintseva & Leibman, 2000).

The next step in research of the landslide processes is an estimation of their spatial distribution.

Landscape indicators of landslide-affected slopes

On large-scale aerial images, -only young landslides (younger than 100 years old) can be detected. Old and ancient landslides are expressed weakly in morphological structure and do not have direct pattern on the image. For mapping of PLAITS on aerial images, the indirect method—the method of landscape indication based on studying of spatial and temporal variation of a vegetation cover—is applied.

In the investigated areas, the dominating community of hill tops and stable slopes is bush-grass-moss and bush-lichen-moss tundra—the background communities of typical tundra. The vegetation cover on the landslide slopes sharply differs from the background.

There are three basic stages of re-vegetation of landslides, and there are three gradations of landslide' relative ages, respectively: young, old, and ancient (Ukraintseva et al. 2003, Rebristaya et al. 1995). On *young* surfaces of landslides (10–15 years after a landslide occurred), bare soil sites alternate with pioneer meadow groupings of *Phippsia concinna, Tripleurospermum Hookerii*, etc. At the same time, some short bushes (willow, dwarf birch) still remain on young landslides; mosses degrade and wilt, and pioneer plants (cereals, a sedge, a horsetail) appear. On *old* landslides (from 100–300 till 1000 years old), the second stage of re-vegetation is observed—meadow communities with participation of mosses and active renewal of a willow (0.3–1 m height). And finally, associations of *Salix glauca* and *S. lanata* (height: 1.5–2 m) are characteristic for *ancient* landslides (from 1000

to 2000 years old (Leibman et al. 2000)—sparse moss-grass willows on surfaces of sliding and dense grass-moss willows on landslide bodies. High willows occupy the most area on the landslide slopes.

Successive stages of re-vegetation of landslides determine choice of landscape indicators. Two last stages of landslide re-vegetation are poorly distinguishable on aerial images, merging together and creating a small grey texture of bush communities. Thus, the landscape indicators of old and ancient landslides (older than 100–300 years) are high willows (an index *6n*), and modern young landslides are identified by pioneer meadow communities with bare soil surfaces (an index *6p*).

Distribution of landslide-affected slopes on the Bovanenkovsky gas field

On a large-scale landscape map of the Bovanenkovsky gas field (Drozdov & Ukraintseva 2000), the relative age of landslide slopes (young and ancient) in the structure of each landscape is calculated. The maximum distribution of landslide slopes is characteristic for large-hill thermodenudation areas of III marine plain (III m: V = about 57%). The fraction of young landslides from the total area of landslide slopes for all districts does not exceed 20–30% that indicates some attenuation of process (Fig. 3).

Landslide slopes in typical tundra

The map of natural complexes of nnorthwestern Siberia (scale 1:1,000,000) published in 1991 was used for extrapolation of the received data on all typical tundra. In the region of typical tundra, eight landscape areas are allocated, for each of which the histogram of morphological structure—a percentage of landscape and land area—is determined. This allowed extrapolation of results of calculations by a principle of landscape analogies. The legend for a landscape map of the Bovanenkovsky gas field was generalized and is made consistent with a legend of the published map.

Evaluation of the distribution of landslide slopes in typical tundra of western Siberia is presented in Table 1.

Areas of landslide processes occupy more than 16% of a total area of typical tundra zone. It is a high percentage, considering that landslides occur only in the most elevated locations. The maximum activity of landslide development—over 30% of the area—is characteristic for central Yamal (area 12) and western Gudan (area 14), where hilly sites (V) consisting of permafrost marine loam and clay with salinity over 0.5% (Dubikov 2002) prevail. Landslide slopes occupy about 15–20% of the area of Western Yamal (area 11), Gydansky ridge (area 16), and Tanamo-Yenisey valley (area 18). The structure of these areas almost does not concede to the first two, but the fraction of sand covering salted marine clay increases. The fraction of landslide slopes is minimal in low, strongly boggy, mainly sandy areas (A) with widely-developed river network: east Yamal (area 13), valleys of the rRivers Juribej (area 15) and Tanama (area 17) on Gudan Peninsula.

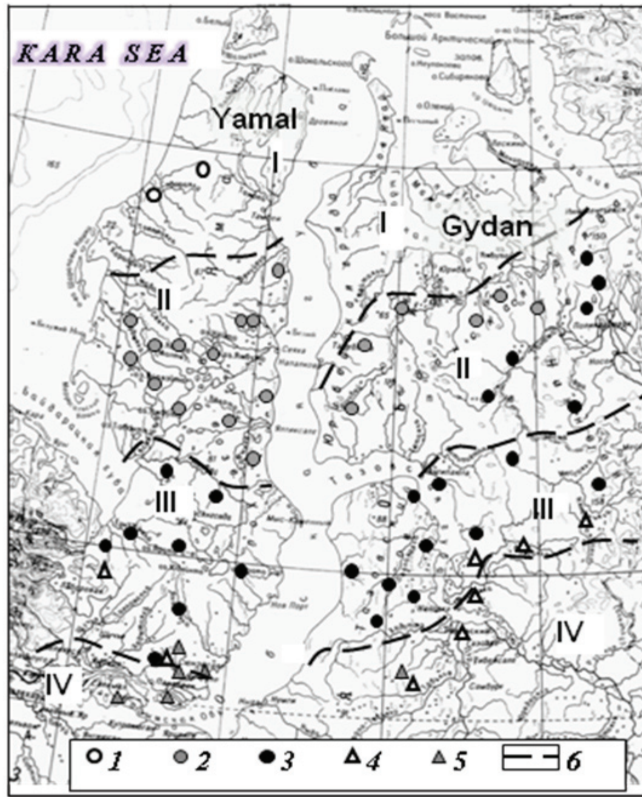

Figure 4. Nenets toponymics (denominations) on the West Siberian topographical map. 1–*pyasyada, tartsya (*nude); 2–nero, *nerka,, neruta* (willow shrub, willow canopy, *Salix sp.*); 3–*pae, paya* (alder shrub, *Alnus fruticosa*); 4–*kharv* (larch, *Larix sibirica*); 5–*khadita* (fir, *Picea obovata*); 6–limits of subzones. Zone and subzone: I-arctic tundra; II–typical (subarctic) tundra; III–southern (low) tundra; IV–forest-tundra.

Willow tundra in Nenets toponymics

The main feature of toponymics of the Nenets people living in the Far North in severe climatic conditions is their deep penetration into nature. To survive in tundra, every Nenets knows (notices) seasonal rhythms of nature and is able to predict the approach of sharp changes of weather and extreme natural phenomena by monitoring the behavior of animals or the state of the vegetation. Figure 4 shows zone borders from the map of northwestern Siberia and the distribution of Nenets toponymics characterising the vegetative cover.

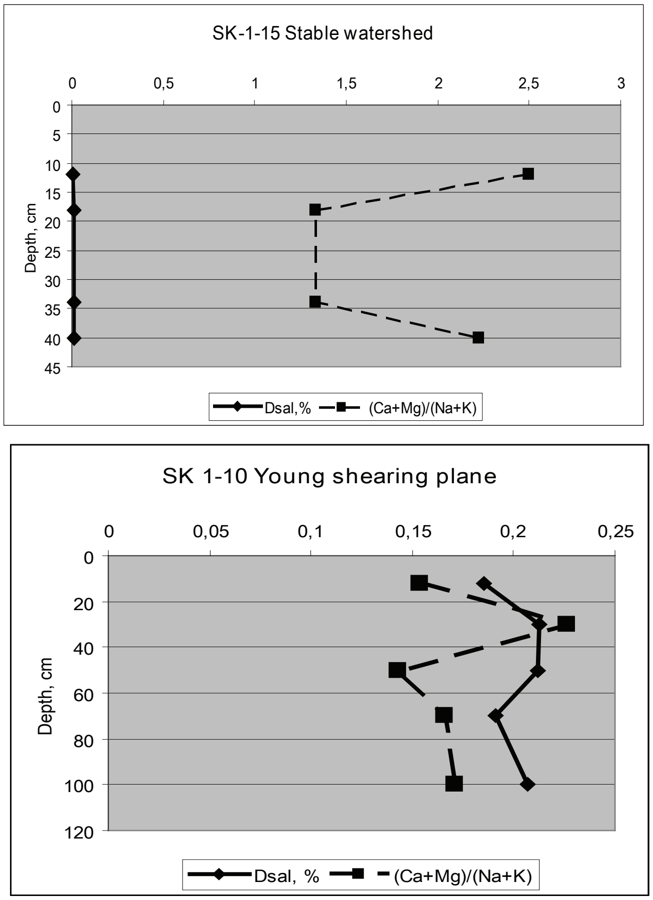

Figure 5. Salinity and cation ratio in active layer profiles on Cape Shaitansky, Western Taimyr. Top panel–stable watershed; bottom panel–young shearing plane.

Thus, the typical terms for the Arctic tundra are *pyasyada* (bald) and *tartsya* (nude). In typical tundra, the names *nero*, *nerka*, *neruta*, and *neromo* (willow shrub, willow canopy) are very common. Borders of southern tundra are underlined by various names with a root base of *pae* or *payu,* corresponding to alder shrubs. The northern limit in the spread of these names on the Yamal Peninsula is the lower part of River Juribej. And it was 40 km from the mouth of Juribej, where the first and the most northern curtains of alder shrubs have been observed on the aerial images.

Toponymic areas repeat outlines of natural zones and subzones, being a little displaced to the north. In the eastern (Prienisejsky) part of the region, the warming effect of the Yenisey River accounts for the especially considerable displacement of toponymic area of alder and larch to the north.

Toponymic areas of alder shrubs and tree species are not in the focus of the present study of landslide slopes distribution. They are shown on the map to illustrate high correlation of Nenets' toponymics to the nature laws. The alder shrub is not an indicator of subzones in southern tundra since it grows mainly in valleys of the rivers (dependent sites). Willow tundra, on the contrary, is widespread on the watersheds (independent sites) where they can be the indicator of ancient landslide activity (Ukraintseva 2004).

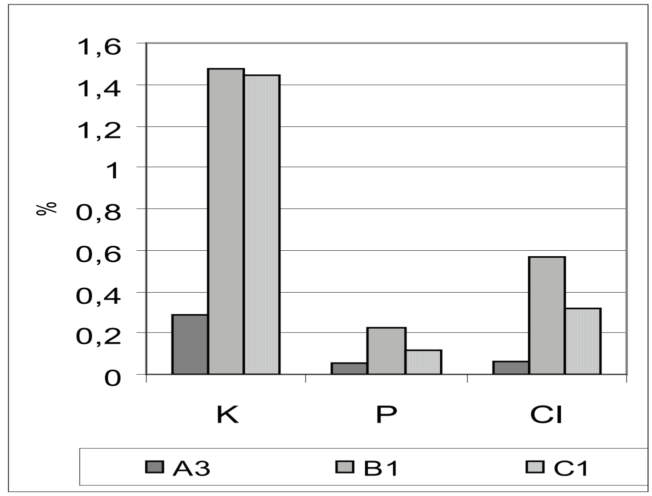

Figure 6. Potassium, phosphorous, and chlorine in grasses on Cape Shaitansky. A3–stable site; B1–shearing plain; C1–landslide body.

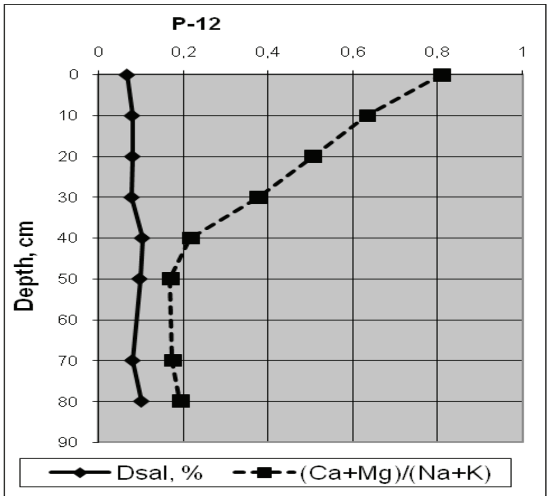
Landslides in the Arctic Tundra

Cryogen landslides with glide faces formed by the roof of the salty marine permafrost are widespread on the Yamal and Gudan Peninsulas, on the Taimyr coast of the Yenisey Gulf (from Dixon to Cape Shaitansky), as well as on the islands of the Canadian Archipelago (Ukraintseva et al. 2004, Harry & Dallimore, 1989, Lewkowicz et al 1990). Bare landslide surfaces with salt outcrops are well observed and overgrown with pioneer grasses and herbs with halophytes (vegetation cover varies from 10% to 80%). Landslide age being estimated by vegetation development ranges from a few to several dozen years.

Cryogen landslides are studied in Yenisey Gulf near Cape Shaitansky. The salinity and marine cation ratio (Dubikov 2002) in active layer witnesses the marine origin of sediments (Fig. 5). A joint plot of vertical distribution of salinity and cation ratio clearly illustrates the degree of diagenetic transformation of the marine deposits. On the young shearing plane, the saline marine clay got into the active layer only recently, and its desalination is still in the initial stage. The values of clay salinity on the young shearing plane profile (Fig. 5, bottom panel) are close to 0.2%, which is higher than cation ratio values (salinity curve is to the right from the cation ratio curve). The active layer of stable watershed and slopes was long-term flushed due to drainage and precipitation during the warm seasons of the year. In these areas, the salinity of the active layer is close to zero (Fig. 5, top panel), and the salinity curve is to the left from the cation ratio curve.

Grasses growing on the shearing plain and landslide bodies were considerably more enriched with chlorine, phosphorous, and potassium relative to stable areas, therefore marking leaching of these elements in stable conditions (Fig. 6).



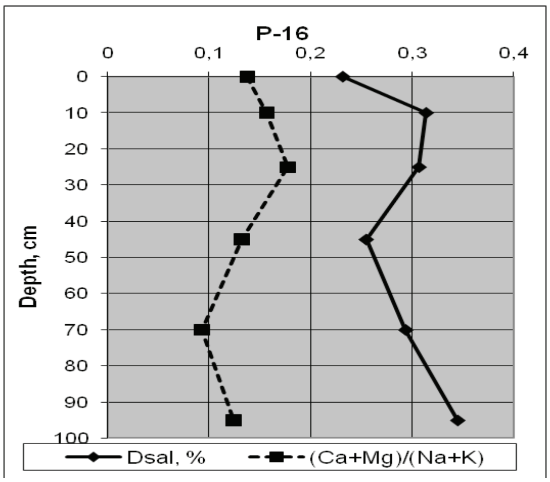


Figure 7. Salinity and cation ratio in active layer profiles on Pelyadkinsky gas field, Southern Gydan. Top panel–young shearing plane; bottom panel–the same shearing plane after repeated landslide event.

Landslides in the Low (Southern) Tundra

The 10–20-year-old landslide events have been studied in 2003–2005 in the Pelyatkinsky gas field located in southern tundra. Salinity and ratios of continental and marine cations also showed the initial marine origin of the sediments in these areas (Fig. 7). Unlike typical and arctic tundra, landslide events in southern tundra bring already significantly diagenetically reworked marine sediments to the active layer (Fig. 7, top panel); thus, cryogen sliding in these areas can be traced by thick layers of diagenetically reworked deposits. After repeated landslide events on the same slope in 2004, the saline marine layer has been exposed at the surface (Fig. 7, bottom panel). As a result, the saline marine permafrost lies twice as deep compared to modern thaw-depth: at 2.5 m depth or even deeper.

The slope is overgrown with low dwarf birch and undershrub-moss tundra. Despite the long-term desalination process, chlorine content is still higher in horsetail and willow leaves inhabiting shearing plains and landslide bodies as compared to the stable background surface (Fig. 8).

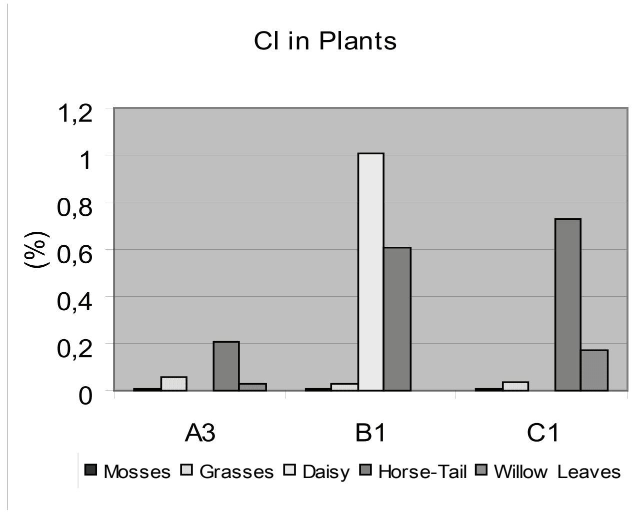

Figure 8. Chlorine in plants. For sites, see comments to Figure 6.

Conclusions

In the arctic tundra, young cryogenic landslides formed by the roof of the saline marine permafrost are widespread. Bare landslide shearing planes with salt outcrops are well observed and overgrown with pioneer grasses and herbs with halophytes. Landslide age estimated from vegetation development ranges from a few to several dozen years.

In the typical (subarctic) tundra, cryogen landslides are mostly widespread and extensively investigated. Areas of cryogenic landslide slopes have been evaluated using the landscape indicator technique, and they occupy close to 16% of the total area of the subzone. The cryogenic landslide process is the leading landscape-forming process in the typical tundra of western Siberia.

Maximum landslide activity (more than 50% of the area) is characteristic for the elevated plains of central Yamal and western Gydan, formed by permafrost marine loam and clay with 0.5% salinity and higher. The fraction of young landslide slopes (10–100 years old) is estimated not to exceed 5–30%. This is an indication of the gradual decay of landslide processes in these areas.

In the southern (low) tundra, cryogenic landslides have been active since the Holocene Hypsitermal (7000–8000 years ago). At the present time, the desalination process of landslide slopes is finished. The slopes are covered with thick mosses and high willow shrubs partially replaced by dwarf birch. Thick layers of old diagenetically reworked deposits containing a mixture of iron-enriched and buried organic-enriched sediments might be the only indicators that cryogenic sliding took place on these hill slopes.

Thus, during the Holocene, landslide processes slowly moved further north, causing the consequent spread of willow communities with high bio-productivity to the north. Southern tundra (at present the process is finished) formed 5000–8000 years ago; typical tundra (active process, widespread high willows), 2000–0 years ago; and arctic tundra (the beginning stage, young landslide slopes with grass cover and sparse willow restoration), 20–30 years ago. The indicator of the final stage of the landslide process is the replacement of high willow shrubs by typical zonal vegetation with a thick lichen-moss-litter layer.

Therefore, the presented study has demonstrated that the dynamic process of cryogen sliding caused by increase of heat, moisture, and seasonal thaw-depth is moving to the north. This can be considered as an additional indication of the global warming tendency in the arctic climate.

Abstract

Several lines of evidence indicate that permafrost is present at elevations above ca. 775 m a.s.l. in the Mount Alvear region of the Sierras de Alvear, Fuegian Andes, Argentina. Ground temperatures recorded to depths of 1.3 m in sorted circles remain near 0°C in late summer and suggest perennial frozen ground at a depth of approximately 1.5 to 2 m. Three active rock glaciers occur in the upper Alvear Valley. On the flat surface to the east of the Alvear Glacier, sorted circles are located in the centres of poorly-defined polygons. The latter are interpreted to reflect either joint widening in underlying bedrock or thermal-contraction cracking in bedrock. Collectively, this evidence suggests the presence of permafrost on the higher summits of the Fuegian Andes.

Keywords: Argentina; Fuegian Andes; ground thermal regime; mountain permafrost; rock glacier.

Introduction

The distribution and characteristics of mountain permafrost in the southernmost Andes are, to date, poorly known. This contribution provides both geomorphological and instrumental (ground temperature records) evidence for the occurrence of permafrost in the high levels of the Sierras de Alvear, Tierra del Fuego, Argentina (Fig. 1). The central sector of the Fuegian Andes is characterized by the presence of a wide variety of cryogenic landforms related to ground freezing and/or to nivation activity (e.g., frost-heaved clasts, patterned ground, debris lobes, clast pavements, and protalus ramparts) (Valcárcel-Díaz et al. 2006), and to permafrost occurrence (rock glaciers). According to Corte (1997), the lower limit of permafrost in the Fuegian Andes is located at 900 m a.s.l.

The research presented in this contribution has focused on an unnamed summit and the upper Alvear Valley (54°40′S, 68°02′W), both located ca. 2.5 km to the E of Mount Alvear and the Eastern Alvear Glacier, at elevations ranging from 775 to 1077 m a.s.l. The summit is a nearly flat, clast-covered surface with occasional rock outcrops. The upper Alvear Valley shows steep slopes and is bounded by an arête and a near-vertical rock wall. The bedrock is composed of Late-Jurassic basalts, porphyrites, and slates (Olivero & Martinioni 2001). Southern Tierra del Fuego climate is cold-temperate and wet (Tuhkanen 1992). Air temperature measured from January 2005 to January 2006, at 1050 m a.s.l. near the upper col of the Alvear Valley was -2°C. No precipitation data are available for these mountains. Snowfalls are frequent and may take place year-round, even during summer. Strong and persistent winds blow on the summit area, where gusts exceeding 140 km/h have been recorded. Vegetation cover is extremely scarce and is limited to communities of lichens and mosses.

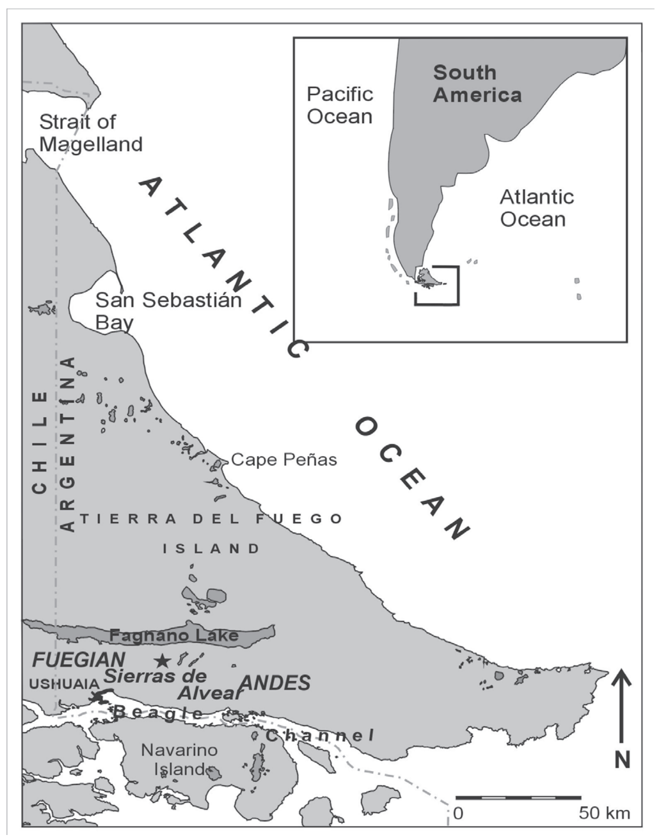

Figure 1. Location of the Sierras de Alvear.

Geomorphological Observations

A geomorphological survey, focused on the identification of potentially active landforms indicative of permafrost, was carried out in the summit area and the upper Alvear Valley.

The nearly flat summit is almost entirely covered by a sheet of rock rubble, composed of basalt and porphyrite angular clasts, overlying solid bedrock. The thickness of the rubble sheet is roughly estimated to exceed 1 m. However, small outcrops of bedrock occur, showing evidence of widespread and intense mechanical weathering. Poorly defined polygons, 4 to 5 m wide, delimited by shallow furrows or trenches 30 to 50 cm deep, have developed in the underlying bedrock. Small depressions or stone pits have formed in the intersections of the furrows. Sorted circles (“stony earth circles”), composed of an exterior border of coarse clasts enclosing an inner sector of sands, silts, and isolated larger clasts, occur in the centers of the polygons (Fig. 2). The latter are interpreted to reflect either joint or fracture widening in underlying bedrock or thermal-contraction cracking of the bedrock. Although it has yet to be proven if the polygons are presently active, the inner nonsorted circles show present-day activity related to seasonal freezing.

Three rock glaciers occur at the foot of the northwestern ridge of the upper Alvear Valley. According to shape, one is complex, the second is lobate, and the third is tongue-shaped. All of them are of reduced dimensions, but nevertheless, seem to be presently active. As the tongue-shaped rock glacier is better-developed than the others, the geomorphological survey was conducted on it. This is a small, talus-derived rock glacier 150 m long, 70 m wide, and 22 m high (Fig. 3). It is located at the foot of a southwest-facing, near-vertical rock wall, and it extends downwards to 775 m a.s.l. The root area grades into a steep talus slope (mean gradient is 36°). It is predominantly composed of angular, slate blocks, embedded in finer debris, and it is directly connected with its source area. The shales that form the rock wall are densely jointed and foliated, being highly susceptible to frost weathering and favoring talus production. Under present climatic conditions, talus production is considerable. Transport of debris from the talus to the root area of the rock glacier seems to be steady. This landform shows some of the features stated by Barsch (1996) as to be distinctive of active rock glaciers, e.g., steep front and side slopes (mean gradient is 38°), and exposure of fine, light-colored, unweathered material in the front and side slopes.

Figure 2. Oblique aerial view of nonsorted circles and polygons developed on the summit surface. Arrow indicates shallow borehole site.

Figure 3. View of the tongue-shaped rock glacier of the upper Alvear Valley. Arrows indicate the front slope of the complex rock glacier.

Methods

A shallow borehole equipped with thermistor probes was set up in the summit area. The aim was to get temperature records that could prove the occurrence of permafrost. Due to logistical problems, a similar borehole could not be drilled in the tongue-shaped rock glacier of the upper Alvear Valley.

The borehole is 2 cm in diameter, and it was made in the centre of a nonsorted circle located at 1057 m. a.s.l. (Fig. 2), using a battery-powered drill. Drilling was mainly conducted through a thick layer of frost-weathered rock rubble, up to a depth of 130 cm. Further deepening of the drill hole was impeded by the presence of solid bedrock. Thermistor probes were fixed with adhesive tape to a wooden rod 1.5 cm in diameter. The rod was then inserted into the drill hole, and the probes were installed at depths of 1, 5, 10, 20, 35, 70, 100, and 130 cm. Only the records corresponding to the probes located at depths of 1, 70, and 130 cm will be discussed in this paper. Temperature probes have a resolution of 0.03°C and an accuracy of ±0.25°C. Data were read and stored hourly using “U12” multi-channel data loggers (from Onset Computer Corp.).

The time span covered by the temperature records extended from mid-February 2006 to the end of January 2007.

Results

Figure 4 shows the temperature curves obtained from the shallow borehole of the summit. Ground temperature evolution at the surface (1 cm depth) is mainly characterized by the occurrence of short-term fluctuations throughout

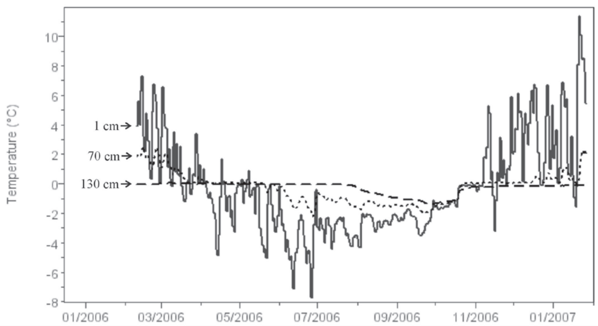

Figure 4. Temperature curves displaying daily mean values, obtained at depths of 1, 70, and 130 cm in the shallow borehole of the summit.

the year, including winter. The mean temperature of the recording period was -0.3°C. Minimum temperature occurred in early winter (end of June) and was -7°C. Temperature at the end of the winter (mid-September) was slightly below -3°C. Seasonal freezing extended from early April to early November and was interrupted on three occasions by daily above zero fluctuations. The end of the seasonal freezing (period from mid-October to early November) was characterized by an increase in temperature, attaining a nearly constant value close to 0°C, probably due to snow melting and heat transfer by percolating melt water. Daily frost mainly takes place during late spring and summer.

The evolution of ground temperature at a depth of 70 cm during the seasonal freezing period, shows a general trend similar to that at 1 cm depth. Surface daily fluctuations have been filtered at this depth, and the mean temperature was -0.28°C. Similar to the upper thermistor, the minimum temperature occurred in early winter (end of June) and in this case was -2.3°C. Seasonal freezing was not interrupted and extended from mid-May to early November. Two zero curtains occurred immediately before (from mid-April to mid-May) and after (from the end of October to mid-December) the seasonal freezing period.

Ground temperature at a depth of 130 cm continuously remained below 0°C, except from a short period of 20 days with positive values (from early to mid-March), in which a maximum temperature of 0.05°C was attained. The mean temperature was -0.28°C, and the minimum temperature occurred in early spring (end of September) and was -1.39°C. Short-term temperature fluctuations have been completely filtered at this depth, and only the annual cooling and warming cycle is observed.

Discussion

Evidence of the occurrence of perennial frozen ground in the summit area is provided by the temperature records obtained in the shallow borehole. Ground temperature at a depth of 1.3 m remained subzero almost year-round (mean temperature was -0.28°C), except for a short period in late summer (from early to mid-March), when it experienced slightly above 0°C values.

Winter short-term fluctuations observed in the surficial level of the borehole suggest the presence of a thin snow cover. The summit is swept by persistent and strong winds, limiting snow cover build-up. Direct exposure to the cold atmosphere throughout winter takes place, allowing deep frost penetration into the ground. Bearing this evidence in mind, permafrost is estimated to occur at depths below ca. 1.5 –2 m in the summit area.

The occurrence of permafrost in the upper Alvear Valley can only be inferred from the geomorphological evidence of activity observed in rock glaciers.

It is difficult to establish the lower altitudinal limit of the permafrost belt with the currently available data. However, if we consider the active rock glaciers of the upper Alvear Valley as permafrost indicators, then we can propose the approximate lower limit of discontinuous permafrost. This limit is roughly indicated by the elevation reached by rock glacier fronts (Barsch 1996). In our case, the lower limit of discontinuous permafrost would be at ca. 800–775 m a.s.l. Patches of sporadic permafrost could exist at lower elevation in particularly suitable topoclimatic locations.

The suggested limit is lower than that proposed by Corte (1997), who estimated the lower limit of permafrost in the mountains of Tierra del Fuego to be at 900 m a.s.l.

Conclusions

Preliminary observations suggest the occurrence of permafrost at 1057 m. a.s.l. in the unnamed summit located to the E of Mount Alvear and the Eastern Alvear Glacier, at depths below ca. 1.5–2 m. However, a longer time series from the summit borehole is needed to obtain definitive results.

The lower limit of the discontinuous permafrost in the studied area is tentatively placed at ca. 800–775 m a.s.l., according to the elevation reached by the front of active rock glaciers.

Further research is needed in order to gain a better understanding about mountain permafrost distribution and characteristics in the Sierras de Alvear. Proposed future work comprises geoelectric surveys and the drilling and equipment of new shallow boreholes (particularly in the rock glaciers of the the upper Alvear Valley).

Acknowledgments

The authors want to thank Professor Hugh M. French for his help and valuable suggestions during the 2007 field season. Thanks are also due to Mr Luis Lavado, helicopter pilot, for his logistical support. Two anonymous reviewers provided valuable comments that helped to improve the initial version of the paper. Their advice is greatly appreciated. This research has been funded by the Ministerio de Educación y Ciencia (Spain) projects CGL2004-03380/BOS and POL2006-09071, and it is a contribution to the International Polar Year.

Appearance of Heinrich Events on Pollen Plots of Late Pleistocene Ice Wedges

Alla C. Vasil'chuk
Geography Department, Lomonosov's Moscow University, Moscow, Russia

Yurij K. Vasil'chuk
Geography and Geology Departments, Lomonosov's Moscow University, Moscow, Russia

Abstract

The palynological characteristics of large ice wedges and surrounding syngenetic yedoma sediments at three locations in the Lower Kolyma River Valley in northeast Yakutia are presented. AMS ^{14}C dating of micro-organic and pollen concentrates from the ice wedges reveal sharp oscillations of pollen and spore spectra, and permit correlation of these rhythms with Heinrich events. The variability of global, regional, and local pollen components in yedoma sediments linked with periodical rhythms is discussed.

Keywords: ice wedge; Heinrich events; pollen; Yakutia.

Introduction

Coolings of the North Atlantic Ocean associated with Heinrich events appeared throughout the various natural systems at global and regional scales. For example, traces of Heinrich events are recorded in sediments of Lake Baikal as variations in diatoms and Fe(II)/Fe(III) ratios (Grygar et al. 2006), and maximum terminal position of glaciers in the Swiss and Austrian Alps (Ivy-Ochs et al. 2006). Regional response of Siberian landscapes linked to the North Atlantic's thermohaline circulation is indicated by oxygen-isotope analysis of syngenetic ice wedges and by pollen data from well-dated cross-sections of ice-wedge complexes. Simulation of Late Pleistocene circulation (Sarnthein et al. 2002, Lowe et al. 2006) shows that there was positive feedback for the northern Eurasian region. We suppose that Heinrich Events were characterized as times of low summer temperatures. Hence pollen spectra could be potential archives of Heinrich Events. Pollen is well preserved in ice-wedge ice because of low temperatures, the stable conditions of this closed system and the low microbial activity. ^{14}C dating of fossil pollen grains contained in ground ice could therefore provide new information about past environments. The pollen concentration in ice wedges is very similar to those of Arctic ice caps: approximately 10 to 1000 grains/l. As with Arctic ice caps (Bourgeois 2000), the pollen assemblages from ice wedges in arctic and subarctic tundra comprise a high percentage of far-travelled pollen, primarily tree pollen. The regional tundra pollen input is essential also, and the local pollen contribution is very small. The penecontemporaneous pollen grains and spores are also found in ice wedges (Vasil'chuk et al. 2003, 2005a, b, Vasil'chuk 2005, 2007).

To interpret the pollen variations in ice wedges and their host sediments we apply Yu.Vasil'chuk's (1992) multistage model of large syngenetic ice-wedge ice formation. The ice wedges develop as large pulses of subaquaeous deposition alternate with subaerial conditions of ice-wedge growth. The main water source for ice wedges is snowmelt water during the subaerial stage and mixtures of snowmelt, river or lake water during the subaqueous stage. Water enters frost cracks in spring, when snow melting and flooding take place. During the subaqueous stage "reworked" pollen and spores may enter into ice wedges.

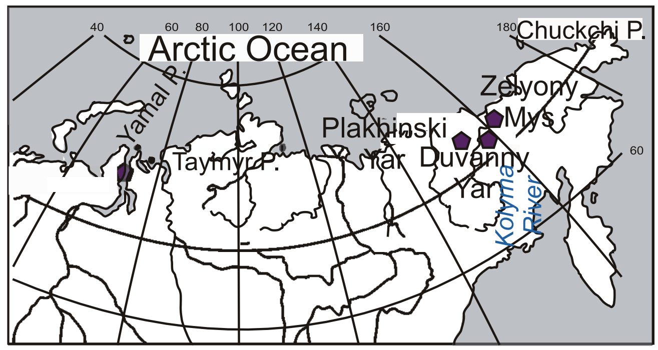

Figure 1. Location of ice-wedge sections in the Lower Kolyma River area of northeast Yakutia: Duvanny Yar, Plakhinskii Yar, and Zelyony Mys.

Regional Setting

The locations of the study sites in the Lower Kolyma River area of northeast Yakutia are shown in Figure 1. Vertical cross-sections through ice-wedge complexes were examined at Duvanny Yar, (69°N, 158°E); at Plakhinskii Yar, on the left bank of the Stadukhinskaya stream (68°40'N, 160°17'E); and At Zelyony Mys (70°N, 160°E), in northern taiga near the boundary with forest tundra. The mean winter air temperature is -22°C. This sequence with a depth of 22–24 m is especially valuable for palaeogeographical reconstruction because of the abundance of multistage ice wedges. The dominance of herb immature pollen indicates a very short vegetation period.

Results and Discussion

The Plakhinskii Yar exposure reveals syngenetic permafrost sediments with thick ice wedges. Here we present the results of a palynological study of ice wedges (16 samples) and the surrounding sediments (30 samples).

The pollen plot from sediments is dated by ^{14}C from 26 to 11 kyr BP, and the ice wedges are dated from 17 to 11 kyr (Fig. 2).

The sediments are characterized by a dominance of immature herb pollen (55.8–97.0%). Two intervals of very short vegetation periods are identified on the pollen plot: 24–21 kyr BP (9–12 m) and 17–11 kyr BP (3–6 m).

Larix pollen is found at a depth of 6.3 m in the sediments and also in the ice wedge at a depth of 8.2–8.8 m. The difference may be the depth of frost cracking at that time.

Every maximum of immature pollen comes before a local maximum of *Artemisia* and *Pinus pumila*. The pollen spectra of ice wedges show regional vegetation changes from 14 to 17 kyr; i.e., during the first Heinrich event. The *Artemisia* maximum (36.6%) coincides with a local maximum of immature pollen (42.2%) and a minimal amount of *Betula nana* pollen.

In the upper part of the plot the *Artemisia* content decreases and *Poaceae* increases together with *Selaginella sibirica* and *Pinus pumila.*

There are three development stages of vegetation cover. The first stage is single *Larix* trees, *Betula* sect. *Nanae* and *Poaceae-Artemisia* grass tundra. The second stage is the maximum development of herbaceous nival meadows (a very short vegetation period) with *Artemisia.* The third stage is grassland tundra.

Because the ^{14}C dates approximately correlate with H1, we suggest that pollen phase changes indicate this global climatic change. The structure of H2, according to ^{14}C-dates (21–23 kyr BP), can be followed only in the pollen plot of the sediments. The indicator of most extreme conditions is the maximum immature pollen, comes before the local *Artemisia* maximum (Vasil'chuk 2005, 2007).

The *Zelyony Mys* 36 m exposure of ice wedges occurs in loamy syngenetic sediments. There is no organic material in the upper 10 m. The lower 26 m consist of three layers of high and low peat content. Large ice wedges have shoulders at levels of peaty layers. The tops of small ice wedges are located at the level of the shoulders. The cryogenic structure is caused by subaqueous conditions of sedimentation and subaerial freezing of the sediment, together with peaty layers and ice-wedge growth (Vasil'chuk 1992).

According to the ^{14}C-dates, the duration of the subaerial stage is about 2–3 kyr, and that of the subaqueous one is about 1–1.5 kyr. From 37 to 27 kyr BP there were three subaerial periods. Gophers' holes mark subaerial horizons, when ice wedges grew in width. Seeds from the holes are dated at 30.5 and 32.8 kyr.

Figure 3 shows the results of a palynological study of ice wedges (11 samples) and the surrounding sediments (45 samples). The pollen plot of the sediments is dated by ^{14}C from 36–38 to 22–23 kyr BP, and the ice wedges date from 27 to 13 kyr. Every maximum of immature pollen corresponds with a local maximum of *Selaginella sibirica* and a local minimum of *Pinus pumila*. Most *Varia* is represented by *Brassicaceae* and *Rosaceae*. The seeds and pollen of *Potentilla nivea L., Draba cinerea Adam., Ranunculus repens L.*, are found in gophers' holes at a depth of 5–15 m (Vasil'chuk 2005).

Simultaneous changes in both local and regional components indicate regional or global changes of seasonal vegetation conditions. Maxima of *Pinus sibirica* are located immediately under peaty layers. Peaty layers contain high concentrations (up to 26%) of shrub pollen, mainly *Betula* sect. *Nanae*. But shrub remains have not been found.

There are three rhythms in the pollen plot of sediments, expressed by variations of local and regional components. At the base of the lower rhythm, the maximum percentages of *Selaginella sibirica* (about 40%) are replaced with maximum percentages of *Artemisia* (14.2%), *Poaceae* (16.4%) and *Betula* sect. *Nanae* (18.1%).

The most unfavorable conditions (very short vegetation season) are recorded by maximum percentages of unmatured pollen in the peaty layer at a depth of 24–22 m. The peat contains "reworked" organic material, as indicated by inverted ^{14}C dates. There is no penecontemporaneous pollen, but the content of coal particles is about 250%. Then the percentages of unmatured herb pollen decreases from 87 to 19%. Simultaneously there are increases in the content of *Pinus sylvestris* (21%) and *Betula* sect. *Nanae*. (19%) together with twin peaks of *Selaginella sibirica (*37–41%).

We suggest that sediments at a depth of 22 m accumulated at the erosion level caused by H3, about 29–27 kyr BP.

The next rhythm has another structure. The peak of *Betula* sect. *Nanae* (22.5%) is replaced with a maximum of *Pinus sylvestris* (19.8%), *Selaginella sibirica* (29.2%) and a very low content of *Poaceae.* This "suggests an" increase of the accumulation rate of sediments at the thermal minimum and subsequent improvement of vegetation season conditions.

Due to difference of the scales between the plots of sediment and ice wedges, we can look after regional changes of pollen rain of this rhythm at the pollen plot of the ice wedge. The maximum *Poaceae* and *Selaginella sibirica* is replaced by a *Pinus sylvestris* peak conterminous with maximum percentages of *Varia* at a depth of 20–18 m. According AMS-^{14}C dates of ice and the similar variations of regional components, we suggest that this rhythm coincides with H2 (about 23 kyr BP).

In the upper part of the pollen plot, *Pinus sylvestris* pollen disappears. The same variation of pollen is observed as at Plakhinskii Yar, and is correlated with H2. The *Artemisia* maximum is replaced by a peak of immature *Varia* pollen. The content decreases and *Poaceae* increases together with *Selaginella sibirica* and *Pinus pumila.* The final stage of H2 is absent in the ice-wedge record.

In the *Duvanny Yar exposure* large syngenetic ice wedges occurred in a 55 m thick section of loam (Fig. 4). The wedges are up to 3–3.5 m wide in the bottom of the cross-section, and up to 1.0–1.5 m wide in the upper part.

On the basis of more than 50 ^{14}C conventional dates of the host sediments we conclude that ice-wedge formation occurred from 37 to 17 kyr BP (Fig. 4). The age of the beginning of sediment accumulation is confirmed by a ^{14}C date of 31,200 yr BP from ice-wedge ice at a height about 6 m above sea level (Fig. 3), as well as by AMS ^{14}C dating of

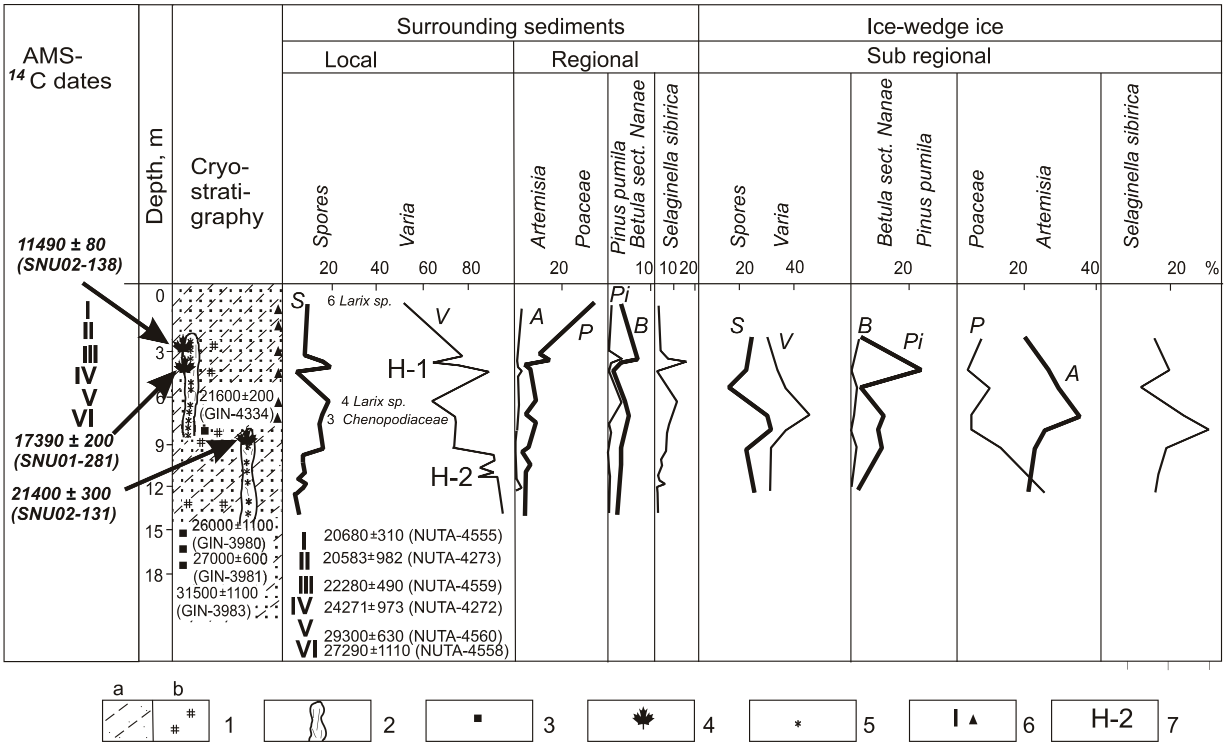

Figure 2. Pollen and spores plot of Plakhinskii Yar ice-wedge cross-section (after Vasil'chuk 2007 with corrections): 1 – sediments: a – sandy loam, b – peat remains in edoma sediments, 2 – large syngenetic ice wedges 3 – sampling point in surrounding sediments for radiocarbon dating; 3 – 4 sampling point of for AMS radiocarbon dating; 3 –of micro organic from ice-wedge ice 4 – of pollen concentrate from ice-wedge ice, 5 – 6 – sampling point for palynological analysis: 5 – from surrounding sediments, 6 – from ice-wedge ice; 7 - a cold phase of Heinrich events on pollen curve. Latin letters near to pollen curves indicate first letter of the name of the appropriate plant. NUTA – radiocarbon dates of Fukuda et al. (1997).

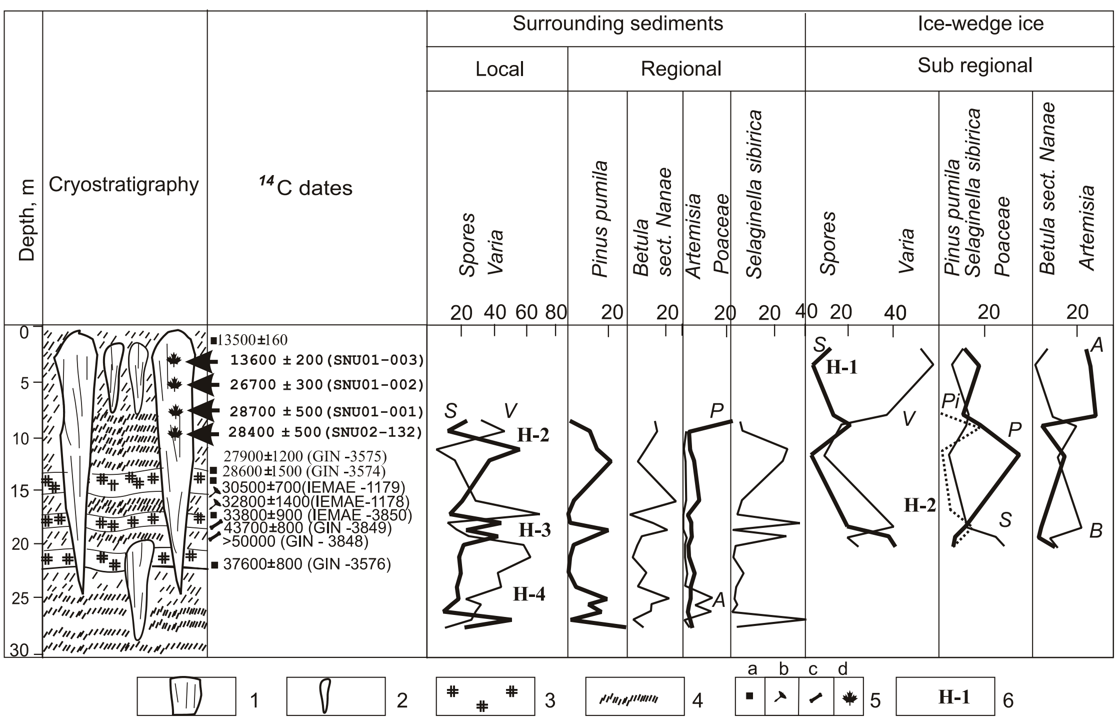

Figure 3. Pollen and spores plot of the Zelyony Mys ice-wedge cross-section: 1 – large syngenetic ice wedge 2 – small buried ice wedge 3 – peat remains; 4 – sandy loam; 5 – sampling point for ^{14}C dating: a – rootlets, b –seeds, c – bones; d – micro organic remains ≤ 200µm; 6 – cold phase of Heinrich events on pollen curve. Latin letters near the pollen curve indicate first letter of the name of the appropriate plant.

separate fractions of plant organic material separated using a microscope from samples of mixed plant detritus.

Here we present the results of a palynological study of sediments (93 samples) and their contained ice wedges (23 samples). The pollen plot of sediments dated by ^{14}C is from 31 to 14 kyr BP. The ice wedges have been dated from 25 to 14 kyr BP (Vasil'chuk 2007, Vasil'chuk & Vasil'chuk 1998, Vasil'chuk et al. 2004).

A main feature of the Duvanny Yar pollen plot is the stable ratio between local components. This suggests that sediment accumulation took place during stable local conditions. Various herbs and *Selaginella sibirica* represent local vegetation. Minimal salt concentrations correspond to high percentages of *Varia* and *Poaceae*, whereas maximum salt concentration corresponds with a peak of *Selaginella sibirica*.

Larix pollen is found in ice wedges, indicating that larch occurred as isolated trees in that vegetation community. The three small peaks of Artemisia percentages (4.5–5.1%) indicate short-term dry periods. It is possible to assume that the sediment at the depth of 15–19 m accumulated at 27–29 kyr BP and corresponds to H3. It is also possible to correlate an increase of *Poaceae* with a warm phase, and a subsequent maximum of Artemisia with H2 (21–23 kyr BP). In the upper part of the plot is observed a typical distribution of the components for H1 (16.5–14 kyr BP).

Pollen spectra of ice wedges demonstrate regional peculiarities of two rhythms of vegetation cover changes. The lower one, at a depth of 11.6–21 m, is similar to the lower rhythm of the ice-wedge plot of Zelyony Mys. The maximum spores percentages correspond with the *Poaceae* peak, which is replaced by *Artemisia* and then by *Varia* peak. We equate this rhythm with H2 (21–23 kyr BP).

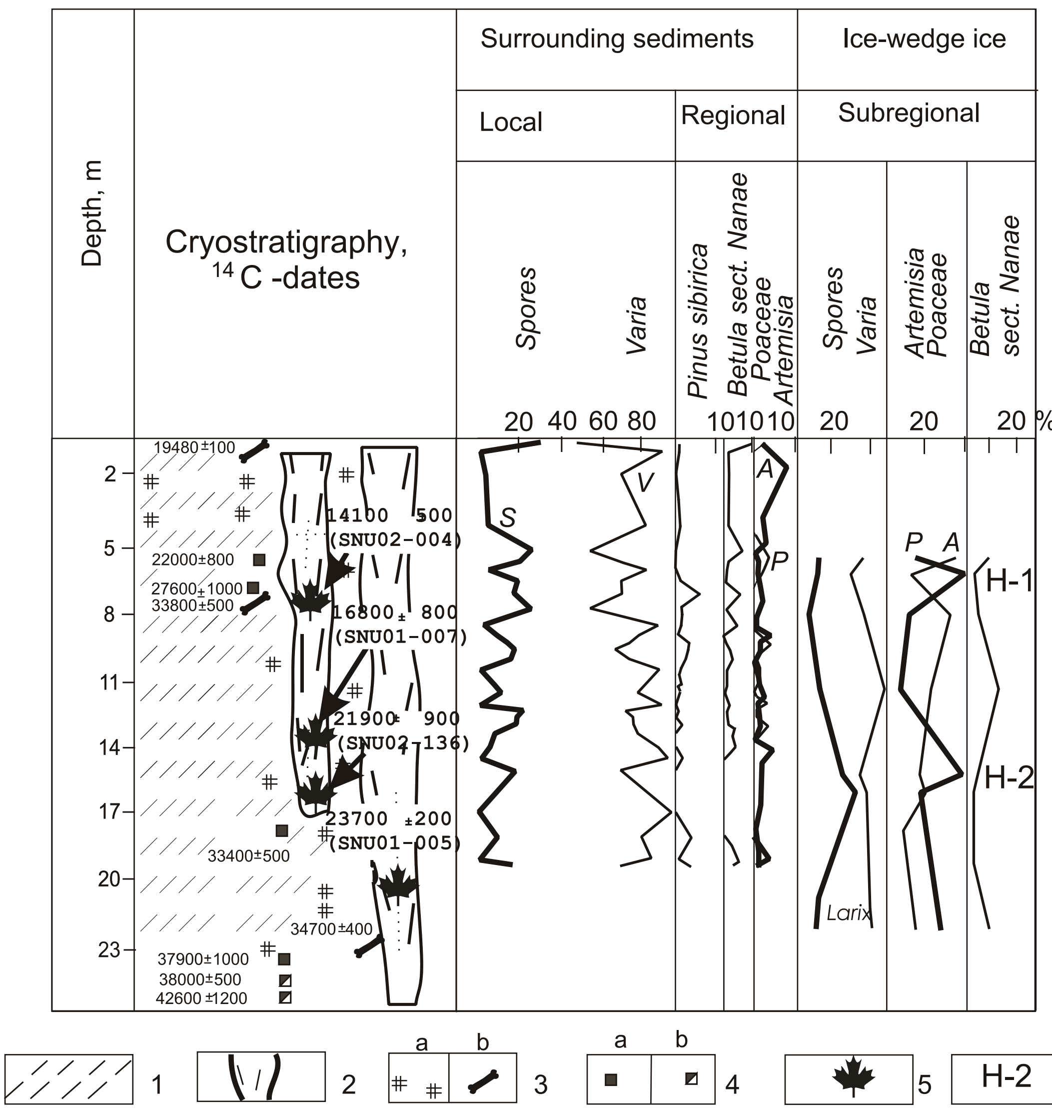

Figure 4. Pollen and spores plot of Duvanny Yar ice-wedge cross-section (after Vasil'chuk 2007 with corrections): 1 – sandy loam; 2 — large syngenetic ice wedge; 3-a – plant remains and peat, b – bones; 4 – sampling point for radiocarbon dating: a – rootlets, b –branches; 5 – sampling point from ice-wedge ice: for AMS ^{14}C dating, of pollen concentrate; 6 – a cold phase of Heinrich events on pollen curve. Latin letters near to pollen curves indicate first letter of the name of the appropriate plant.

The structure of upper rhythm (11.6–5.5 m) is similar to variations of the main components observed in ice wedges of Plakhinskii Yar. The fluctuations of the contents of *Poaceae* and *Artemisia* pollen are opposite. The *Betula* sect. *Nanae* peak follows Artemisia. This rhythm corresponds to H1 (16.5–14 kyr BP).

Changes of vegetation cover are found at the same time intervals. They may correspond with Heinrich events (Bond et al. 1997, Veiga-Pires et al. 1999, Vidal et al. 1999, Ivy-Ochs et al. 2006, Parnell et al. 2007, Sepulchre et al. 2007). Every event has a specific appearance.

H1 is divided into three phases on the basis of pollen plots of the syngenetic sediments and ice wedges. The first pollen phase corresponds to relatively high temperatures and normal humidity, nival meadows and Pleistocene mesic tundra with a mosaic of shrubs and trees (*Betula* and *Larix*).

The second phase corresponds to low temperatures during the vegetation growth season, a very short vegetation season, low humidity and a maximum distribution of nival meadow vegetation (*Varia* and *Selaginella sibirica* or *Bryales*). The regional pollen rain is characterized by a prevalence of Artemisia pollen. The third phase corresponds to relatively high temperatures and increased humidity. *Poaceae* and *Varia* are prevalent and *Pinus pumila* pollen is represented in the regional pollen rain.

H2 is expressed by a change of a combination of peaks of *Poaceae* and *Selaginella sibirica,* by maximum immature pollen of *Varia* and then by the appearance of *Pinus sylvestris* pollen. This rhythm in the Lower Kolyma plain was asymmetrical.

The warm phase before the thermal minimum was relatively dry and long in comparison with the thermal minimum stage. A difference between the local and regional pollen rain was observed. The maximum distribution of vegetation of nival meadows took place simultaneously with the appearance of *Pinus* pollen.

H3 is characterized by consecutive changes of local peaks of *Betula* sect. *Nanae*, *Poaceae* and *Artemisia* and the disappearance of *Pinus pumila*.

H4 is characterized by an absolute maximum of *Selaginella sibirica*, then a sharp decrease of the total concentration of pollen and then twin peaks of *Poaceae* and *Artemisia* and *Betula* sect. *Nanae* pecentages growth.

These sharp oscillations of pollen and spores caused by global changes are recorded in other pollen plots of polygonal ice-wedge complexes of northern Eurasia. It is possible to find millennial scale events in Holocene ice-wedge complexes also as manifestations of a pervasive millennial-scale climate cycle operating independently of the glacial-interglacial climate state (Bond et al. 1997).

Dansgaard-Oeschger Events on Isotope Plots of Siberian Ice Wedges

Yurij K. Vasil'chuk and Alla C. Vasil'chuk
Geology and Geography Department, Lomonosov's Moscow University, Moscow, Russia,

Abstract

Hydrogen and oxygen isotope records with a resolution of 100–200 years were obtained from ice-wedge ice at four locations in Siberia. Micro-organic inclusions and pollen concentrates from ice wedges allowed precise AMS radiocarbon dating of the isotope records and comparison with GISP2 and GRIP ice cores. Separate Dansgaard-Oeschger events are distinguished within the ice-wedge ice and correlated with the Greenland ice cores.

Keywords: Dansgaard-Oeschger events; ice wedge; radiocarbon; stable isotope.

Introduction

Isotope records of Siberian ice wedges have become available from 50 sequences of syngenetic permafrost sediments of northern Eurasia (Vasil'chuk 1992, 2006). Late Pleistocene and Holocene syngenetic ice wedges have been studied throughout the Yamal Peninsula to the Chukotka and Magadan regions, and from northern Yakutia to the Aldan and Vilyui River valleys and to the Chara depression (Trans-Baikal Region) (Vasil'chuk 1992). At first we inferred a local origin for dramatic cyclic oscillations of stable isotope values within ice-wedge ice. However, the first radiocarbon dates of micro inclusions, alkaline extract and pollen concentrate directly in ice-wedge ice (Vasil'chuk 1992, 2006, Yu.Vasil'chuk et al. 1999, 2000, 2001, 2004, Vasil'chuk & Kotlyakov 2000) have fixed stable isotope curves of ice wedges onto a ^{14}C scale, allowing us to evaluate the duration of the oscillations.

A variety of multi-millennial oscillations from ice wedges with a dominant periodicity of ca. 1.5 kyr was obtained. Several parameters of ice-wedge isotope curves show some correlation with the GISP2 and GRIP $\delta^{18}O$ records (Dansgaard et al. 1993, Grootes et al. 1993, Jouzel et al. 2007), although not all of the same amplitude or frequency. Such changes might be associated with the response of winter temperatures in Siberia to freshwater anomalies in the North Atlantic, which dramatically reduce the transport of the meridional overturning cell. This paper addresses this question with ice wedge records dated by ^{14}C AMS. Four ice-wedge complexes are located in Yakutia, and one is in northwest Siberia. This enables us to follow the changes depending on longitude and distance from the Atlantic.

Regional Setting

We present several cross-sections with syngenetic ice wedges studied in detail. The Seyaha cross-section is located in typical tundra of northwest Siberia. Sections at Duvanny Yar, Plakhinskii Yar and Bison are located in forest tundra in the Lower Kolyma River Valley in northeastern Yakutia, and one at Mamontova Gora is located in taiga in Central Yakutia (Fig. 1). The ice wedges of these cross-sections have been dated directly by ^{14}C AMS.

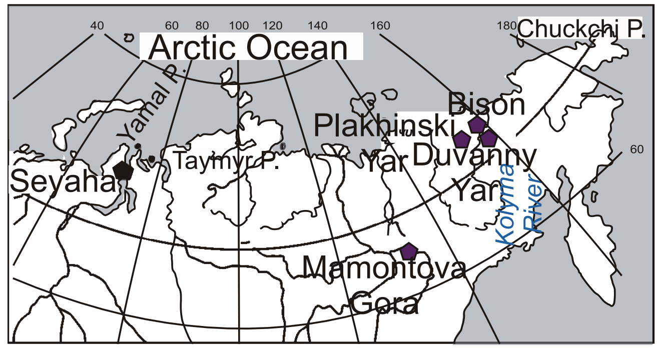

Figure 1. Location of Siberia ice wedge sections: Seyaha cross-section (70°10′N, 72°34′E, Yamal Peninsula, northwest Siberia), Duvanny Yar (69°N, 158°E, Lower Kolyma River, northeast Yakutia), Plakhinskii Yar (69°40′N, 160°17′E, Lower Kolyma River, northeast Yakutia), Bison (68°15′N, 150°45′E) (Lower Kolyma River, northeast Yakutia).

Dating Strategy

Many parts of cross-sections from modern permafrost areas can be dated by ^{14}C; however, date-inversions are common in permafrost, and this requires a special study.

In Arctic regions inversion of dates on different fractions of organic material is more likely the rule than anthe exception (Vasil'chuk & Vasil'chuk 1997). Contamination by old material is the main problem in ^{14}C dating of permafrost sediments because of the low decay rate of organic material and repeated re-deposition of old organic material (Nelson et al. 1988). The search for the most reliable subject for dating is a prominent part in a dating strategy for syngenetic permafrost sediments. So we suppose that the youngest ^{14}C date from a number dates of various fractions of the same sample or from the same layer is the most reliable method for determining the apparent age of syngenetic permafrost sediments and ice wedges.

Several different fractions were dated in the ice wedges, including organic micro-inclusions, alkali extracts and pollen concentrates. The micro-inclusions most likely originated from contemporaneous plant material and in most cases provided the youngest dates. Alkali extracts were older than micro-inclusions, with the difference between them ranging from 1100 years to more than 7900 years. It is evident that there is a correlation between ^{14}C-dates of pollen concentrate and re-deposited pollen and spores content. The youngest date corresponded to the minimum amount of re-deposited pollen and spores. This indicates a high probability of old organic contamination in organic material within permafrost. In a case like that it is impossible to calibrate AMS dates from ice-wedge complexes. So the comparison of ice-wedge isotope profiles with GRIP and GISP curves is approximate and the correlations could be done with shifts of 1500–2000 years.

However, in such a case where pollen concentrate from syngenetic ice wedges was relatively free from organic particles and contained well-preserved pollen and spores of typical Late Pleistocene tundra plants (dwarf birch and especially thin-walled pollen such as *Salix* or *Liliaceae*), the pollen concentrate ^{14}C date was the youngest (Vasil'chuk et al. 2005). The youngest numbers of ^{14}C AMS dates are utilized for dating of isotope profiles. The majority of them are the dates of micro-organic material; some dates are from pollen concentrate (Fig. 2, Table 1). In any case, the youngest date was picked as a base of ^{14}C scale.

AMS dating of ice wedges confirms the vertical stratification of ice-wedge ice, that is, where younger ice is located above older ice (i.e., syngenetic accumulation).

Results

Hydrogen and oxygen isotope records from ice-wedge ice with a resolution of 100–200 years were obtained from well-dated Siberian cross-sections. In each case the isotope profile was sampled along the axis of a single ice wedge.

1. Seyaha cross-section: the $\delta^{18}O$ values range from -25.0 to -20.4‰ (modern ice wedge $\delta^{18}O$ values range from -19.0 to -17‰). Direct ^{14}C AMS dates of micro-inclusions from ice are from 14,700 to 20,900 yr BP.
2. Duvanny Yar cross-section: $\delta^{18}O$ values range from -32.7 to -28.7‰ (modern ice wedge $\delta^{18}O$ values range from -24 to -27‰). Direct ^{14}C AMS dates of micro-inclusions from ice are from 14,100 to 25,900 yr BP.
3. Plakhinskii Yar cross-section: $\delta^{18}O$ values range from -34.7 to -28.7‰ (modern ice wedge $\delta^{18}O$ values range from -24 to -27‰). Direct ^{14}C AMS dates of micro inclusions from ice are from 11,400 to 21,400 yr BP.
4. Bison cross-section: $\delta^{18}O$ values range from -33.79 to -28.7‰ (modern ice wedge $\delta^{18}O$ values range from -24 to -27‰). Direct ^{14}C AMS dates of micro inclusions and pollen from ice are from 26,400 to 32,600 yr BP.
5. Mamontova Gora cross-section: the $\delta^{18}O$ values range from -29.0 to -25.4‰ (modern ice wedge $\delta^{18}O$ values range from -19.0 to -17‰). Direct ^{14}C AMS dates of micro inclusions from ice are from 18,900 to 13,900 yr BP. ^{14}C dating of stable isotope records from the ice-wedge ice shows millennial scale changes of isotope composition. These oscillations can be compared with Greenland ice-sheet records. The plots from each ice-wedge system could be separated into episodes correlating with Dansgaard-Oeschger events lasting 1–2.5 kyr (Fig. 2). AMS ^{14}C dates of the ice yields the age of the stable isotope shift.

The key points for the comparison of the ice-wedge ice record are found at the GISP2 and GRIP $\delta^{18}O$ records as positive shifts at the stable isotope curves.

The large $\delta^{18}O$ oscillations recorded in the Seyaha ice-wedge ice are ^{14}C dated to between 20,900 and 14,000 yr BP (Fig. 2a). A positive shift of $\delta^{18}O$ values of almost 4‰ and then a negative one of 4.2‰ from 17 to 15 m depths (dated about 17–15 kyr BP) in ice-wedge ice corresponds to a warm oscillation of D/O event 1 in the Greenland record: the Bølling and Allerød episodes.

Detailed AMS dating of Bison ice-wedge ice is based on 6 micro-organic dates and 5 pollen concentrate dates, allowing selection of the youngest dates from 32,600 up to 26,400 yr BP (Fig. 2b). The stable isotope record of this cross-section can be compared with some parts of the GISP2 ice core. Several episodes can be correlated with from 3 to 7 D/O events lasting 1–2 kyr. However, the shift of $\delta^{18}O$ values in this section is negligible (from -33.2 up to -32‰). This fact could be caused by reduced climatic response on global changes.

Similar to the Seyaha stable isotope profile, a significant oscillation of $\delta^{18}O$ values is observed in the upper part of Plakhinskii Yar ice-wedge ice record, which is ^{14}C dated 21,400–11,400 yr BP (Fig. 2c). A positive shift of $\delta^{18}O$ values of almost 4‰ and then a negative one of 3.5‰ from 4.5 to 1.5 m depths (dated about 15–11.5 kyr BP) in ice-wedge ice corresponds to D/O event 1 and possibly D/O event 2.

Oscillating $\delta^{18}O$ values are observed in the middle part of Duvanny Yar ice-wedge ice record, which is ^{14}C dated 23,700–14,100 yr BP (Fig. 2e). A positive shift of $\delta^{18}O$ values of about 4‰ and then a negative one in ice-wedge ice corresponds to D/O event 1. A second oscillation in underlying ice dated about 22,000–23,000 yr BP probably corresponds with to D/O event 2.

The 3‰ oscillation of $\delta^{18}O$ values in the Mamontova Gora ice-wedge ice is dated about 14,000–15,000 yr BP (Fig. 2f). It may correspond to D/O event 1.

Discussion and Conclusions

Ice-wedge ice originates from snow. Such ground ice is a natural archive of climatic changes. There are some differences, however, between the palaeotemperature interpretation of ice cores and ice-wedge ice. Ice cores are repositories of past precipitation.

One of the backbones of ice-core palaeoclimate reconstructions is the use of δD and $\delta^{18}O$ stable isotopes in the ice, which have classically been interpreted as indicating local to regional temperature (Dansgaard 1964).

The tritium concentration is low in all ice samples. It does not exceed 1.5 TU, indicating the absence of any exchange processes of Late Pleistocene ice-wedge ice with the external environment and high preservation of primary properties of ice-wedge ice, including its isotope characteristics.

The starting point for the analysis is to decide on criteria for defining DO events and determining the transition times.

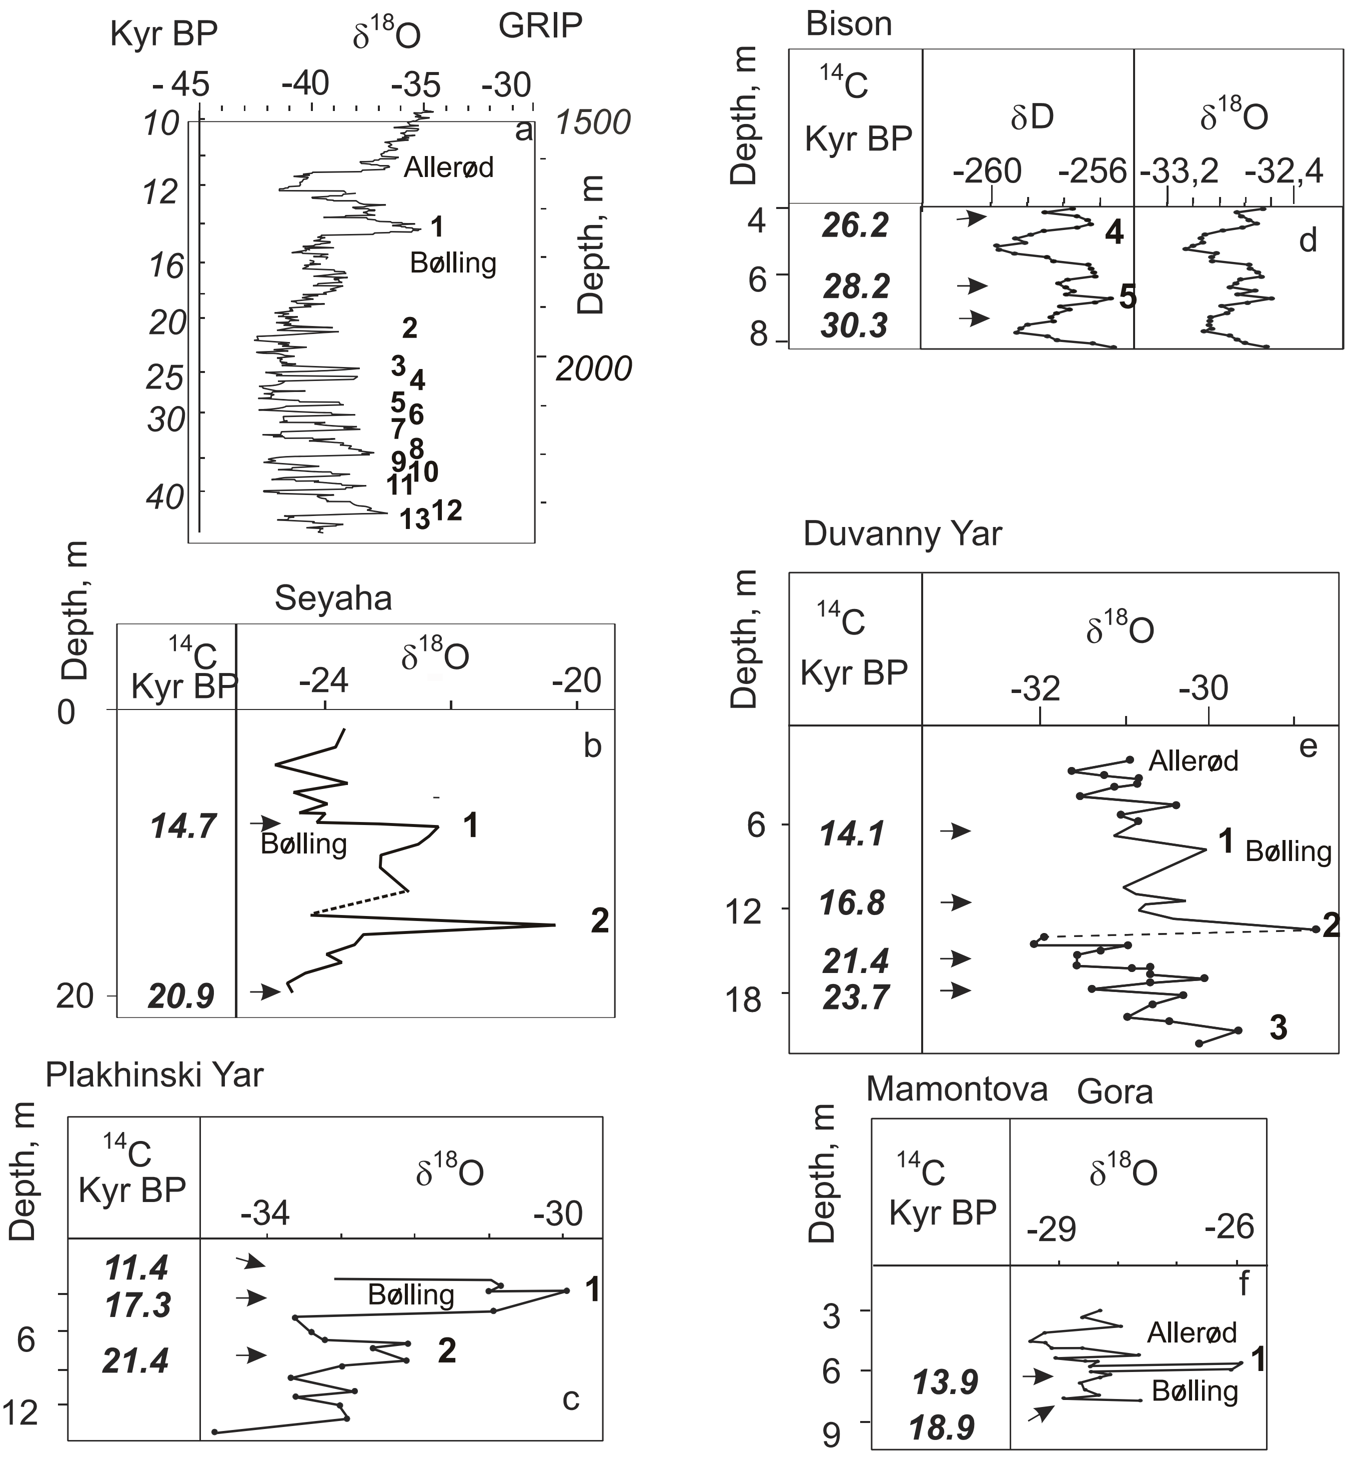

Figure 2. Comparison of Dangaard-Oeschger events of Siberian ice-wedge ice: a – fragment of GRIP ice core (Dansgaard et al. 1993); b – Seyaha cross-section, Yamal Peninsula; c – Plakhinskii Yar, Lower Kolyma River; d – Bison, Lower Kolyma River; e – middle part of Duvanny Yar; Lower Kolyma River; f – Mamontova Gora, Aldan River. Numbers – suggested number of D/O event.

The "canonical" numbered DO events were identified visually (Dansgaard et al. 1993). Schulz (2002) defined the DO events from a positive 2 permil anomaly in the 12 kyr highpass filtered isotope signal. By that DO9 is disregarded. Rahmstorf (2003) defined a criterion for increase of 2 per mil within 200 years on the 2 m sampled record (approx. 100 years lowpass). In this way DO9 is omitted and an event "A" in the Allerød period is included. Alley et al. (2001) use a bandpass procedure by which 43 events in the glacial period were defined. Ditlevsen et al. (2005, 2007) defined first upcrossings of an upper level following upcrossings of a lower level as a criterion. In this way the critical dependence on the (arbitrary) lowpass filter and crossing levels is to a large extent avoided (Ditlevsen et al. 2005). Using this

Table 1. Direct AMS radiocarbon dates of organic micro inclusions from Siberian ice wedge.

* AMS ^{14}C dating of pollen concentrate

criterion several additional DO events are identified, such as DO2, which is split into two separate events.

The sampling of ice-wedge ice for isotope analysis with a vertical interval of 10–15 cm and a horizontal interval of 3–5 cm corresponds to a resolution of 60–100 years according to layer counting and ^{14}C AMS dating. The isotope records of ice wedges are shorter in comparison with Greenland ice cores. Moreover, ice-wedge records may contain gaps when ice-wedge formation stopped.

Having ^{14}C dated organic micro-inclusions in ice-wedges we can attempt to compare their stable isotope records with such records in polar ice. In the GRIP ice core, $\delta^{18}O$ values from 35 to 25 kyr BP range from -38‰ to -43‰ (Dansgaard et al. 1993) This is a factor of two higher than that in simultaneous Bison ice wedges (from -33.25 to -32.40‰). Such sharp excursions could be caused by Atlantic ice cover changes, especially in summer, whereas winter conditions were much more stable. The 100-year resolution of the Bison ice wedge isotope record shows changes of mean winter temperatures of the air. A number of matching points can be identified between the GRIP core and two fragments of ice wedges in Bison (see Fig.2). It is enough to identify similar sequences of major and minor events in the interval 35–25 kyr BP as in GRIP.

The d_{exc} values differ from those inherent in modern snow, d_{exc} – about 10‰. It is supposed that there was a difference in the mode of evaporation above the oceans during the Late Pleistocene, confirming the earlier data on small d_{exc} values for Late Pleistocene ice-wedge ice in comparison with Late Pleistocene Antarctic ice (Jouzel et al. 2007). Slight isotope variations of Bison ice-wedge ice do not give sufficient evidence for division into warm and cold periods from 25 to 35 kyr BP.

Late Quaternary climate instability implies rapid, closely linked changes in the Earth's environmental systems: hydrosphere, atmosphere, cryosphere and biosphere. Ice-wedge ice is one of the natural archives reflecting climatic changes. Direct AMS ^{14}C dating of ice-wedges enabled comparison of their stable isotope contents with those in polar ice. Ice wedges, however, cover a shorter time span than ice cores. By means of AMS ^{14}C-dating, paleoenvironmental proxies from ice wedges can be "stacked".

Variations of stable isotope ratios in ice wedges are similar to those in the ice cores. The range of $\delta^{18}O$ values from ice-wedge ice is about 2‰, indicating precipitation during wintertime and mean winter temperatures. In polar ice cores $\delta^{18}O$ is proportional to the difference between the mean annual temperature of the air above the inversion layer from which it was precipitated and the temperature of the precipitation source region. Atlantic ice cover changes especially in summer, whereas winter conditions were much more stable.

Several other ice-wedge sections have previously been analyzed (Vasil'chuk et al. 2005, Vasil'chuk 2006). At Zelyony Mys (69°N, 160°E, Lower Kolyma River) the ^{14}C dates range from 13,600 to 28,400 yr BP, and $\delta^{18}O$ values range from -34.1 to -29.4‰. At Mamontova Gora (64°N., 134°E, Aldan River) the ^{14}C dates range from 13,900 to 18,400 yr BP, and $\delta^{18}O$ values range from -29.4 to -25.9‰. At Phoenix (68°34'N, 158°34'E, Magadan Region) the youngest ^{14}C date is 11,000 yr BP, and $\delta^{18}O$ varies from -32.2 to -32.6‰ at the top to -24.9‰ at the bottom.

The most negative isotopic shifts are observed between 16.5–14 and 11–12 kyr BP. They demonstrate that a single spectral peak (indicating a ~1500 yr cycle) is characteristic of the records in both the Greenland ice sheet and Siberian ice wedges.

Especially interesting is the coincidence of D-O events 1 and 2 with distant ice-wedge sequences at Seyaha and Duvanny Yar.

Diverse palaeoclimatic evidence, including marine sediment data, pollen profiles, and glacial snow line data, indicates that the effects of at least some events were felt on a global scale (Broecker 1993). Recently well-dated curves with identifiable D-O events have been obtained for the last 10–60 kyr. Dansgaard-Oeschger events are described in the southern Aegean Sea (Geraga et al. 2005), by coccolithophores from the Gulf of Cadiz (NE Atlantic) and Alboran Sea (W Mediterranean) (Colmenero-Hidalgo et al. 2004), in bottom sediments in the Okhotsk Sea (Goldberg et al. 2005), and in the northern area of the East China Sea (Ijiri et al. 2005). Isotope records of Siberian ice wedges also demonstrate millennium scale oscillations (Vasilchuk et al. 2004). Stable oxygen and hydrogen isotope analysis of the ice in combination with adequate radiocarbon dates is one of the best tools available to obtain palaeotemperature information for the last 40 thousand years.

Several episodes lasting 1–2.5 kyr can be distinguished in isotope plots from each ice-wedge system. The AMS dates yields a precise age of the observed stable isotope shift. The ice-wedge records for northern Siberia are consistent in providing a chronological framework for this region. A ~1500 yr cycle characterizing both the Greenland ice sheet and Siberian ice wedges is observed.

Acknowledgments

The authors are grateful to Prof. H.Jungner, Dr. J. van der Plicht and Prof. J.-C.Kim for ^{14}C dating of pollen and micro inclusions in ice-wedge ice and organic material in host sediments, Prof. M.Geyh, Dr. W.Papesch, Prof. D.Rank and E.Sonninen for stable isotope analyses, and Dr. J.Murton for improvements to the final text.

Abstract

Active-layer monitoring in northern West Siberia started in 1972 at the Nadym site. Sites at Marre-Sale polar station in 1978 and Vaskiny Dachi polygon followed in 1991. Measurements are obtained within dominating landscape units and aimed at establishing active layer and ground temperature changes in various bioclimatic zones and landscapes. In 1993 the CALM (Circumpolar Active Layer Monitoring) project was launched, and monitoring began on the 100 x 100 m CALM grids at Nadym and Vaskiny Dachi and 1000 x 1000 m grid at Marre-Sale. The focus was on the active-layer dynamics in connection to climate change. Results obtained at the CALM grids, as well as at previously established sites and transects, facilitate estimation of the main factors involved in active-layer dynamics on various landscape units of the Tundra and Northern Taiga bioclimatic subzones under climate fluctuations. Results reveal that active-layer depth in mires is very sensitive to climate changes, while peatlands are least sensitive.

Keywords: active layer; climate change; ground temperature; monitoring; northern taiga; typical tundra.

Introduction

The northern part of the West Siberian lowland is characterized by relatively flat topography, variable drainage, marine and continental climate, and well developed latitudinal zonality (Melnikov 1983). Northern West Siberia is divided into three bioclimatic subzones according to the thermal and moisture balances: northern taiga, forest-tundra, and tundra. Surficial geology is dominated by sandy-clayey Pleistocene deposits. Permafrost distribution is continuous north of 67°N and discontinuous south of this latitude.

Active layer monitoring in northern West Siberia has been ongoing at the Nadym site (Northern Taiga subzone) since 1972, at Marre-Sale since 1978, and at the Vaskiny Dachi site since 1991 (both in Typical Tundra subzone, coastal and inland localization) (Fig. 1). The Marre-Sale and Vaskiny Dachi research sites are in the continuous permafrost zone, while permafrost distribution at Nadym is discontinuous.

Active layer/landscape interrelations are largely controlled by the composition and moisture content of the constituent soils. The maximum active layer is characteristic of sands, especially in recent blowouts that lack vegetative cover and are well drained. In the northern taiga, the maximum active layer may also occur in mires and dry tundra with peaty hummocks. The minimum active layer is found at the sites with relatively thick organic cover, mainly on fine-grained soils in poorly drained environments.

Observations are performed at environmentally homogeneous sites 10 x 10 m in size and along transects several hundred meters long that cross dominant landscape units (Table 1). Active-layer and permafrost temperatures are measured in boreholes up to 10 m deep at the same sites. Studies are aimed at establishing active-layer and ground temperature changes in bioclimatic subzones and landscape units within the context of climate change.

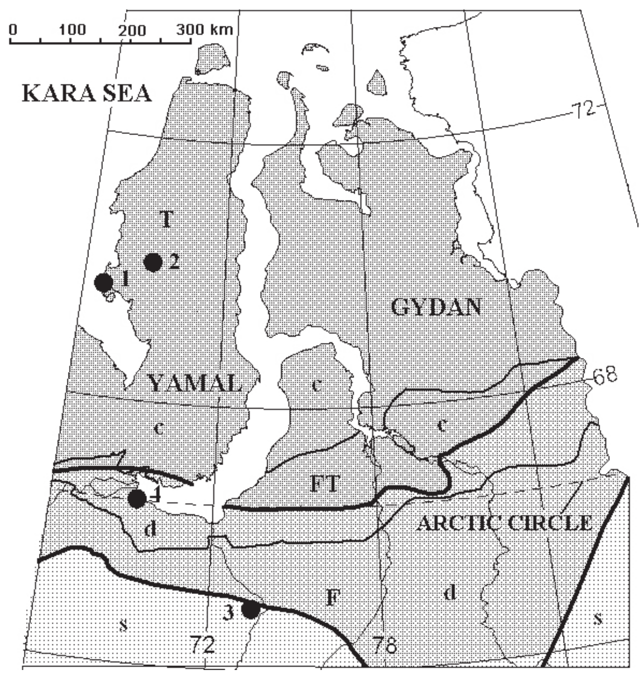

Figure 1. Location of the Marre-Sale (1), Vaskiny Dachi (2), and Nadym (3) research sites, and Salekhard weather station (4). Permafrost zones: c – continuous, d – discontinuous, s – sporadic.

In 1993–1995, observations following the protocol of the CALM (Circumpolar Active Layer Monitoring) project started on the 100 x 100 m CALM grids at Nadym and Vaskiny Dachi and on 1000 x 1000 m at Marre-Sale. The primary focus was on the active-layer dynamics in connection to climate change (Brown et al. 2001). The active layer studies within the framework of the CALM project were conducted for a number of years both on CALM sites, and on additional grids and profiles (Table 1).

Table 1. Metadata summary for CALM grid and additional grids and transects.

Research site	Observation unit	Unit size, m	Years of record
Marre-Sale	CALM grid (R3*), borehole 2 m deep	1000x1000	1995-2007
	Grid 1, borehole 10 m deep	10x10	1978-2007
	Grid 17, borehole 10 m deep	10x10	1978-2007
	Grid 36, borehole 10 m deep	10x10	1987-2007,
Vaskiny Dachi	CALM grid (R5*), borehole 2 m deep	100x100	1993-2007, 1999-2007
	Transect boreholes 5-10 m deep	320	1989-2006 1989-1993
Nadym	CALM grid (R1*), borehole 2 m deep	100x100	1997-2007
	transects 5x200 m	1000	1972-2007
	18 grids, boreholes 10 m deep	10x10	1972-2007

* CALM grid numbers are given as in (Brown et al. 2001).

Methods

Northern West Siberian north is known for wide distribution of saline marine deposits, and thus measuring the active layer in this area is not trivial. The salinity of clay in the active layer in the Typical Tundra subzone may be as high as 1.6% (Leibman & Streletskaya 1997). Some parts of the slope were subjected to landsliding that removed washout deposits to expose saline clay. Salinity in the active layer strongly correlates with the age of a landslide event (Ukraintseva et al. 2000).

In fine-grained soils mechanical strength changes gradually with decreasing unfrozen water content. When clayey soil is saline, the changes are much less apparent. At the same time, the freezing point departs from zero. Thermal measurements to determine the 0°C temperature position, when compared to insertion of a metal probe, show that in clayey soils the probe is inserted to a depth of 5 cm to 25 cm deeper than that of the 0°C isotherm depth (Leibman 1998); by comparison, Mackay (1977) measured a difference of 23 cm in early summer. In sand and silt the probe insertion can be even less than the 0°C isotherm depth due to higher mechanical resistance of the sandy-silty thawed layer. The probe can be inserted into the clay to a depth where ground temperatures are -0.5°C to -1.0°C according to our measurements (-0.6°C to -0.9°C in Mackay 1977).

CALM protocol (Brown et al. 2001) was applied from 1993–1995. Replicate thaw-depth measurements were performed using a metal probe in late August or early September, when the depth of seasonal thaw was close to maximum. The measurement error for the probe is about 1 cm. At the same time, in aeolian sands of the Marre-Sale grid in the warmest years the active layer depth may exceed the probe length (>160 cm). At Vaskiny Dachi, measurement error can be large owing to the presence of saline soils. In warm years thaw depth (or depth of penetration) at some Vaskiny Dachi probing points exceeds the probe length (180 cm) in the clayey active layer with the surface recently exposed by landsliding (Leibman 1998). Accordingly in this study, observations from such probing points were eliminated from calculations to better follow the interannual dynamics of active layer depth. The thaw index was calculated using monthly averages from weather records at the nearest meteorological stations.

A landscape survey was performed at each site based on the classification suggested in Melnikov et al. (1983). Determined were: structure of vegetative complexes and coverage as suggested in Moskalenko (1999); organic layer thickness by direct field measurements in similar areas adjacent to the probing point; density, moisture content, and chemical properties of soils, grain size, water content by volumetric weighting, and ionic analysis in water extraction. Geochemical tests were performed at Vaskiny Dachi to locate probing points with erroneous measurements due to recent landsliding.

Most of these methods were used since the 1970s and were improved within the framework of the CALM project. Measuring along the transects and within the landscape units started in the 1970s. Transects were set to cross the majority of the landscape units according to the results of a landscape survey. This approach is most common in the geocryological surveys in Russia, allowing us to extrapolate key site monitoring data to regions of similar landscape structure. This method helps when using remotely sensed imagery to map parameters not directly measured from space.

Climate

According to the climate zoning of the Russian Arctic (Prick 1971), the northern West Siberian lowland belongs to the Eastern region of the Atlantic sector of the Arctic Ocean. This region is subject to the strong impact of circulation processes from the mid-latitudes, specifically the Icelandic depression, and is subdivided into three zones. The northern tundra subzone of northern Yamal and Gydan peninsulas is characterized by marine arctic climate. The middle zones of typical and southern tundra of the Yamal, Gydan, and Tazovsky peninsulas are territories with marine sub-Arctic climate. The southern zone of forest-tundra and northern taiga is of moderate-continental climate.

The most important climatic parameters affecting permafrost dynamics are air temperature and snow cover depth. Northern West Siberia, due to climatic zoning mentioned above, is characterized by highly variable mean annual air temperature. At the Kara sea coast, mean annual air temperature decreases from -7.6°C on the southwestern coast of the Kara sea (Ust-Kara weather station, 69°12′N, 65°07′E) up to -11.3°C on the northeastern coast of Gydan (Gyda weather station, 70°53′N, 78°31′E) (Temperature of air and soils 1966). Inland there are few weather stations with short-term records. Within the study area, the southernmost inland station is Nadym, with the highest mean annual air temperature (-5.7°C). Calculations based on the short-term air temperature records show that the mean annual air temperature at Central Yamal decreases eastward, with a minimum at the main watershed of Yamal and at Vaskiny Dachi as low as -9°C (Belopukhova et al. 1989). At Marre-Sale the weather station mean annual air temperature is about -8°C.

Permafrost dynamics, including that of the active-layer depth, is linked to air temperature fluctuations. It is generally accepted that climate warming has been observed during the last 30–35 years (Pavlov 2003). Warming is more intensive inland, while along the coasts it is less expressed (Pavlov & Malkova 2005).

Figure 2 shows a time series of the mean annual air temperature at the West Siberian weather stations Salekhard, Marre-Sale, and Nadym. One can see that starting in the 1970s, there is a mean annual air temperature increase. Warming is rather synchronous across the entire region, though with local deviations. However, the degree differs. According to estimates by Pavlov & Malkova (2005) for northern West Siberia maximum warming is noted on the Tazovsky peninsula (Nadym area), exceeding 1.5°C. The least warming is in northern Yamal (0.7°C).

In analyzing long-term records for diurnal air temperature we noted that in the past 25 years in the tundra zone, the warm period has increased by 5–6 days, while in the northern taiga it increased by 15–17 days. The duration of the cold period decreased accordingly.

The thermal regime of permafrost is strongly affected by the thickness and regime of snow accumulation. In Marre-Sale the average perennial snow depth is 20–30 cm, while at Nadym it is as high as 50–60 cm, with year to year deviation. Total snow thickness tends to increase northward in West Siberia.

Results and Discussion

Results of active layer measurements at the monitoring sites located on the dominant landscape units are presented as Figures 3 and 4. The graphs show that active layer dynamics generally follow the sum of positive air temperatures, or thawing degree-days (DDT). However, one can see that short-term active layer records cannot characterize real trends in active layer evolution due to the oscillating nature of active layer dynamics. Still, it is apparent from the time series that all the landscape units show a tendency to increase over time since the 1970s until the recent. Trends of active-layer deepening within similar landscape units in the typical tundra are of smaller magnitude compared to the northern taiga. In the peatlands, active-layer changes are small, while in the mires and wet tundra they are much higher (Vasiliev et al. 2003, Melnikov et al. 2004). The same climate warming in the northern taiga is two times greater compared to the typical tundra.

Climate warming affects ground temperature, so permafrost reaction to climate change can be expressed in

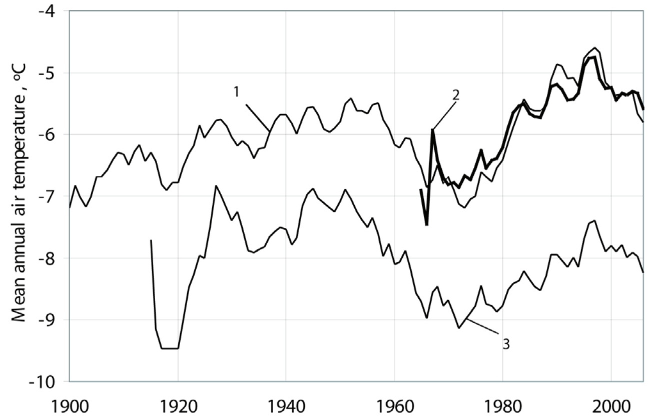

Figure 2. Ten-year moving averages of mean annual air temperature for Salekhard (1), Nadym (2), and Marre-Sale (3) weather stations.

mean annual ground temperature dynamics. In northern West Siberia the depth of zero annual temperature amplitude is about 10 m, the depth of most boreholes at the research sites. Results from the Marre-Sale and Nadym borehole temperature measurements, collected under conditions of changing climate at a depth of ~10 m, are shown in Figure 5. These traces also show oscillations that are similar to those for the active-layer depth. However, the mean annual ground temperature increase is more clearly marked since the 1970s. It is especially well observed at the Nadym site. At this station, in peatlands, the mean annual ground temperature rose from -0.9°C to -0.1°C. In the mires the mean annual ground temperature rose from -0.3°C to -0.1°C. Thus, in the discontinuous permafrost zone of the West Siberian northern taiga, recent climate warming has already caused a critical ground temperature increase approaching entire permafrost degradation.

In the typical tundra subzone, a ground temperature increase is observed as well. As snow cover here is less thick and its impact is not very pronounced, ground temperature shows a strong correlation with air temperature (Fig. 6). As a first approximation, the linear trend is applied. The slope of the straight-line approximation differs for each landscape unit. We suppose that the slope trend characterizes the annual ground temperature response of a particular landscape unit to climate fluctuations. The maximum slope is typical of flat peatlands, whereas the minimum slope is typical of mires. All other landscape units are characterized by intermediate values of annual ground temperature versus annual air temperature.

Conclusions

The study of permafrost reaction to climate change through active-layer depth dynamics was initiated within the framework of the CALM program. The response to climate changes of dominant landscape units in typical tundra and northern taiga subzones, as manifested by the active-layer depth, is evaluated quantitatively.

The active layer depth in mires is very sensitive to climate

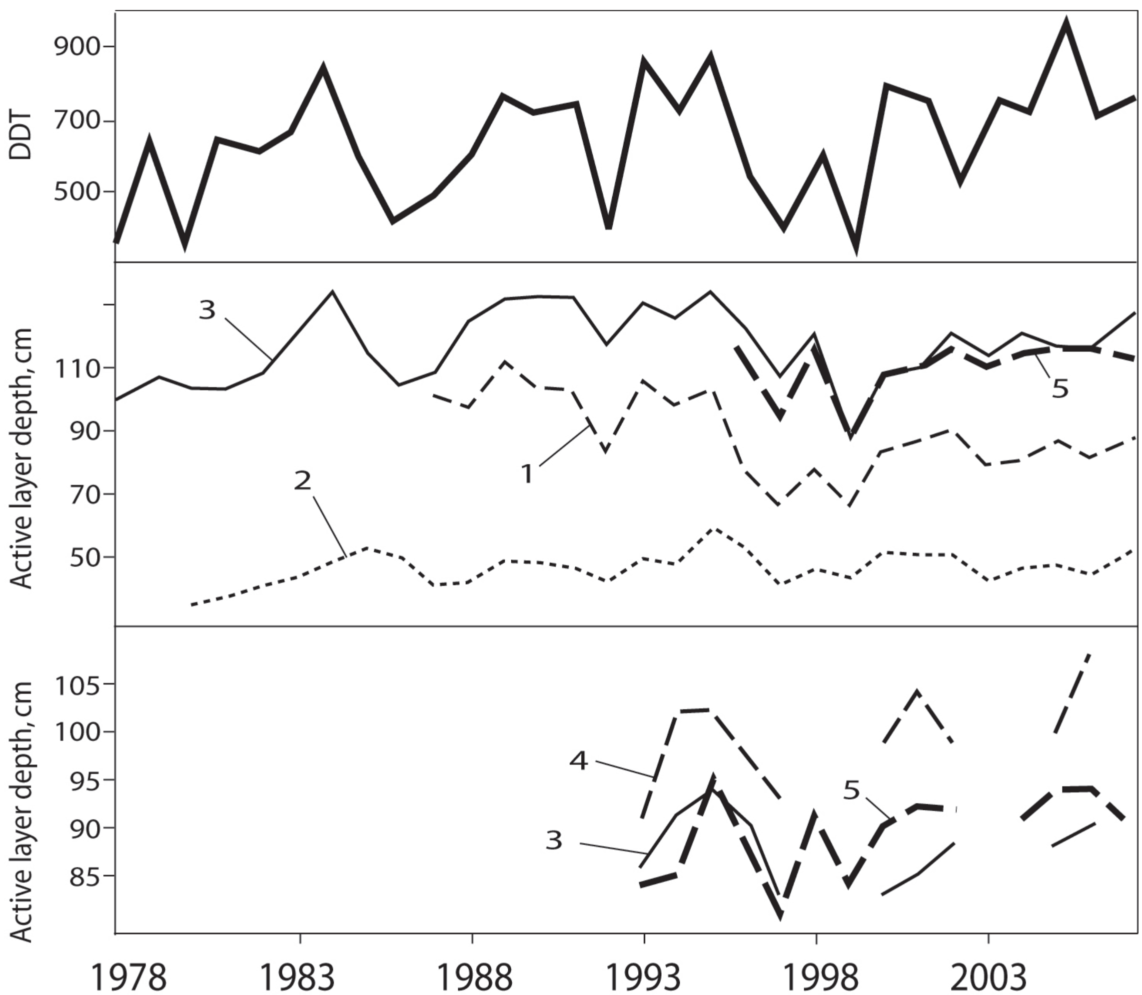

Figure 3. Time series of thaw index (DDT, upper pane), and average active layer depths on the dominating landscape units and CALM grid average in Marre-Sale (middle pane) and Vaskiny Dachi (lower pane): 1, mire; 2, peatland; 3, wet tundra; 4, dry tundra; 5, CALM grid average.

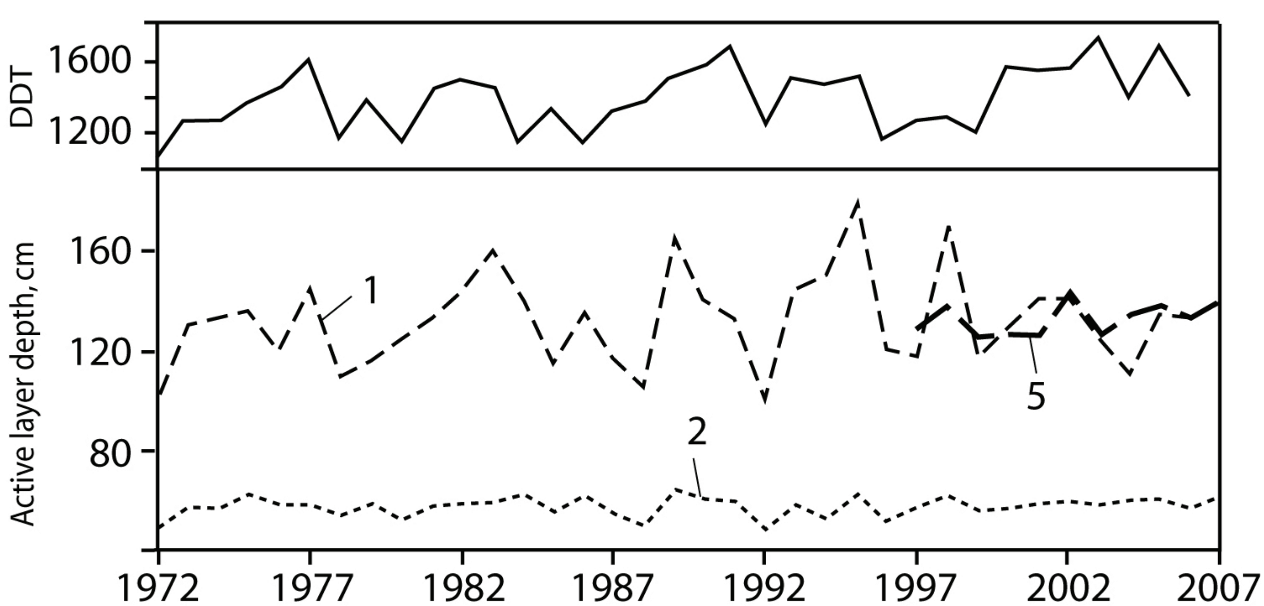

Figure 4. Time series of DDT (upper pane), and average active layer depths (lower pane) on the dominating landscape units and CALM grid average in Nadym area: 1, mire; 2, peatland; 5, CALM grid average.

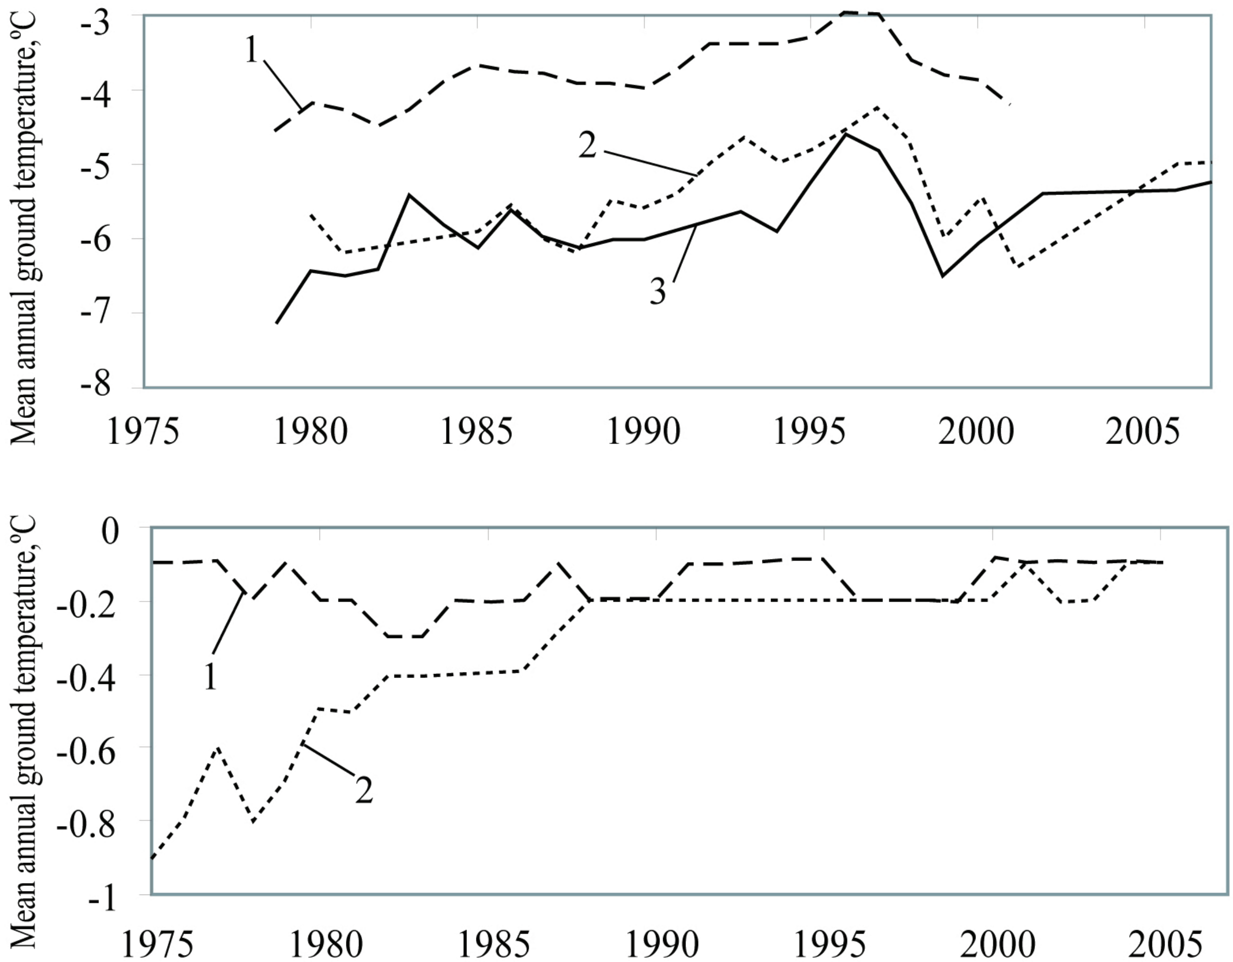

Figure 5. Time series of average ground temperature (depth of ~10 m) at Marre-Sale (upper pane) and Nadym (lower pane) sites: 1, mire; 2, peatland; 3, wet tundra.

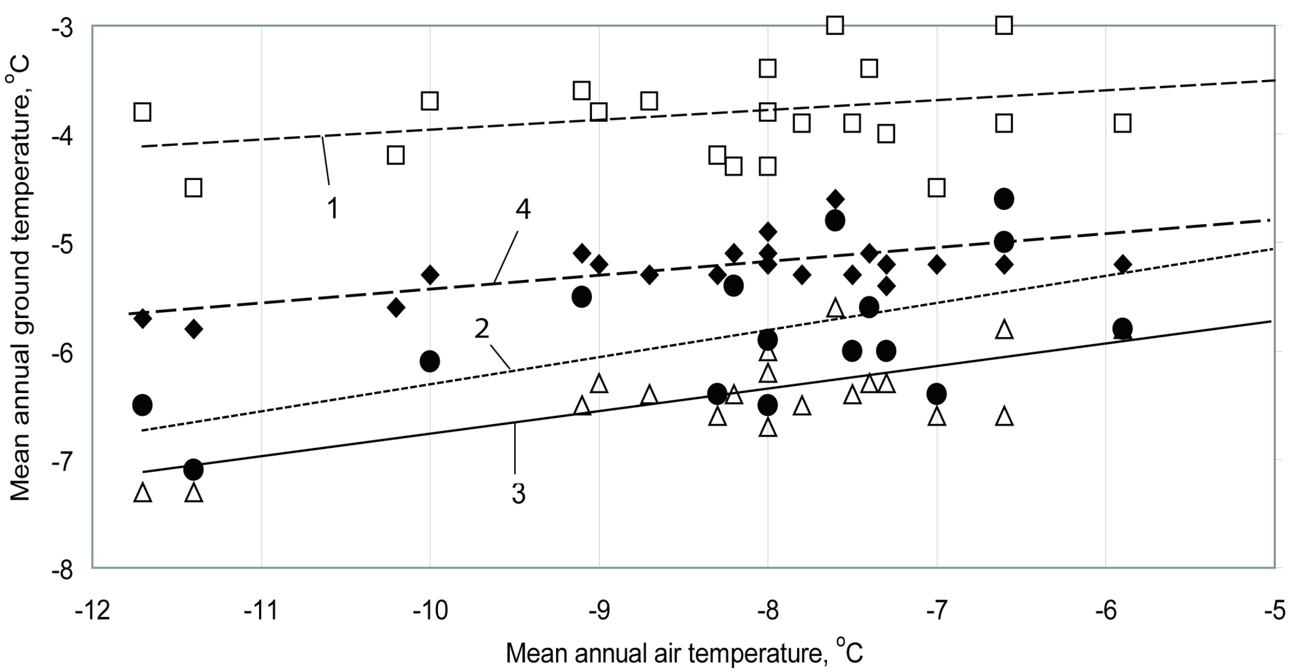

Figure 6. Correlation of mean annual air and ground temperature in Marre-Sale: 1, mire; 2, peatland; 3, wet tundra; 4, dry tundra.

change, while peatlands are least sensitive. And vice versa, the average annual ground temperature of permafrost changes considerably in the peatlands, while only minor changes are noted in mires. The landscape response to climate change expressed through the active layer is opposite to the response expressed through the average annual ground temperature.

Thus, analysis of the monitoring data allows us to conclude that the reaction of permafrost landscapes in northern West Siberia to climate change can develop in two directions. For some landscape units maximum increase of the active-layer depth is observed under the minimum change of mean annual ground temperature. For other landscapes with maximum change of mean annual ground temperature, minimum change of the active layer depth is characteristic. We cannot expect coincidence of both parameter maxima or minima within any environment.

Relation Between Soil Temperature and Late 20th Century Climatic Change in Yakutia

I.S. Vasiliev
Melnikov Permafrost Institute, SB RAS, Yakutsk, Russia

Abstract

This report presents analysis of the relationships of mean annual soil temperature at a depth of 1.6 m to air freezing index and snow depth, based on data from 40 weather stations in Yakutia. These relationships are discussed for the regional groups distinguished on the basis of linear trends in soil temperature. In the high-latitude lowland regions showing a negative trend, the decrease in mean annual soil temperature, with the freezing index remaining stable, is attributed to the persistence of snow cover long after the onset of positive air temperatures retarding soil warming, rather than to the increased snow depth and density. In the regions with a positive trend, the increase in mean annual soil temperature is caused by the weakening of the Asian anticyclone in winter. In the mountainous regions, soil temperatures are determined by local temperature-controlling factors, showing a decrease in cold landscapes and an increase in warm landscapes.

Keywords: freezing index; mean annual soil temperature; snow depth; trend.

Introduction

Changes in mean annual air temperature in the high latitudes of the Northern Hemisphere have been analyzed during the last 30 years by many investigators, using various approaches (Climate Change 1990, Ghil & Vautard 1991, Zhang & Osterkamp 1993, Pavlov 1994, 1997, Drozdov & Lugina 1996, Varlamov & Skachkov 1996, Balobaev 1997, Zukert & Zamolodchikov 1997, Gavrilova & Cherdonova 1997, Varlamov et al. 1998, Fedorov and Svinoboev 2000, Gedalof & Smith 2001, Harris 2002, 2005, and others).

Along with assessing the changes in air temperature, it is important to determine the responses of near-surface permafrost, particularly upper soil layers, to climatic variation. Pavlov (1997) reported data from several sites near Igarka and Vorkuta, indicating an increase in the mean annual permafrost temperatures to a depth of 10 m. Other studies also indicate a warming trend in ground temperature in Russia, on the North Slope of Alaska, along the Arctic coasts of Canada, and in the Northern Hemisphere as a whole (Osterkamp & Romanovsky 1999, Gilichinsky et al. 2000, Chudinova et al. 2001, 2003, Izrael et al. 2002, 2006, Frauenfeld et al. 2004, 2006, Smith et al. 2003). For Yakutia, it was shown previously (Vasiliev 1999) that linear trends in soil temperature at 1.6 m were of opposite sign in different regions (Fig. 1), which were provisionally grouped into three zones based on the character of soil temperature variation (Fig. 2).

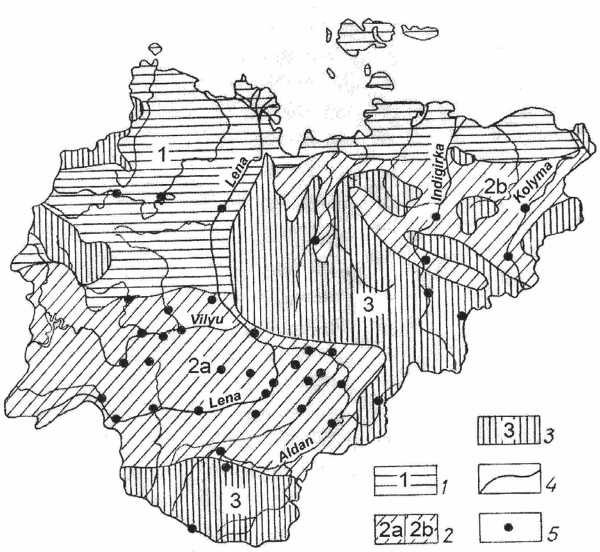

Figure 1. Map showing the location of soil temperature measurement sites and the regional groups identified based on linear trends: 1 – regions with negative trends; 2(a, b) – regions with positive trends; 3 – mountainous regions with opposing trends; 4 – group boundaries; 5 – weather stations.

This report presents analysis of the relationships of mean annual soil temperature at a depth of 1.6 m ($T_{m\ 1.6}$) to air freezing index ($\sum_{at}<0$) and snow depth (h_s).

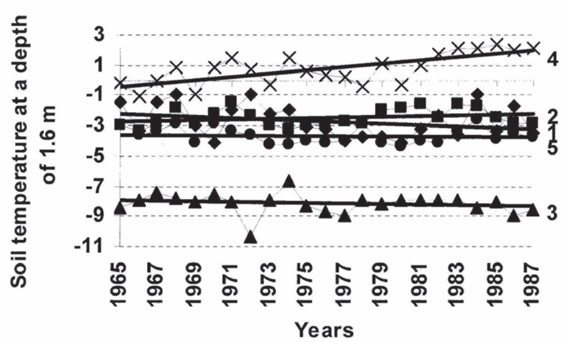

Figure 2. Variations and linear trends of mean annual soil temperature at 1.6 m for the Jarjan (1), Pokrovsk (2), Predporozhnaya (3), Gorelyy (4) and Nagornyy (5) weather stations.

Method

Regular instrumental measurements of soil temperature have been made in Yakutia since 1931. Soil temperature records of various lengths are available from 50 weather stations. However, the relocation of sites and the discontinuance of measurements introduce inhomogeneities into the temperature series. Of the 50 stations, only 16 continue to make soil temperature observations, 12 stations were closed by 1987, 9 stations by 1989 and 3 by 1994. Moreover, in the 1970s–1980s, instruments were relocated at 12 stations. Only homogeneous data sets from the same sites can provide a general picture of how the parameters under discussion have varied in the region. Therefore, soil temperature records from 40 weather stations for only the period from 1965 to 1987 have been used in the present study. Data on air freezing index and snow depth, which are compared to soil temperature, cover the same period (Fig. 3).

Results

Relations between $T_{m\,1.6}$, $\sum_{at}<0$ and h_s have been analyzed for the three regional groups distinguished in the previous study: (1) northern plains with a negative trend of $T_{m\,1.6}$; (2a) southwestern and central plains and (2b) northeastern plains and intermontane depressions, where $T_{m\,1.6}$ shows a steady increasing trend; and (3) mountains, exhibiting either stable or opposing $T_{m\,1.6}$ trends.

1. The northern plains with a negative trend of $T_{m\,1.6}$ include the tundra and north-taiga areas of western Yakutia and the tundra areas of eastern Yakutia (see Fig. 2, line 1). Air freezing indices were temporally stable at most stations of the region (Fig. 3, plot 1a), while snow depths slightly increased during the study period. The linear trend in h_s is 0.14–0.36 cm per year (Saskylakh, Sukhana and Siktyakh stations). At Jarjan, no trend is noted, although some increase in h_s occurred in the 1980s (Fig. 3, plot 1b). In the northernmost areas, increased snow depth is known to have a cooling effect on the soil thermal regime (Dostovalov & Kudryavtsev 1967, p. 252). The negative effect of snow cover in these regions can be due to three main reasons. First, snow density increases from south to north up to 0.2–0.3 g/cm^3 in mid winter and to 0.35–0.4 g/cm^3 in late winter. The high snow densities are caused by strong winds with speeds increasing to 20 m/s during snow storms. The frequency of storm winds is 20–40 days/yr in northern Yakutia, increasing to 60–80 days/yr on the Arctic islands. It is known that the higher that snow density is, the lower is the insulating effect of snow cover, even with increased thickness. Second, snow cover disappears as late as mid-June in northern Yakutia and late June on the Arctic islands, and the duration of the snow-covered season is 230–240 days in the north and 290–300 days on the Arctic islands. Under these severe climatic conditions, snowmelt occurs very slowly after air temperatures rise above 0ºC, thus retarding soil warming. This 2–3 week delay results in a decrease in mean annual permafrost temperature. Third, it is a common knowledge that the snow cover of long duration increases the albedo and this also has a negative effect on mean annual ground temperature. With no changes in $\sum_{at}<0$, the decrease in $T_{m\,1.6}$ therefore appears to result from the persistence of snow cover long after the onset of positive air temperatures retarding soil warming, rather than to the increased snow depth and density. The soils in northern Yakutia showed a rise in the early 1980s, while according to Pavlov (1997) the mean annual soil temperatures in northern West Siberia began warming a decade earlier. Although Jarjan records indicate a negative linear trend of temporal $T_{m\,1.6}$ variation (see Fig. 2, plot 1), its extremely low values (–4ºC) occurred at $\sum_{at}<0$ = –6000 degree-day/year or lower and h_s = 20 cm or less (see Fig. 4, plots 1a and 1b).

2a. In western Yakutia, winters have become milder with a decrease in $\sum_{at}<0$ at 3-9 degree-day/year. According to the graphical relationship, h_s increased at a trend of 0.18–1.18 cm/year (Berdigestyakh and Vilyuisk stations). In Central Yakutia, where h_s shows temporal stability, winters also tend to become milder, resulting in increased $T_{m\,1.6}$. This is attributed to the general weakening of the Asian anticyclone. The plot constructed from the Pokrovsk weather station data indicates that $T_{m\,1.6}$ increases to –1.3ºC at $\sum_{at}<0$ = –5300 degree-day/year and h_s = 40 cm and decreases to –3.4ºC at $\sum_{at}<0$ = –5700 and h_s < 30 (Fig. 4, plots 2a and 2b). In southwestern Yakutia, trends toward lower $\sum_{at}<0$ and greater h_s, resulting in increased $T_{m\,1.6}$, suggest stronger winter advection in the westerlies.

2b. The northeastern plains of the north-taiga zone and the major intermontane depressions also show a positive trend in $T_{m\,1.6}$. Winters became much warmer throughout the region, where $\sum_{at}<0$ decreased at a rate of 13.6–27 to 59 degree-day per year (Batagai, Srednekolymsk, Delyankir and Ust-Moma). During winter, these areas are predominantly under the influence of the Asian anticyclone and the cyclones bringing precipitation from the Pacific Ocean (Kazurova 1961, Gavrilova & Cherdonova 1997). Because the winter snow cover is thin, its insulating effect is small. At the same time, a decrease in h_s of 0.13–0.4 cm per year is observed in the region (Batagai and Zyrianka stations). The reduction of $\sum_{at}<0$ is accompanied by an increase in $T_{m\,1.6}$ despite a tendency toward thinner h_s, which can also be explained by the instability or lesser influence of the Asian anticyclone.

3. In the mountainous regions, the changes in $\sum_{at}<0$ suggest a warming throughout the region during winter. Decreasing trends of 13.6–15.9 degree-day/year in $\sum_{at}<0$ and 0.09–0.36 cm/year in h_s are found. The plot for the Predporozhnaya weather station (Fig. 4, plots 3a and 3b) indicates that $T_{m\,1.6}$ varies inter-annually from–6.7 to–10.3ºC, when $\sum_{at}<0$ increases from –6500 to –6600 degree-day/year and и h_s decreases from 35 to 10 cm. $T_{m\,1.6}$ shows a closer relationship to h_s than to $\sum_{at}<0$. At this site characterized by relatively cold winter temperatures, cooling of $T_{m\,1.6}$ is associated with the decreasing trend in already shallow snow depth.

In the northern and central parts of the Aldan Plateau, the increase in $T_{m\,1.6}$ is directly related to the reduction of $\sum_{at}<0$ and the increase in h_s. At the Gorelyy weather station, a trend of $T_{m\,1.6}$ was 0.09ºC per year during the period from 1966 to 1985 (Fig. 2, line 4). The linear relationship for this site

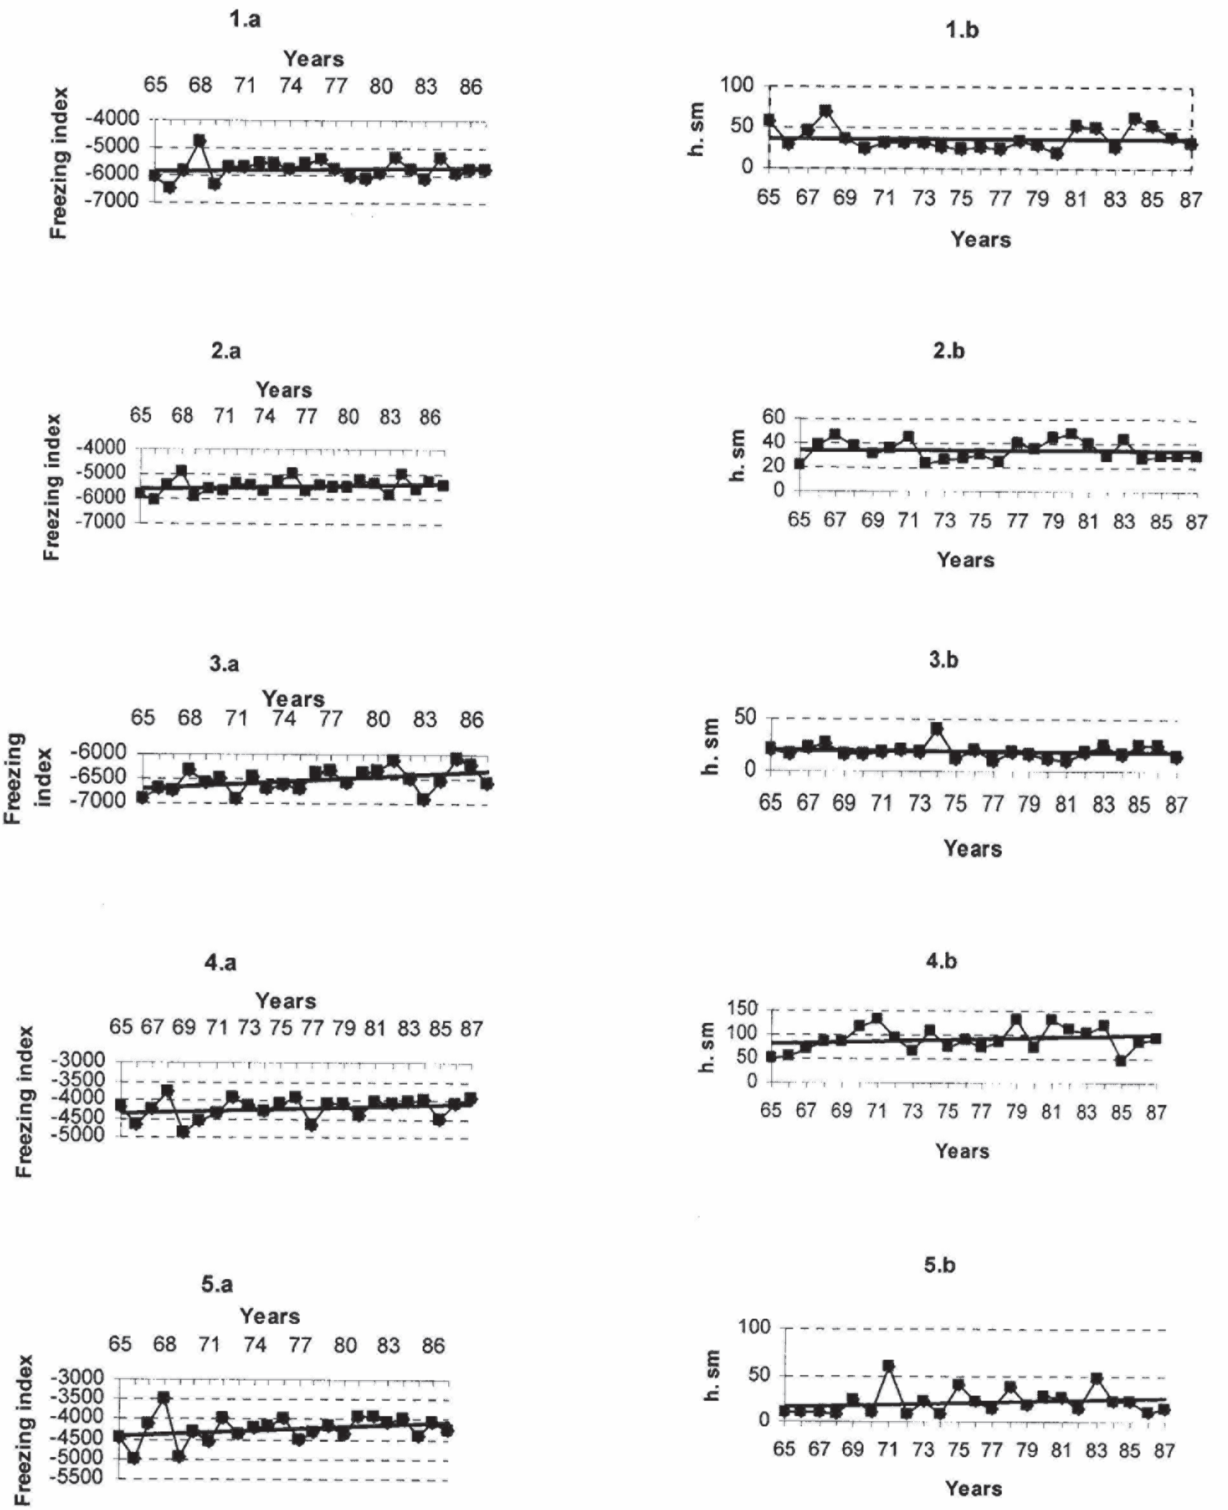

Figure 3. Variations of mean annual freezing index (a) and snow depth (b) for the same station (see Fig. 1).

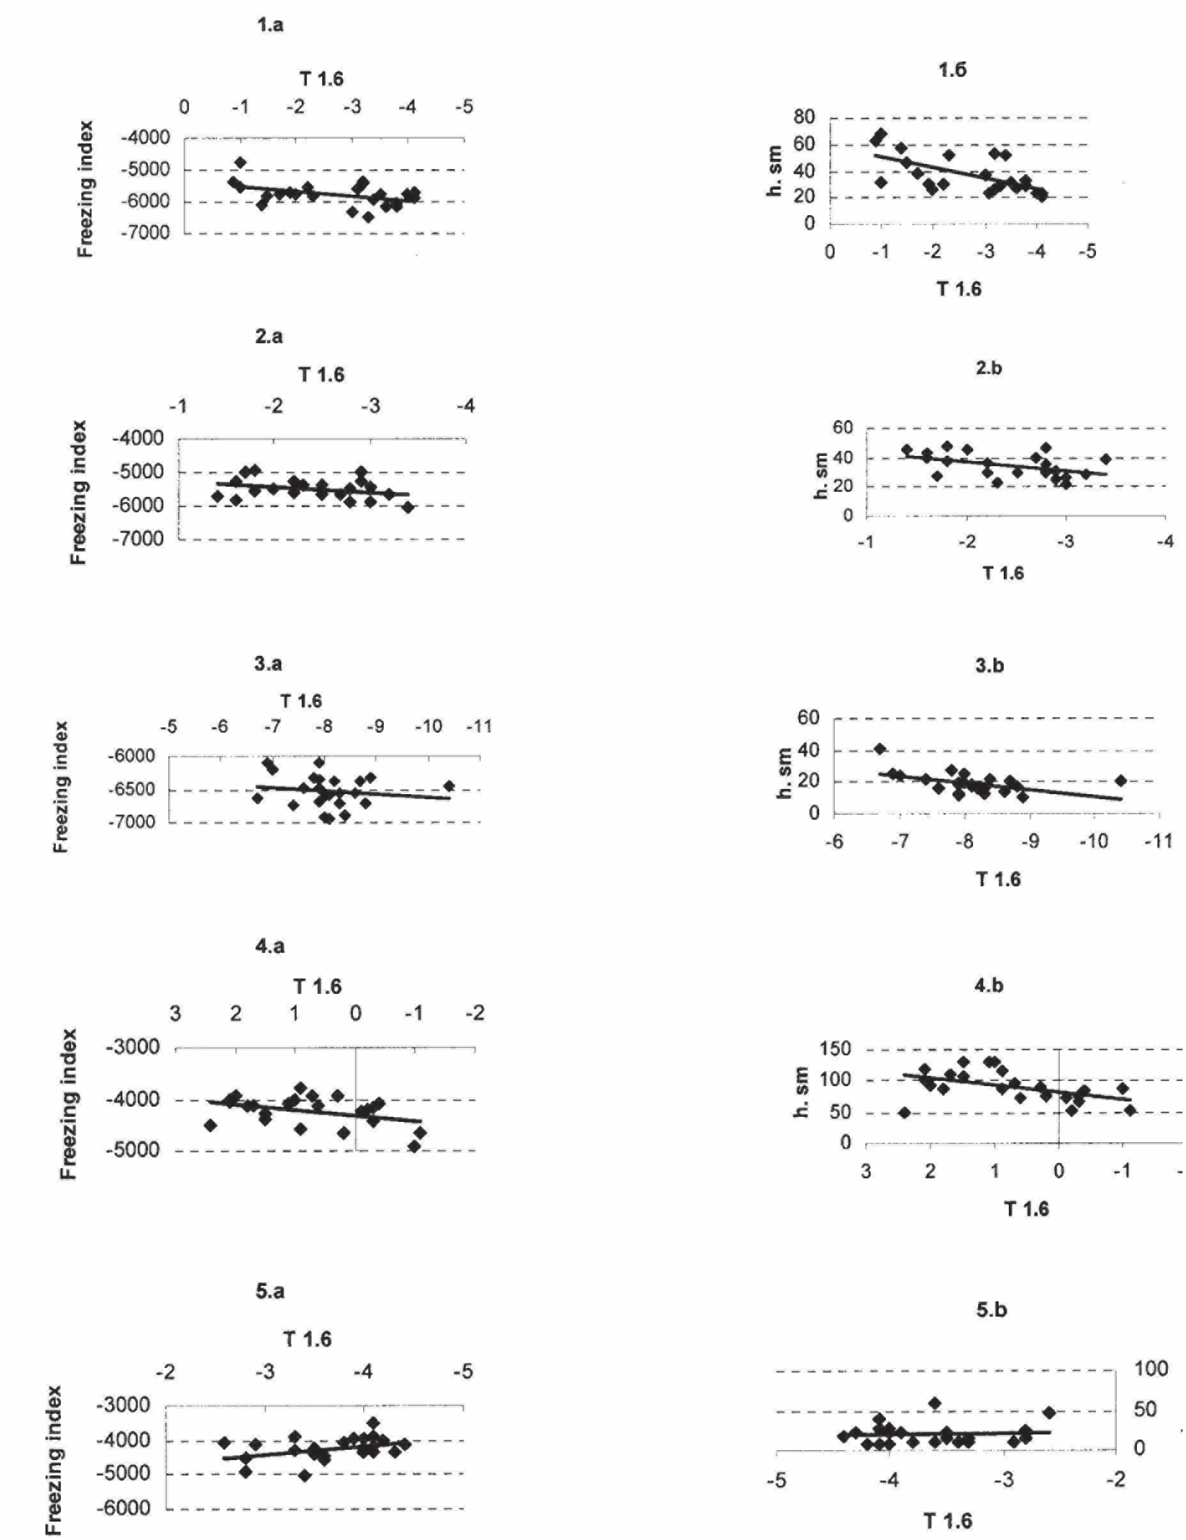

Figure 4. Relation of mean annual soil temperature variation at 1.6 m to air freezing index (a) and snow depth (b) for the same stations (see Fig. 2).

shows that $T_{m\ 1.6}$ increases from –1 to +2.4ºC with changes in $\sum_{at}<0$ from –4400 to –4000 degree-day/year and in h_s from 70 to cm (Fig. 4, plots 4a and 4b).

In the southernmost part of Yakutia, on the northern megaslope of the Stanovoy Range, $T_{m\ 1.6}$ is found to be temporally stable exhibiting a very slight negative trend (0.01ºC per year) at Nagornyy (Fig. 2, line 5). Comparison of $T_{m\ 1.6}$ with $\sum_{at}<0$ variation (Fig. 4, plot 5a) leads to the misleading conclusion that $T_{m\ 1.6}$. decreases with decreasing $\sum_{at}<0$. The slight progressive decrease in $T_{m\ 1.6}$ with positive trends in $\sum_{at}<0$ and h_s (see Fig. 4, plot 5b) is attributed to the persistence of snow cover long after the onset of positive air temperatures, because the station is located at a relatively high elevation (861 m a.s.l.) on a north-facing slope. Besides, the Timpton valley narrows here to 800 m, while shortly downstream it is 2–2.5 km wide, resulting in strong local winds which can also cause significant soil cooling. Thus, in the mountainous regions, some decrease in $\sum_{at}<0$ and increase in h_s do not lead to an increase in $T_{m\ 1.6}$.

Conclusions

● In the northern regions of Yakutia, the decreasing trend in $T_{m\ 1.6}$, with the freezing index remaining stable, appears to be due to the persistence of snow cover long after the onset of positive air temperatures retarding soil warming, rather than to the increased snow depth and density.

● In the north of Yakutia, a recent rise of $T_{m\ 1.6}$ occurred in the early 1980s, while in northern East Siberia an increase was observed since the early 1970s.

● In the middle-taiga areas of western and central Yakutia, in the north-taiga areas of eastern Yakutia, and in the intermontane basins, the increase of $T_{m\ 1.6}$ is attributed to the instability or lesser influence of the Asian anticyclone. In southwestern Yakutia, it is caused by stronger advection of the westerlies.

● In the mountains, $T_{m\ 1.6}$ variation under present climate are largely determined by local temperature-forming factors, showing a decrease in cold landscapes and an increase in warm landscapes.

Abstract

Evaluation of organic matter content and the amount of greenhouse gases released in polar areas of Northern Yakutia, as well as the study of polar landscape stability in the face of climate warming, now demand systematization of the data on landscape structure of the Northern Yakutia lowlands. In this study, such systematization is performed on the basis of classifying and mapping major terrain complexes in the northern Kolyma Lowlands.

Keywords: global warming; landscape; mapping; permafrost; terrain complex; thermokarst.

Introduction

Active research in the Kolyma Lowlands started in the late 1950s. The greatest interest in this territory lies in the peculiarities of its formation during the Pleistocene. A considerable number of publications are devoted to the origin and stratigraphy of the Pleistocene deposits, Pleistocene flora and fauna, and to general paleo-reconstructions.

Since the 1990s, the Kolyma Lowland has become a key region for studies of possible permafrost degradation, which can be triggered by global warming. Degradation of permafrost is likely to be followed by significant release of methane and carbon dioxide (Rivkina et al. 1996, Rivkina et al. 2006, Walter et al. 2006). To answer the questions triggered by these studies, it is necessary to calculate the quantity of organic matter and amount of greenhouse gases released from it, and then to forecast future development of thermokarst. This, in turn, demands conducting studies of modern landscapes and systematization of present day concepts of the terrain structure. Detailed landscape studies for the northern Kolyma Lowland have not yet been implemented. To fill this gap, we set a task to define and distinguish the major landscapes types (Terrain Complexes) of the northern Kolyma Lowland, to classify them, to identify patterns of their distribution, and to map them using Geographic Information Systems for acquiring the desired parameters.

Objects and Methods of Research

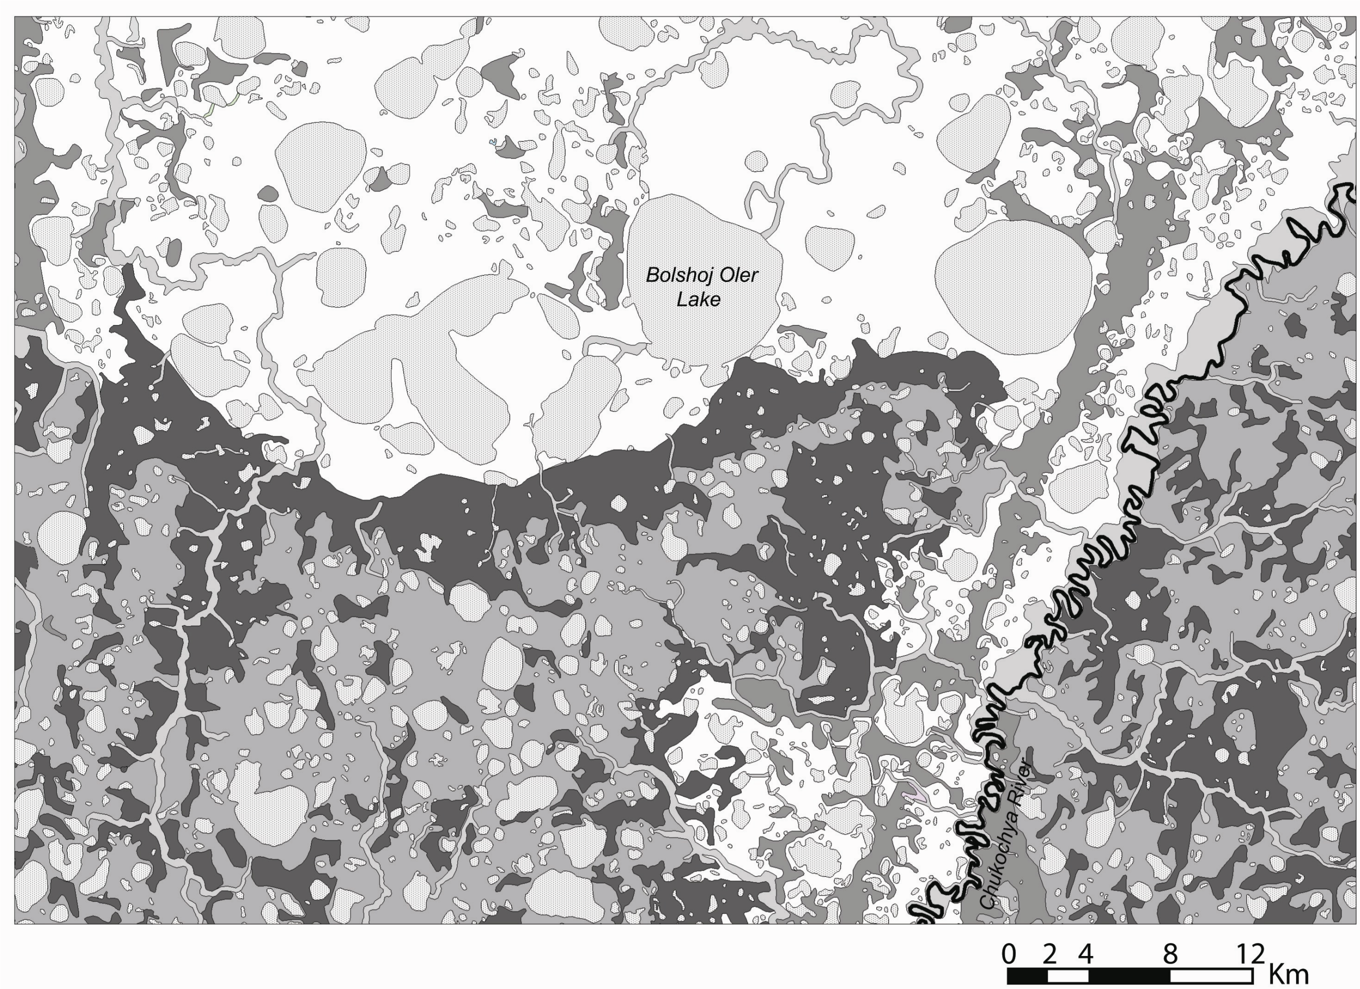
Objects of research

Our investigations are based on field data, collected during expeditions to this region (1980-2000), the studies of A.N. Fedorov (Fedorov 1991), and the permafrost-landscape map of Yakutian ASSR at 1:2500000 scale edited by P.I. Melnikov (1991). After analysis of field data, existing maps and publications, we selected the key study region for our research, which is a 6500 km^2 area in the Kolyma Lowlands located between the Alazeya River and Chukochya River in their middle flows (central coordinate is 69°30′N, 156°0′E). The region is located within the continuous permafrost zone; it belongs to the Alazeya-Kolyma lake-thermokarst province (Fedorov 1991). Comparison of the key region structure with the structure of other Northern Yakutia lowland areas shows that it is typical and reflects major patterns of tundra landscape development in the Holocene impacted by active thermokarst processes.

The key study region is characterized by flat and gently sloping thaw-lake depressions (thaw-lake basins), and the remnants of the Late Pleistocene surface formed by ice-rich deposit with polygonal ice wedges (named in the literature *Ice Complex* or *yedoma*). Based on paleogeographical data, we presume that during the Pleistocene the region was a flat plain underlain by ice-rich silts with ice wedges. At the Late Pleistocene-Holocene boundary, the active structural change began as a result of climate warming. Under the impact of thermo-erosional and thermokarst processes, the Ice Complex areas have been reduced, and they now represent different stages of thermokarst evolution. Some surfaces (relatively high elevation yedoma remnants) have not yet been reworked by thermokarst and have the thickest strata with ice wedges. Other surfaces have been partly reworked, and some have been transformed into thaw-lake basin depressions due to thawing of ground ice.

Methods of research

Allocation and mapping of landscapes first requires the determination of the basin mapping unit. A.N. Fedorov recommended distinguishing the hierarchy of local territorial geosystems on the basis of identifying leading factors among different characteristics, and considers the resulting boundaries to be absolute (Fedorov 1991). Another approach is suggested by Gr.A. Isachenko (Isachenko & Reznikov 1996, Isachenko 1998), who distinguish within a particular landscape different types of units characterized by relatively stable parameters:



Type of terrain	Index	Depth of permafrost table (m)	Sediments	Absolute elevations, m	Prevailing soils	Dominant type of vegetation
1. Drained surface of Yedoma remnants (gradient 0-15º) with initial forms of developing thermokarst (High Yedoma)		0.5–0.6	Ice-rich Late Pleistocene silts with polygonal ice wedges (Ice Complex)	40–80	Cryosols, gleysols	Gramineous-dryas, sedge-herbaceous shrub-moss
2. Slightly drained surface of Yedoma remnants (gradient 0-10º), with initial forms of developing thermokarst (Low Yedoma)		0.4–0.5	Ice-rich Late Pleistocene silts with polygonal ice wedges and overlaid with taberal deposits (thawed and refrozen sediments)	20–40	Gleysols histosols	Sedge-Herbaceous shrub-moss
3. Waterlogged flat surface with polygonal nano- and mesorelief, and numerous small lakes (Upper thaw-lake depressions)		0.2–0.4	Ice-rich lacustrine-alas deposits of thaw-lake basins with partially remained polygonal ice wedges	20–40	Gleysols histosols	Sedge-cotton grass, Herbaceous shrub- moss
4. Heavily waterlogged flat surface with polygonal nano- and mesorelief, and numerous lakes (Low thaw-lake depressions)		0.2–0.3	Ice-rich lacustrine-alas deposits of thaw-lake basins	10–30	Histosols, Gleysols	Sedge-moss
5. River valleys complex (with terraces)		0.3–0.8	Fluvial silty-sandy deposits	0–20	Fluvisols, histosols	Moss-shrub, Sedge-moss

Figure 1. Portion of terrain complexes map of the key study region.

1. similar position in relief (single meso-scale landform);
2. similar composition and cryogenic structure of subsurface layers;
3. similar drainage conditions.

These characteristics determine the hydrographical network, distribution of lakes and bogs, soils and vegetation. They also define the so-called “rigid design” of the territory, which acts as a reference frame for study of long-term (hundreds of years) processes of landscapes development (Isachenko & Reznikov 1996). This approach corresponds to our tasks including the forecasting of terrain evolution at the onset of global warming.

Figure 1 shows the landscape map based on topographic maps of 1:200000 scale and confronted with Landsat 7 ETM+ satellite images. For charting, we used MapInfo 7.0 and ArcView 3.2. Topographic maps of 1:200000 scale are most useful for our task because they show every substantial roughness while, at the same time, make it possible to cover large territories. Another important property of this scale is its comparativeness with existing satellite images.

Results

On the basis of Isachenko’s (1998) approach, we have distinguished five major types of terrain complexes in the key region: high yedomas, low yedomas, upper thaw-lake depressions, low thaw-lake depressions and river valleys. We have charted the digital landscape map of the key region at a 1:200,000 scale (Fig. 1). Analysis of the map shows that the largest part of the territory is the interstream area between the Alazeya River and the Chukochya River. In the north is located an extensive low thaw-lake depression. It is filled with many lakes (as large as 50 km^2); the surface is flat so the drainage is limited. Within the depression only small remnants (not larger then 4 km^2) of low yedoma are still preserved. Only along the major river valleys are vast remnants of low yedoma present, some of them as large as 50 km^2. Southward the territory of upper thaw-lake basins is located. There are a number of high yedoma remnants found here (with areas not larger then 6 km^2). Large areas of yedoma are adjacent to river valleys and low thaw-lake depressions. The right bank of the Chukochya River is also an upper thaw-lake basin, where large areas of high yedoma are preserved (up to 60 km^2). The latter are being drained by tributaries of the Chukochya River. The presence of vast high yedoma here is associated with exposed Oler sequence deposits containing low ice content and lacking polygonal ice wedges (Sher 1971). Thus, it determines the greater ruggedness of the surface and therefore the better drainage of the territory.

Table 1 shows that most common types of terrain complexes are thaw-lake depressions formed due to thawing ice wedges. They occupy 64.8% of the territory. The area of low and upper thaw-lake basins is 34.8% and 30.0%, respectively, of the total area of the key region. The area occupied by lakes in the upper and lower thaw-lake depressions makes up 21.5% and 29.3%, respectively, of the terrain complex area. High and low yedomas occupy about 26.5% of the territory, and the lake percentage of terrain complexes is 5.4 and 3.2%, respectively.

Lakes are classified according to the area on three groups within each terrain complex: large (>1 km^2), medium (0.1 to 1 km^2) and small (<0.1 km^2) (Table2).

Table 1. Areas occupied by terrain complexes and lakes.

Terrain complexes	Area of terrain complex (with lakes), sq km	Percentage of total area, %	Area of lakes, sq km	Percentage of total area of terrain complex, occupied by lakes, %
High Yedoma	1181.0	18.1	63.5	5.4
Low Yedoma	548.7	8.4	17.8	3.2
Upper thaw-lake depressions	1956.6	30.0	420.0	21.5
Low thaw-lake depressions	2274.3	34.8	665.8	29.3
River valleys	567.1	8.7	18.0	3.2
Total classified area	6527.7	100	1185.1	18.2

Table 2. Distribution of different groups of lakes (number and square) within separate terrain complex.

Groups of lakes	Number	In % of total lake number for terrain complex	Area, sq km	In % of total lake area	In % of terrain complex area
High Yedoma					
<0.1 km^2	204	56.4	11.1	17.4	0.9
0.1–1 km^2	151	41.7	38.4	60.5	3.2
>1 km^2	8	2.2	14.0	22.1	1.2
Low Yedoma					
<0.1 km^2	60	58.3	3.0	16.7	0.5
0.1–1 km^2	41	39.8	9.5	53.2	1.7
>1 km^2	3	2.9	5.3	30.0	1.0
Upper thaw-lake depressions					
<0.1 km^2	551	45.8	29.7	7.1	1.5
0.1–1 km^2	563	46.8	185.9	44.3	9.5
>1 km^2	90	7.5	204.4	48.7	10.4
Low thaw-lake depressions					
<0.1 km^2	373	42.1	22.0	3.3	1.0
0.1–1 km^2	408	46.1	133.2	20.3	5.9
>1 km^2	104	11.8	502.6	76.4	22.1
River valleys					
<0.1 km^2	78	60.5	4.1	22.8	0.7
0.1–1 km^2	49	38,0	10,3	57,1	1,8
>1 km^2	2	1,6	3,6	20,2	0,6

Lakes with areas of more than 1 km^2 occur sporadically within yedomas, and medium lakes predominate here by total area. Small lakes, which existence is connected with the initial stages of thermokarst development, prevail by number. Within the high yedoma terrain complex are found small thermokarst depressions, filled by medium lakes. Large lakes dominate in low thaw-lake basins. They occupy 22.1% of the area of low thaw-lake basins and 76% of summarized area of lakes within this landscape. In upper thaw-lakes basins, areas of large and medium lakes are comparable (10.4 and 9.5% respectively). It demonstrates the potential of increasing the area of medium lakes from climate warming and thawing of polygonal ice wedges.

Conclusions

Allocated terrains (all types except river valleys) represent different stages in the regional development. High yedoma are the remnants of the Late Pleistocene surface. At the end of Pleistocene and the beginning of the Holocene at 12 kyr BP (Schirmaister et al. 2002), as a result of climate warming the active modeling of initial landscape and the formation of vast thaw-lake basins had begun. The most active stage of thermokast development, characterized by maximum total area occupied by thaw-lake basins (present upper thaw-lake depressions), took place 7–5 kyr BP (Kachurin 1961, Grosse 2005). A substantial proportion of thaw-lake basins formed during this time later underwent further development from thermokarst and thermo-erosional process, especially at watershed locations. On that part of the region where thermokarst processes ceased or stopped, low yedomas were formed with partly melted polygonal ice wedges overlain by tabular deposits.

The next stage of active thermokarst development and formation of low thaw-lake basins took place in the late Holocene 3000–700 years ago (Baulin et al. 1967, Chekhovsky & Shamanova 1976).

The present age is characterized by climate cooling (Schirrmeister et al. 2002), which is confirmed by the absence of track of thermokarst activation during the past 50 years (Voskresensky 2001). More than 80% of the initial Late Pleistocene plains are modeled by thermokarst and thermo-erosional processes. Slopes of yedomas and thaw-lake depressions are gradually flattening and overgrowing by vegetation. The total portion of thaw-lake basins area in the region of research is 18.2%. It is commensurable with other regions with Ice Complex: Bykovsky Penninsula (lower course of river Lena – 14.4%, (Grosse 2005), and the Barrow Peninsula (Alaska) – 22% (Hinkel et al. 2003).

In case the global warming scenario is realized, the most stable areas will be low thaw-lake depressions because at these areas polygonal ice wedges have already melted out, and peat layers with a thick moss mat formed at the surface protects the permafrost substrate from incoming warmth.

Upper thaw-lake basins are subject to partial surface modeling in case of the onset of global warming. Polygonal ice wedges, although partly melted, still exists here; activation of thermokarst and thermo-erosional processes causes further melting and an increase of lake areas is likely.

Even more unstable during climate warming by thermokarst activation will be yedomas. Low yedomas will be more stable then high yedomas because polygonal ice wedges in low yedomas are located deeper, the peat and moss mat is thicker, and permafrost is more resistant to thermokarst (waterlogged areas are more frequent here).

High yedomas are the most unstable areas and are highly susceptible to thermokarst and thermo-erosional processes because polygonal ice wedges are very close to the surface, which in turn is characterized by free drainage. Peat and vegetation are uncommon and don't provide thermal insulation.

The information obtained about terrain structure and terrain complex distribution and evolution patterns helps to forecast thermokarst development in the northern Yakutia coastal lowlands at the onset of global warming.

This study is the first stage of northern Kolyma Lowland landscapes research. We consider it as a basis for other studies of northern coastal lowlands of Yakutia.

Numerical Studies of Permafrost Effects on Groundwater Flow

Patrik Vidstrand
Chalmers University of Technology, Gothenburg, Sweden

Jens-Ove Näslund
Swedish Nuclear Fuel and Waste Management Company, Stockholm, Sweden

Juha Hartikainen
Helsinki University of Technology, Espoo, Finland

Abstract

Despite the inferred present global warming trend, future climate during the long life-span of a nuclear waste repository could well include periods of permafrost development in all of Sweden. The occurrence of permafrost in soil and bedrock can alter significantly surface boundary conditions that affect groundwater recharge and discharge as well as the deeper circulation of groundwater in the bedrock presently investigated for the potential to accommodate nuclear waste. Within the safety assessments, generic studies on deep groundwater circulation in the presence of permafrost have been conducted. The present study includes a compilation of future permafrost scenarios and their implications on the groundwater flow. The results suggest that for a location where unfrozen taliks are present, sporadic permafrost will reduce while continuous permafrost will enhance groundwater flow. The study, although generic in character, is conclusive on the importance of permafrost in controlling both local and regional groundwater flow systems.

Keywords: climate scenario; groundwater flow; permafrost; taliks.

Introduction

Over the life-span of relevance for a nuclear waste geological repository, climate models predict future climatic situations that result in permafrost development, glacial conditions, and changes in shoreline elevation with possibilities for both elevated and submerged situations. Conditions of permafrost as surface boundary cause changes within the subsurface environment in hydrogeological properties as well as in the hydrogeochemistry.

Permafrost is defined as ground that is at or below 0°C for at least two consecutive years (French 1996). This definition has the implication that permafrost does not necessarily need to be frozen ground. However, the greatest impact on the subsurface hydrology from permafrost is the phase change related to the freezing of water. Frozen water creates an almost impervious stratum, which inhibits groundwater recharge but also the possibility of discharge, highlighting the possibility of high groundwater pressure beneath the permafrost (McEwan & de Marsily 1991, Boulton et al. 1993, Haldorsen & Heim 1999). One possible change due to permafrost is a re-organization of the regional as well as local groundwater flow regimes caused by the occurrence of frozen and nonfrozen areas within the ground.

This study mainly addresses the possible effects of different upper boundary conditions. The different scenarios considered are based on climate scenarios for the Forsmark site in Northern Uppland, Sweden; with special attention to the SFR geological repository for low and intermediate radioactive substances.

Even though the study is a hydrogeological flow study, it was not intended to create a realistic representation of the "true" groundwater flow situation. The purpose was instead to provide a safety analysis with quantification of, and uncertainty indicators for, the possible effects of different upper boundary conditions. Overall, the strategy was to use simplified models in the simulation of scenario cases to provide the safety analysis with relative flux values and uncertainty ranges.

Site Description

The site for this study is found in the Forsmark area in Northern Uppland, on the east coast of Sweden; some 200 km northwest of Stockholm. The site is one of the candidate sites for siting a nuclear waste deep geological repository in Sweden, but also hosts an active repository for low and intermediate nuclear waste (SFR).

The corrected precipitation in Forsmark for the measurement period August 1, 2003, to July 31, 2004, was

Figure 1. Location of the study area.

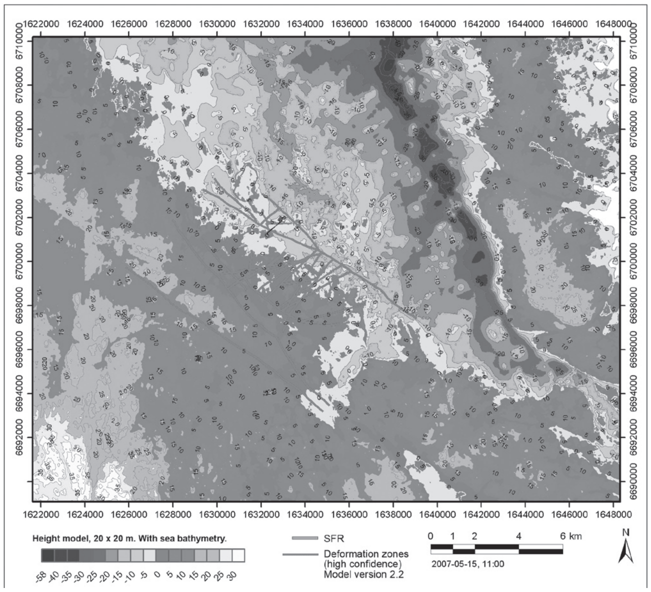

Figure 2. Local topography of the SFR region and the high confidence large-scale deformation zones as defined in the site investigation program.

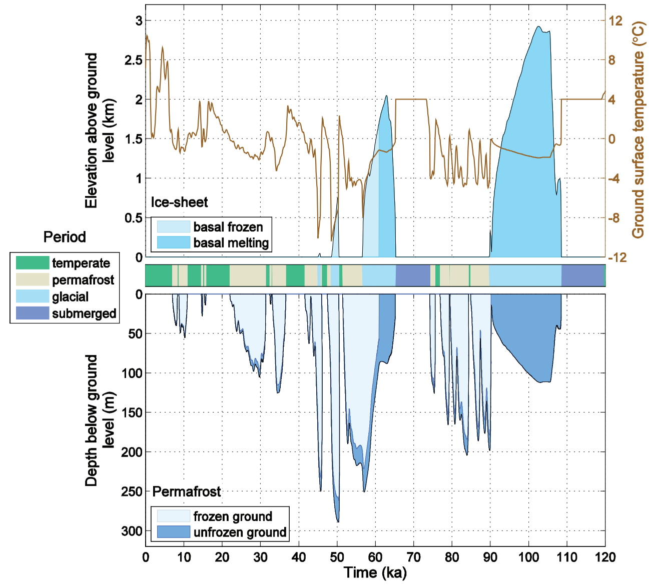

Figure 3. A climate scenario for the Forsmark region, including prevailing climate domains and climate related variables for a timeframe of 120,000 years in the future.

630 mm. The total "potential evapotranspiration" as reported in Lindborg (2005) was 472 mm for the same period. These numbers are in alignment with the long-term statistics from the Swedish Meteorological and Hydrological Institute (SMHI) for nearby stations as reported in Larsson-McCann et al. (2002). Based on these numbers, the net precipitation and the ground hydraulic properties indicate an excess of water in order to keep the groundwater table close to the surface. A permafrost environment may be significantly dryer as compared to present day conditions. However, the topography and geology at the site support a groundwater table close to the surface even if the net recharge is decreased to only one tenth. Hence, it is justified to assume a fully saturated subsurface and a groundwater table close to the surface as well as a prescribed pressure boundary condition at the surface also during permafrost conditions.

The local topography of the SFR region and the high-confidence large-scale deformation zones as defined in the site investigation programme is presented in Figure 2.

Future Climate and Permafrost Development

Climate-related changes, such as changes in shoreline elevation and development of permafrost and ice sheets, are the most important naturally occurring external factors affecting a nuclear waste repository in a time perspective from tens to hundreds of thousands of years.

It is not possible to predict the evolution of the climate in a 100,000-year time perspective with enough confidence for a safety assessment. However, the extremes within which the climate of Sweden may vary can be estimated with reasonable confidence. Within these limits, characteristic climate-related conditions of importance for repository safety can be identified. The conceivable climate-related conditions can be represented as *climate-driven process domains* (Boulton et al. 2001) where such a domain is defined as *a climatically determined environment in which a set of characteristic processes of importance for repository safety appear.* In the following, these climate-driven process domains are referred to as *climate domains.*

The identified relevant climate domains are named as

- *The temperate domain*
- *The permafrost domain*
- *The glacial domain*

The purpose of identifying climate domains is to create a framework for the assessment of issues of importance for repository safety associated with particular climatically determined environments that may occur in Sweden. If it can be shown that a repository fulfills the safety requirements independent of the prevailing climate domain, and the possible transitions between them, then the uncertainty regarding their exact timing in the future is less important. In addition to these climate domains, it is necessary to consider the periods for which the site is submerged by the Baltic Sea.

Figure 3 shows an example of a future scenario at Forsmark in a 120,000-year time frame in the future (SKB 2006). The scenario based on the evolution of the last glaciation, the Weichselian, and involves all the three climate domains. The permafrost domain is defined as periglacial regions that contain permafrost. It is a cold region without the presence of an ice sheet. The permafrost can occur in sporadic, discontinuous, or continuous forms. Regions belonging to the permafrost domain are not necessarily the same as regions with a climate that *supports* permafrost; i.e., as long as permafrost is present and not underlying an ice sheet, the region is defined as belonging to the permafrost domain, regardless of the prevailing temperature at the ground surface. Thereby, the climate in the permafrost domain can be warm diminishing permafrost. This way of defining the

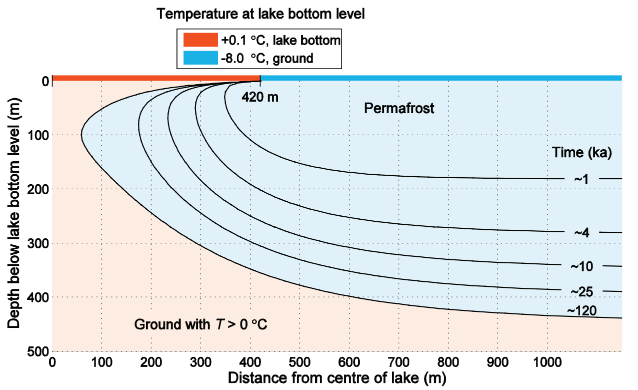

Figure 4. Evolution of permafrost in the vicinity of a circular lake of radius of 420 m at Forsmark when a constant lake bottom temperature of +0.1ºC, and a constant ground temperature of –8ºC at lake bottom level are assigned.

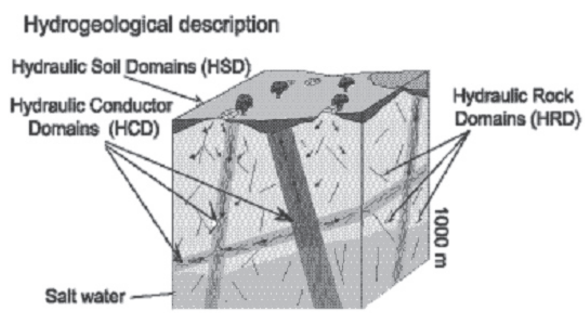

Figure 5. The Quaternary deposits and the crystalline bedrock are divided into separate hydraulic domains named the Hydraulic Soil Domains (HSD), Hydraulic Rock Mass Domains (HRD), and Hydraulic Conductor Domains (HCD). Within each domain, the hydraulic properties are represented by mean values or by spatially distributed statistical distributions (after Rhén et al. 2003).

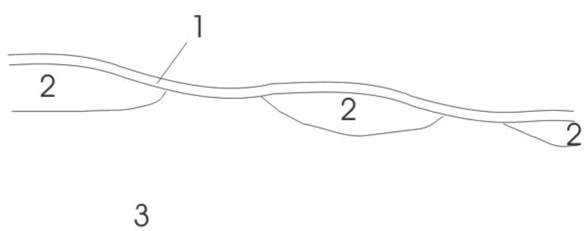

Figure 6. Illustration of conceptual model when permafrost is present.

domain is used because the presence of permafrost is more important for the safety function of the repository than the actual temperature at the ground surface. In general, the permafrost domain has a climate colder than the temperate domain and warmer than the glacial domain.

Large water bodies affect permafrost development and the presence of taliks. A talik can exist beneath a water body when its bottom temperature remains above the freezing point. Figure 4 demonstrates that an open talik can survive beneath a circular shallow lake, if its radius is greater than the thickness of ambient permafrost (SKB 2006).

Hydrogeological Numerical Flow Modeling

Basis

The computer code DarcyTools has been developed for simulations of groundwater flow and mass transport in porous and fractured media; the code uses continuum equations. Detailed descriptions of the concepts, methods, and equations of DarcyTools are documented in Svensson et al. (2004).

The modeling methodology used in this study followed SKB´s system approach for hydrogeological modeling (Rhén et al. 2003), which herein is much simplified. This approach divides the geosphere into three types of Hydraulic Domains, representing the Quaternary deposits, or Hydraulic Soil Domain (HSD), the fracture zones (HCD), and the rock mass between the fracture zones (HRD) (Fig. 5).

This study was conducted in two dimensions, even though such an approach is not necessarily well suited to the representation of fracture systems. Also, the study did not concentrate on a surface hydrology and, hence, did not include any soil cover (soil domain). The bedrock is in principle assumed to be a homogeneous porous medium with isotropic characteristics.

Common to all cases is no-flow boundary conditions on the lateral (side) boundaries and at the bottom for the sake of simplicity; sensitivity studies where the lateral boundaries were specified as hydrostatic showed no change in the results. The model is a fresh water model. The upper boundary is a spatially distributed specified pressure boundary assessed for the different surface conditions (climate domains); i.e., the groundwater table is fixed close to or at the ground surface. All simulations are steady-state.

All assigned hydrogeological properties are homogeneous within their specified model domains (Fig. 6):

- Unfrozen bedrock [3] (deep bedrock) has a hydraulic conductivity of $3 \cdot 10^{-8}$ m/s;
- Frozen bedrock [2] (permafrost) has a hydraulic conductivity of $3 \cdot 10^{-14}$ m/s;
- An active layer [1], if present, has a hydraulic conductivity of $3\ 10^{-4}$ m/s.

An active layer is present for all cases with assumed maximum infiltration capacity. Sensitivity to less available water has been tested where the active layer is removed and replaced with no-flow bodies along the surface boundary.

Reference case

These results are considered to be a representation of the present-day conditions. However, the simulations are a simplification in terms of conceptual model as well as flow dimensions and hydrogeological properties.

For simulations of the reference case, the hydraulic conductivity was specified as a homogeneous value of $3 \cdot 10^{-8}$ m/s. The upper boundary has a prescribed pressure at ground surface, which mimics a case of maximum infiltration (groundwater recharge). The regional topographic gradient is 3 m per km, but applies in combination with a more local gradient created by a sinusoidal surface with a wavelength of 5 km and amplitude of 10 m. Further, the groundwater throughout the domain is taken to be fresh water.

Figure 7. Permeability structure of the reference case. The four dots in the right upper model domain corner indicate the locations for synthetic repositories through which the flow is investigated.

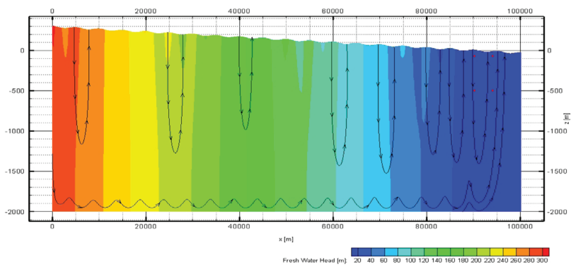

Figure 8. Fresh water heads of the steady-state solution of the reference case.

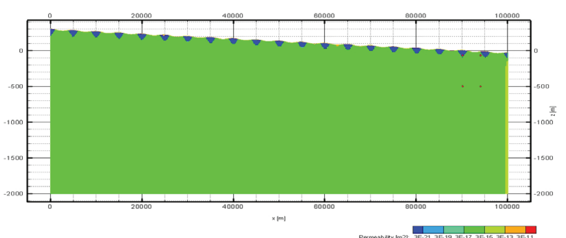

Figure 9. Conceptual model for the case of sporadic permafrost.

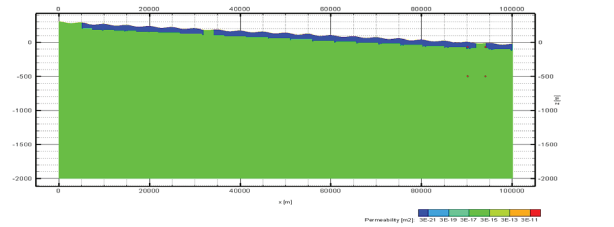

Figure 10. Conceptual model for the case of continuous permafrost.

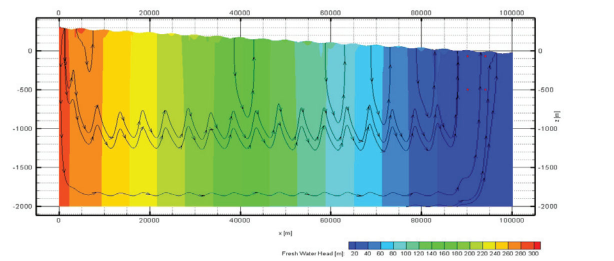

Figure 11. Fresh water heads of the steady-state solution for the sporadic permafrost case.

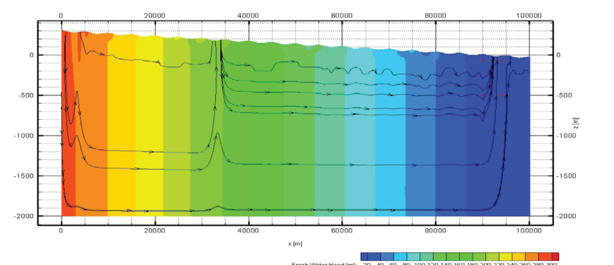

Figure 12. Fresh water heads of the steady-state solution for the continuous permafrost case.

Figure 8 presents the fresh water head of the steady-state solution of the reference case. The head situation along with the illustrative streamlines indicates the strong influence of the local topographic gradient. However, these results are strongly dependent on the shape of the local topography; for a case with only a regional gradient the flow also is regional with discharge only in the sea. A smaller local topographic variation yields more regional flow as compared with the reference case. These effects also affect the magnitude of the flux and were hence the subject of the sensitivity study presented below.

It should be noted that regions located beneath sea elevation (zero m altitude) all have a fresh water head of zero independent of where the sea bottom is located.

Permafrost cases

The sporadic permafrost case is illustrated below (Fig. 9). The maximum depth of permafrost is 100 m. The chosen maximum permafrost depth is used since it is adequate for illustration purposes.

The continuous permafrost case is illustrated below (Fig. 10). The maximum depth of permafrost is again due to illustrative reasons set to 100 m. Open taliks are located between the extensive areas of permafrost.

Figure 11 presents the fresh water head of the steady-state solution of the maximum infiltration case for sporadic permafrost. The maximum infiltration case is conducted with a fully saturated active layer on top of all frozen regions. The head situation along with the illustrative streamlines indicates the influence of the patches of frozen ground on the regional flow.

Figure 12 presents the fresh water head of the steady-state solution of the maximum infiltration case for continuous permafrost. The head situation along with the illustrative streamlines indicates the strong influence of the open taliks and of the regional topographical gradient. The flow is from one open talik toward the next, downstream, open talik. The results further indicate that a talik located along the regional gradient acts as a discharge location but also, at the same time, recharges water into the system.

Discussion

Two different groundwater flow scenarios involving the presence of permafrost have been studied. These are (1) a sporadic permafrost distribution, in which the groundwater within local topographic highs is frozen, and (2) a continuous permafrost distribution, in which extensive permafrost exists all over the model domain, only locally bypassed by open taliks (i.e., unfrozen regions in the permafrost).

The sporadic permafrost produces a situation where the regional groundwater flow becomes more important and the flow driven by local topographical differences becomes less important. This yields a smaller total flow for the sporadic permafrost scenario as compared with the reference case.

The continuous permafrost case yields an increase in the water flux all over a talik where discharge of water is occurring; a situation where a talik contains regions of both recharge and discharge is possible according to the conceptual model used, but is more likely to occur in regional up-stream locations than at the location of SFR repository. However, after emerging from the sea by shoreline displacement, when permafrost first is encountered, the location of SFR will be on a hill side. The location is more on the shaded side and hence it is possible for it to have early permafrost development. Hence the location may become frozen relatively early. However, the location of the shoreline when the first permafrost arrives is not well determined, and for a situation in which the SFR is still beneath water at that time, a talik could be formed above it. A sensitivity test of the location of the measurement volume within a talik indicates that a continuous permafrost situation could enhance the water flux through the facility by up to one order of magnitude.

The continuous permafrost situation may have a smaller impact, if the amount of available water is small, an effect different from that found in the sporadic permafrost case. A situation with less available water is mimicked by replacing the active layer with no-flow bodies (frozen) along the surface boundary. However, the decrease of flow in a dry scenario is not so large that it counteracts the effect of a talik in increasing the flow.

Even though it was not an investigated issue of the study it is, as expected, clear that for both the sporadic and continuous permafrost cases the total flow of groundwater through the model domain is decreased as compared to the reference case. This effect is most dominant when no active layer is part of the simulations. However, as described above this does not by necessity mean that the flow through the investigated generic repository volume is decreased.

In relation to thermal permafrost simulations, it should be noted that for most simulated episodes of possible future permafrost the frozen groundwater has reached a depth exceeding that of the SFR repository. If the ground surrounding the repository is frozen, the groundwater flow becomes negligible, but other problems arise, such as possible failures of the buffer material.

Conclusions

The upper boundary conditions have a significant impact on the groundwater flow in the geosphere. Permafrost and the development from sporadic permafrost to continuous permafrost yield increased groundwater flows in unfrozen parts of the domain. The increase is one order of magnitude or less. In the permafrost, the flow is negligible.

The characteristic of the surface in regard to being a recharge or discharge area affects the results. In general, a discharge area will experience an increase in groundwater flow under changed conditions.

Abstract

The Antarctic Peninsula is experiencing one of the fastest increases in mean annual air temperatures (ca. 2.5ºC in the last 50 years) on Earth. If the observed warming trend continues as indicated by climate models, the region could suffer widespread permafrost degradation. This paper presents field observations of geomorphological features linked to permafrost and ground-ice degradation at two study areas: northwest Hurd Peninsula (Livingston Island) and Deception Island along the Antarctic Peninsula. These observations include thermokarst features, debris flows, active-layer detachment slides, and rockfalls. The processes observed may be linked not only to an increase in temperature, but also to increased rainfall, which can trigger debris flows and other processes. On Deception Island some thermokarst features may be related to anomalous geothermal heat flux from volcanic activity.

Keywords: active layer; Antarctic; debris flow; permafrost; thermokarst.

Introduction

The Antarctic Peninsula is experiencing the strongest warming signal in the Southern Hemisphere, with mean annual air temperatures (MAAT) increasing ca. 3ºC since 1951 (Marshall et al. 2002, Meredith & King 2005, Turner et al. 2005). However, the region of strongest warming is limited in area, with the highest increases near Faraday/Vernadsky Stations and lesser increases near the northern tip of the Peninsula and the Orcadas Islands (King & Comiso 2003, Turner et al. 2007). Global Climate Model (GCM) projections for 2001–2100 suggest that the strongest warming will extend into the Antarctic continent, with values even greater than those expected on the Antarctic Peninsula (Chapman & Walsh 2007).

The strong atmospheric warming in the Antarctic Peninsula region has had a substantial effect on glaciers in the last few decades, especially on ice-shelves along the eastern coast (Scambos et al. 2003). The collapse of Larsen-B in 2002 is the most well-known example, but the retreat of mountain and outlet glaciers has been also reported. On Livingston Island (Hurd Peninsula) glaciers have been retreating and equilibrium-line elevations increasing (Ximenis et al. 1999, Molina et al. 2007).

Permafrost is central to the carbon cycle and to the climate system, especially due to CH_4 and CO_2 release following permafrost degradation in organic-rich sediments (Anisimov et al. 1997, Osterkamp 2003). The active-layer thickness and dynamics are also important factors in polar ecology. Since most exchanges of energy, moisture, and gases between the atmospheric and terrestrial systems occur through the active layer, its thickening has important ramifications on geomorphic, hydrologic and biological processes (Nelson & Anisimov 1993). Furthermore, permafrost degradation can cause terrain instability and increase geomorphological hazards and damage to infrastructures. According to the International Panel on Climate Change (IPCC), regions underlain by permafrost have been reduced in extent, and a warming of the ground has been observed in many areas (Anisimov et al 2001, Lemke et al 2007). Permafrost is, therefore, recognized by the (World Climate Research Programme/World Meteorological Organization (WCRP/WMO) as a key element of the Earth System in which research efforts should focus. However, compared with the Arctic, very little is known about the distribution, thickness, and properties of permafrost in Antarctica. The scarcity of data on Antarctic permafrost is reflected in the last IPCC

Figure 1. Location of Deception and Livingston Islands in the Antarctic.

report (Lemke et al. 2007) where it is not even mentioned. The main problem is the limited network of boreholes for monitoring permafrost temperatures and the paucity of active-layer monitoring sites. Turner et al. (2007) mention a reduction in permafrost extent in the Antarctic Peninsula region.

In general, increasing air temperatures will have a direct influence on ground-temperature regimes and, therefore, on permafrost and ground ice. A major consequence of warming of the lower atmosphere is an increase in active-layer thickness, which induces permafrost degradation and amplifies the rates of geomorphic processes. As a consequence, thermokarst features are prone to occur in ice-rich and unconsolidated sediments, active-layer detachment slides and debris flows on sloping ground, and an increase in rockfall activity may occur in rocky terrain.

The northerly location of the Antarctic Peninsula region and the oceanic setting result in a milder and moister climate than in the interior of the Antarctic continent. The northern Antarctic Peninsula is roughly located between the MAAT isotherms of -1 to -8ºC at sea level and, therefore, the northern tip of the Peninsula and especially the South Shetland islands are close to the environmental limits of permafrost occurrence (Bockheim 1995). If the observed warming trend continues, as indicated by climate models, the region might suffer widespread permafrost degradation.

Monitoring of ground temperatures is essential for assessing the reaction of permafrost to global change, but in remote areas the drilling and maintenance of boreholes is problematic. Geomorphological surveying enables identification of the processes related to permafrost degradation and provides important information for assessing the influence of climate change on ground temperatures. However, other techniques are needed, such as geophysical surveying, monitoring of active-layer depths, micrometeorological measurements, and modelling to achieve a more complete overview of the response of permafrost to regional warming.

This paper joins together inputs from two groups researching in the South Shetlands. The group of the Autónoma de Madrid and Valladolid universities (i.e., Serrano & López-Martínez 2000, Smellie et al. 2002, Serrano 2003) has been focusing on geomorphological surveying and mapping of the periglacial processes in the South Shetlands (Fig. 1). The group at the universities of Alcalá de Henares, Lisbon, Zurich, and Karlsruhe (Ramos & Vieira 2003, Vieira & Ramos 2003, Ramos et al. 2007, Hauck et al. 2007) has been monitoring ground temperatures and modelling spatial distribution of permafrost. In this paper a synthesis of observations on geomorphic processes that are seemingly related to permafrost and ground-ice degradation from Hurd Peninsula (Livingston Island) and Deception Island is presented. The next step is a geomorphological and climatological monitoring programme, which is planned to start in 2008–09.

Climate of the South Shetlands

The climate of the South Shetlands is cold-oceanic at sea level with frequent summer rainfalls and a moderate annual temperature range. Mean annual air temperatures are close to -2ºC at sea level and average relative humidity is very high, ranging from 80 to 90% (Simonov 1977, Rakusa-Susczewski 1993). The weather conditions are dominated by the influence of the polar frontal systems, and atmospheric circulation is variable, with the possibility of winter rainfall occurring as far south as Rothera Station (Turner et al. 2007). Temperature data from Hurd Peninsula recorded by our group for the period of 2003–05 at 20 m a.s.l. show values comparable to those at Arctowski Station on King George Island. From April to November average daily temperatures stay generally below 0ºC and from December to March temperatures are generally slightly above 0ºC. Two contrasting seasons in terms of freezing and thawing are, therefore, defined. At 275 m a.s.l. on Reina Sofia Hill the recorded mean annual air temperatures were of ca. -4.2ºC. This corresponds to a lapse rate of -0.8 ºC/100 m and to a freezing season that is about one month longer than at sea level. The climate on Deception Island is similar to Hurd Peninsula.

Geomorphological Setting and Permafrost Distribution

Deception Island

Deception Island is an active stratovolcano with a large collapsed caldera; the most recent eruptions occurred in 1967, 1969, and 1970 (Smellie et al. 2002). In some places there are fumaroles and ground temperature anomalies from continued volcanic activity. Mean annual air temperature at sea level is close to -2ºC. The volcano rim rises to 539 m a.s.l. at Mount Pond, and the island is glaciated to a large extent. As a result of recent eruptions, the island has been covered by volcanic ash and debris, and many of the glaciers remain ash-covered today. Pyroclastic deposits covered snow, and buried snow is still present at some sites. The pyroclastic deposits are very porous and insulating, and give rise to a thin active layer, which varies from 30 to 90 cm in thickness.

Figure 2. Thermokarst bumpy terrain in Deception Island (arrow).

Figure 3. Thermokarst hollows in Deception Island.

On lower valley slopes, exposures of fossil snow (buried-ice) with perennially frozen ice-cemented volcanic debris on top can be observed, testifying to post-eruption aggradation of permafrost. At these sites, ice-cemented permafrost also occurs under the buried-ice layer.

Buried-ice is widespread on Deception Island, especially along the lower slopes, and ice-cemented permafrost occurs down to sea level. Geophysical surveying and trenches show that the permafrost inside the caldera thins near sea level and is absent on beaches near the shore.

Hurd Peninsula (Livingston Island)

Hurd Peninsula is comprised of mountainous terrain and is located on the southern coast of Livingston Island. About 90% of the island is glaciated, with ice-free areas occurring at low altitude, generally on small peninsulas with rugged relief. Our study focused on ice-free areas of the northwestern part of Hurd Peninsula in the vicinity of the Spanish Antarctic Station Juan Carlos I. The bedrock is a low-grade metamorphic turbidite sequence with alternating layers of quartzite and shales; conglomerates and breccias occur in some areas (Miers Bluff Formation). Dolerite dykes and quartz veins are frequent (Arche et al*.,* 1992), with the surficial lithology being very heterogeneous (Pallàs 1996).

The geological setting on Hurd Peninsula is substantially different to that of Deception Island. On the former, bedrock outcrops are prevalent, with only a thin cover of diamictite. Therefore, studying permafrost distribution is much more complex than at Deception, since frozen bedrock is very difficult to identify without a good network of boreholes. Observations from boreholes and geophysical surveying (Electrical Resistivity Tomography and Refraction Seismics Tomography) will allow a first insight into permafrost distribution, and a dense network of boreholes is planned for installation in 2007/08.

The observations indicate that continuous permafrost is present in diamictite and bedrock at least at 275 m a.s.l. At 115 m a.s.l. permafrost probably occurs only at some locations and seems to be controlled by late-lying snow patches. At this altitude in diamictite deposits, during summer, the ground thaws at least down to 1 m depth. On Hurd Peninsula, the limit between continuous and discontinuous permafrost in bedrock is probably located between these two altitudinal limits, 115 and 275 m a.s.l. However, it is possible that at 115 m the active layer is thicker than 1 m. At 35 m a.s.l. ground temperature data indicate that permafrost may be absent in bedrock, or that the active layer is thicker than 2.3 m.

Ice-cored sediments are widely distributed on Hurd Peninsula and occur down to sea level. These are likely of glacigenic origin, but in several cases still show active deformation giving origin to rockglaciers, mostly of the protalus or moraine-derived types.

Permafrost and Ground-Ice Degradation Features

Thermokarst

Thermokarst features have been observed at different sites on Deception Island. Two types of features occur, including thermokarst bumpy terrain and thermokarst hollows.

Bumpy terrain consists on a series of depressions with a small depth/width ratio that cover the terrain continuously (Fig. 2). They appear on the upper parts of the slopes inside the caldera. Preliminary observations suggest that they are more frequent on slopes below 100–150 m a.s.l.

Bumpy terrain is related to the thaw of buried-ice derived from buried snow patches. It is not yet clear if the depressions are solely the consequence of atmospheric warming or if they relate to a dynamic situation mainly induced by the thinning of the insulating layer of pyroclastic material being eroded. The thinning of the sedimentary cover, which is stronger in upper sector of the slopes, induces a decrease of the thermal insulation of the buried-ice layer, allowing for thawing. On the lower slope, the sedimentary cover is thickest due to the accumulation of material transported from upslope. There, a permafrost layer above the buried-ice layer can be observed which is probably linked to an increasing insulation effect due to sediment accretion.

Thermokarst hollows are features of decimetric to metric size and occur isolated or in small groups (Fig. 3). Their depth/width ratio is larger than the bumpy terrain, but they were not studied in detail yet. They appear in flat or

Figure 4. Debris-flow tracks in a talus slope on Hurd Peninsula (Livingston Island).

Figure 5. Debris flows depositing over the surface of the Las Palmas Glacier in Hurd Peninsula (Livingston Island).

gentle sloping terrain. No trenches were excavated, nor was geophysical surveying conducted in these features. They are probably related to localized degradation of massive ice. Their origin is not clear yet, since they can result from a climatic influence, but may also relate to changes in ground heat flux due to the volcanic activity. Geophysical surveying of these thermokarst hollows will be conducted in 2007/08.

Debris flows

Sub-aerial present-day debris-flow activity is a geomorphic process that has been poorly analysed in the literature for maritime Antarctica. Recent debris-flow tracks and deposits have been observed at several sites both on Livingston (Vieira & Ramos 2003) and Deception Islands (Figs. 4, 5, 6). Debris-flow activity is initiated by the saturation of surface unconsolidated material that flows along a channel in the slope, reworking the slope material.

In several mountain regions in the northern hemisphere an increase or altitudinal change in debris-flow activity has been linked to permafrost degradation (Jomelli et al. 2004). In maritime Antarctica, the widespread distribution of permafrost, together with the mountainous terrain and its proximity to the climatic limits of permafrost, a similar consequence of increasing air temperatures is to be expected.

Figure 6. Debris flow tracks in Deception Island.

Figure 7. Active layer detachment slide on Deception Island.

However, rainfall episodes may also be a triggering mechanism for debris flows. The lack of monitoring data does not allow us to precisely define the origin of the debris-flow activity and, therefore, in 2008/09 a monitoring programme for debris-flows will be implemented.

On Deception Island debris-flow tracks are widespread, at least in the inner slopes of the caldera. These are erosional slopes built up of volcanoclastic material. The debris flows form on the upper parts of the slopes and seem to be related to permafrost degradation, since this area is also at a similar geomorphological setting to the bumpy terrain features. The tracks are tens to a few hundred metres long. The predominantly gravely grain-size of the slope material and moderate slope angle limit the downslope movement of the flow; therefore, the debris generally does not contribute significantly to the valley floors. In the 2007/08 campaign a systematical mapping of the debris-flow tracks will be conducted in order to detect their spatial pattern and controlling factors.

On Hurd Peninsula several debris-flow tracks have been observed and one of them is known to have occurred in late spring. Debris flows on Hurd affect mainly talus slopes and lateral moraines. Due to the steep slope angles and slope length they reach more than a hundred metres in length and have been observed being deposited on top of glaciers (Fig. 5).

Active-layer detachment slides

Active-layer detachment slides form from the presence of an impermeable frozen layer at depth. Several small slides of metric dimension have been observed affecting the surface of the ice-cored moraine of the Argentine lobe of Hurd glacier in January 2000 and are related to the degradation of the ice-rich till on the very steep inner slope of the moraine. Other ice-cored moraines near sea level have been detected using electrical resistivity tomography and refraction seismics tomography and they can be subject to these processes of degradation in the near future if the current climate trend continues.

On Deception Island small detachment slides were also found on steep slopes. The mass movements were under 40 m^2 in area (Fig. 7).

Rockfalls

Rockfalls in the mountain permafrost zone have been pointed out as a consequence of permafrost degradation, especially relating to the melting of ice filling rock wall fractures (Davies et al. 2001, Kaab et al. 2005, Gruber & Haeberli 2007). Rockfalls occur on both Hurd Peninsula and Deception Island; however, without proper monitoring it is difficult to access the influence of permafrost degradation on their origin.

Conclusions

The South Shetland Islands are a privileged area to study climate change and its effects on landscape dynamics. Permafrost is widespread and occurs down to sea level. On Deception Island permafrost is continuous throughout most of the area, but on the Hurd Peninsula continuous permafrost likely occurs only above ca. 150 m a.s.l. In the same area discontinuous and sporadic permafrost exist down to sea level, especially in the form of ice-cored moraines and rock glaciers. The mean annual air temperatures at sea level are close to -2ºC, positioning the archipelago near the climatic limit of permafrost. This fact, together with the warming that affects the Antarctic Peninsula region should be responsible for permafrost degradation.

This paper describes landforms and geomorphic processes related to permafrost and ground-ice degradation that seem to result from climate change. Where ground-ice occurs, thermokarst hollows, bumpy terrain, and active-layer detachment slides have been found. The first occurs on flat or gentle sloping ground and the latter on moderate to steep slopes. Debris-flow activity was observed to be widespread on slopes of both. Their genesis has still to be assessed, since they can be linked either to ground warming or to heavy rainfall events. On Deception Island heat flux anomalies caused by volcanic activity can also generate permafrost degradation features. These anomalies are of small areal extent and their locations are known.

The observations presented here are preliminary and constitute a starting point for a new approach that will emphasize monitoring of geomorphological activity in order to detect the influence of climate change on present-day processes. Another interesting issue to be analysed is the control of changing geothermal heat fluxes on permafrost degradation in Deception Island and to assess on the possibility of using permafrost degradation features as indicators of changes in volcanic activity.

Acknowledgments

This study was conducted as part of the project PERMAMODEL within the Spanish Antarctic Program CICyT (CGL2004-20896-E/ANT). Abstract

Maximum thaw depths were measured annually in an unburned stand, a heavily burned stand, and a fireline in and adjacent to the 1971 Wickersham fire. Maximum thaw in the unburned black spruce stand ranged from 36 to 52 cm. In the burned stand, thaw increased each year to a maximum depth of 302 cm in 1995. In 1996, the entire layer of seasonal frost remained, creating a new active layer depth at 78 cm. An unfrozen soil zone (talik) remained between the two frozen layers until 2006 when the entire profile remained frozen. Permafrost returned to the burned site by the formation of a layer of seasonal frost that remained frozen through subsequent years. The fireline displayed a similar pattern with a maximum thaw of 266 cm in 1995 and the establishment of a continuous frozen layer at 69 cm, but the upper frozen layer became discontinuous after several years.

Keywords: active layer; boreal forest; disturbance; fire effects; permafrost.

Introduction

The 1971 Wickersham fire burned 6313 ha in an open black spruce (*Picea mariana* [Mill.] BSP) forest underlain with permafrost in the boreal forest of interior Alaska. As a part of the fire suppression effort, 113 km of fireline were constructed with heavy equipment which removed most of the organic layer and resulted in an increase in depth of thaw. This fire provided an opportunity for long-term studies of the effects of fire and fireline construction on the rate and pattern of permafrost degradation and subsequent recovery. The annual thawing of the active layer in undisturbed vegetation at the site was also documented and vegetation change following the fire was observed. This is one of the longest records of annual active layer measurements in the boreal forest of North America (Brown et al. 2000). Initial results of this study were reported 12 years after the fire (Viereck 1982) and again 33 years after the fire (Viereck et al. 2004).

When wildfire burns through a northern black spruce forest, there is usually a subsequent increase in soil temperature and depth of thaw due largely to reduction in organic layer depth and subsequent loss of thermal insulation (Van Cleve & Viereck 1981, Mackay 1995, Swanson 1996, Burn 1998). Reduced heat loss from decreased evapotranspiration and a lowering of the surface albedo after wildfires also contribute to higher ground surface temperature and an increase in active layer thickness (Mackay 1995, Burn 1998, O'Neill et al. 2002).

We hypothesized that a continuous increase in the active layer would occur initially at the burned site, followed by the return of a shallow active layer by a gradual freezing back from the lower depth (Fig. 1).

This long-term study presents results of 36 years of annual measurements of the active layer in a burned black spruce site, a fireline in which the organic layer was removed, and in an adjacent undisturbed black spruce forest underlain by ice-rich permafrost. The purpose of this paper is to compare annual depth of thaw among these three sites and to document the recovery of vegetation, soil organic layers, and permafrost after fire and fireline construction.

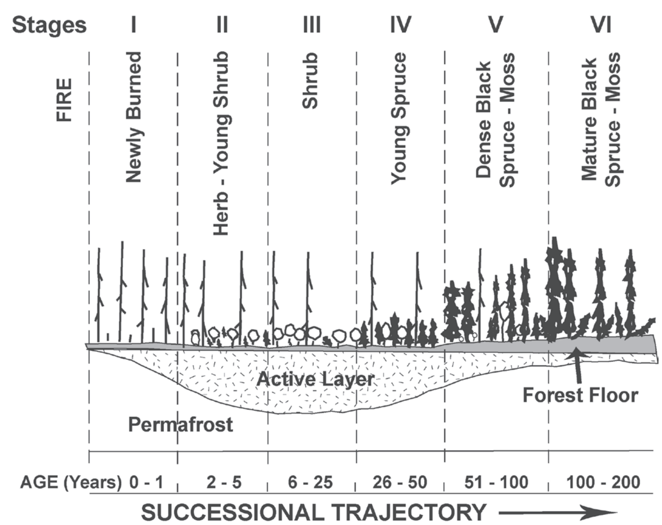

Figure 1. Succession model showing vegetation and active layer changes in a burned black spruce stand. Model modified from Van Cleve & Viereck (1981).

Methods

Study area

The Washington Creek Fire Ecology Research Area, located 50 km northwest of Fairbanks in interior Alaska (65°10′N, 147°54′W, 335 m elevation), was established to study the effects of the June 1971 Wickersham fire. The fire was ignited by lightning and burned 6313 ha in an open black spruce stand underlain by permafrost (Viereck & Dyrness 1979).

The vegetation prior to the fire was a 100- to 150-year-old open black spruce/lichen stand with a moss-derived organic layer 25 to 30 cm thick. The burn severity was originally classified as heavy, but later reduced to moderate. All of the trees and above-ground parts of the mosses, lichens, herbs, and shrubs were killed by the fire, but below-ground parts of some herbs and shrubs remained alive. Approximately one third (10 to 15 cm) of the organic layer was removed by the fire (Viereck & Dyrness 1979). At the time of the fire (June 24–30), the organic layer would have been thawed to only 20 to 30 cm. The soil is in the Saulich series with an active layer that varied from 40 to 50 cm.

Climate

Continuous climate records are not available from the site; the long-term weather record was obtained from the Weather Bureau's Fairbanks airport site. The Fairbanks record was compared with short-term climate studies at the Wickersham site. These include weather records kept at the study site from November 1971 to September 1980 and at the adjacent Washington Creek Fire Ecology Research site from January 1977 to September 1999.

From these records, we have estimated that the mean annual temperature at the Wickersham site is 1°C to 2°C colder than at the Fairbanks airport. Summer months tend to be cooler than Fairbanks, but winter months are warmer because of the lack of a cold inversion layer present during extreme cold spells in Fairbanks (Viereck 1982). The air temperatures at the Fairbanks airport have risen considerably during the period of this study (Hinzman et al. 2006). Since air temperatures at other weather stations in interior Alaska have also risen (Osterkamp & Romanovsky 1999), air temperatures at the Wickersham site are likely to have warmed, but there are no recent measurements to confirm this.

Maximum snow depths for each year at the Fairbanks airport are reported here. Based on only two winters of snowfall records available from the Wickersham fire (1977 and 1980), snow accumulation at the study site is usually about 25 cm greater than in Fairbanks (Viereck 1982).

Experimental design

A 25 m wide fireline was constructed up and down the slope between a heavily burned black spruce stand and an unburned stand, which before the fire was continuous and very similar to the stand that was burned. Most but not all of the organic layer was removed by the bulldozers in the construction of the fireline.

Three study sites were established in: 1) the heavily burned stand, 2) the fireline where vegetation and organic material were removed down to the frozen layer, and 3) the adjacent unburned black spruce stand that served as a control to compare the fireline and burned areas. At each site, 10 permanent probe points were established at 2 m intervals across the slope and perpendicular to the fireline. Maximum thaw depths were measured annually from 1971 to 2006 at each sample point using a metal probe.

A permanent transect of fixed points at 1 m intervals was established across the fireline from the burned stand on the north side to the unburned stand on the south side. At the center of this transect were ten poles that were used as probe sites to obtain the average thaw for the fireline. Across the entire width of the fireline, active layer depths were measured annually. Levels to the soil surface of the transect were made with a theodolite at intervals of three to five years, and changes in surface level relative to a fixed point were measured. Using these surface levels, it was possible to plot the profile of the surface and the depth of the active layer annually across the transect.

In 2002, a 6.5 m deep borehole was drilled in the burned site and a string of thermistors installed at 25 and 50 cm intervals to record temperatures. These temperatures have been logged both manually and with a logger at intermittent periods between 2002 and the present.

Vegetation

The vegetation of each of the sites was recorded at varying intervals. In the early years of the study, the vegetation of the burned and unburned stands was determined with a 20-plot system (Viereck 1982). In 1980, 1995, and 2004, vegetation of the burned, unburned, and fireline sites was measured by plots centered on the ten active layer probe sites. Moss, lichen, herb, and shrub percent cover was measured in 1 m^2 plots centered on the probe poles. Shrub cover was measured on 4 m^2 circular plots centered on the probe poles. Tree density and diameters were measured on larger circular plots.

Organic layer thickness

The thickness of the organic layer was originally measured in the 20 vegetation plots in the burned and unburned stands. Organic layer thickness of the fireline transect was assumed to be negligible at the beginning of the study. Organic layer thickness was remeasured along the probe lines in 1980, 1995, and 2004.

Results

Vegetation

The general vegetation type is a black spruce/moss/lichen community (*Picea mariana* / feathermoss / *Cladonia*–open needleleaf forest community) (Viereck 1982). Previous to the fire, the vegetation consisted of an open canopy of black spruce with an average diameter of 5.2 cm at 1.3 m height, a density of 1240 trees/ha and 45% canopy cover. In 1971, the age of most of the trees was 70 years, but there were a few scattered trees of 135 to 140 years in the stand. There was an open tall shrub layer of *Salix pulchra* and *Betula glandulosa* and a low shrub layer of *Ledum groenlandicum* and *Vaccinium vitis-idaea*. The moss and lichen layer was made up primarily of *Pleurozium schreberi* and scattered *Sphagnum* species, and several species of *Cladonia* and *Peltigera* (Viereck 1982).

Unburned control site: Vegetation data recorded in 1980, 1995, and 2004 at the control site showed that the stand did not change significantly during that period and was similar to that recorded in 1971. Cover of the black spruce canopy was 22% in 2004. There was an open tall shrub layer of 8% mostly of *Salix pulchra* and *Betula glandulosa* and a low shrub layer of 47% *Ledum groenlandicum* and *Vaccinium vitis-idaea*. The moss and lichen layer of 95% cover was made up primarily of *Sphagnum girgensohnii*, *Pleurozium schreberi* and *Cladonia rangiferina.*

Burned site: Revegetation was slow for the first 9 years following the fire, probably as a result of the 10 to 20 cm organic layer that remained after the fire and provided a poor seedbed for invading pioneer species (Viereck 1982). Early revegetation was primarily from roots and underground rhizomes that had survived the fire. *Equisetum sylvaticum* and *Calamagrostis canadensis* and an occasional *Epilobium angustifolium* provided nearly 70% cover by 1980. Early successional mosses, *Ceratodon purpureus* and *Polytrichum juniperinum*, covered 35% of the surface. A few black spruce seedlings had become established, but provided less than 1% cover.

From 1980 to 2004, development of the site toward a mature black spruce stand continued at a somewhat faster pace. Black spruce reestablished with a cover of 17%. The tall shrub cover of *Betula glandulosa* and *Salix pulchra* reached 12%, while a low shrub layer primarily of *Ledum groenlandicum* and *Vaccinium vitis-idaea* developed a cover of 40%. The herbaceous layer of 55% cover is still dominated by *Equisetum sylvaticum* with some scattered clumps of *Calamagrostis canadensis*. The moss layer with 55% cover is still dominated by *Polytrichum juniperinum*, but feather mosses have developed a combined cover of 20%. Although *Ceratodon purpureus* has disappeared from the stand, the first small clumps of *Sphagnum* species (<1% cover) are now present in the stand. There has not been a significant return of any lichens to the stand after 36 years.

Fireline site: Invasion of herbaceous species and shrubs by seed was rapid in the first nine years after the fireline construction because of the exposed mineral soil and the wet condition of the surface. Herbaceous species of wet habitats accounted for nearly all of the 52% herbaceous cover. Since 1980, the herbaceous cover has been reduced drastically to 31% in 1995 and 18% in 2004. Tall shrub cover was nearly constant at 33% to 36% from 1980 to 2004. The moss layer changed dramatically throughout the 36-year period. Total moss cover dropped from 75% in 1980 to 44% in 2004. As of 2004, no lichens had established on the fireline. Although a few black spruce seedlings established near the edge of the fireline transect in the first few years following the fire, they had achieved a cover of only 4% by 2004.

Organic layer thickness

Unburned control site: The study area, situated on Saulich silt loam soils, originally had a combined organic layer thickness of 25 to 30 cm at the time of the fire (Viereck 1982). The profile was comprised of decaying mosses and litter (O1 and O2 layers). The organic layer of the unburned control stand was measured again in 1980 and 1995. The organic layer consisted of mosses and peat, formed primarily of *Sphagnum*. The average thickness of these layers was 33 cm, ranging from 16 to 45 cm.

Burned site: In the burned stand, the fire removed an average of 10 cm of the organic layer, although depths were variable (Viereck 1982). In 1980, the organic layer consisted of a 0 to 3 cm thick moss layer overlying a 1 to 2 cm layer of dark humus. By 1995, the organic layer consisted of 3 cm of mosses, primarily *Polytrichum* species, overlying 5 cm of dry, decaying mosses and the previously developed 2 cm layer of humus for a total organic layer of 10 cm. In 2004, the organic layer still consisted of 3 cm of moss, but the decaying moss layer had decreased to 3 cm and the humus layer had increased to 6 cm, for a total organic layer of 12 cm.

Fireline site: The irregular organic layer of the fireline is difficult to characterize. Although most of the organic layer was removed by the fireline construction, pockets and areas of the original humus layer remained. The surface of the fireline remained very wet, and several semi-aquatic mosses and *Sphagnum* species developed quickly. By 1980, the organic layer consisted of approximately 5 cm of live and decaying mosses overlying 4 to 5 cm of humus, for a total organic layer of 9.3 cm. The overall organic layer thickness was less in 1995 with a small decrease in both the moss and the humus layers. However, by 2004, the overall organic layer had increased to 12 cm. Although the humus layer had decreased since 1995, a fibrous layer of decayed sedges and grasses had developed to account for the increase.

Active layer thickness

The primary objective of this study was to document the changes in the annual depth of thaw (the active layer) following the 1971 fire (Fig. 2).

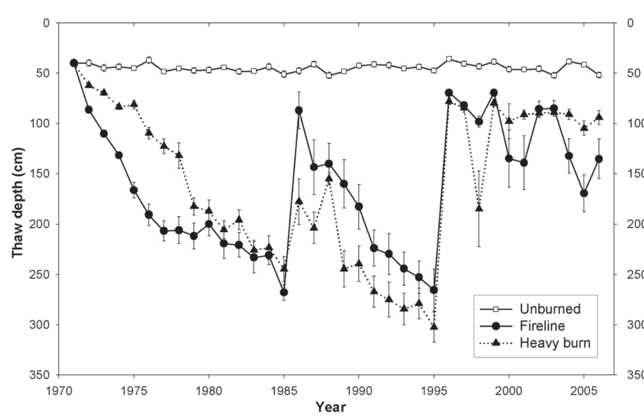

Figure 2. Maximum thaw depth of an unburned black spruce stand, a burned black spruce stand, and a fireline from 1971 to 2006. Values represent the mean (n = 10) and standard error.

Unburned control site: Maximum thaw ranged from 36 cm in 1996 to 52 cm in 1988, 2003, and 2006. The average thaw depth over the 36-year period was 45 cm. There was a tendency for deeper thaws to be associated with higher snowfall the previous winter and higher thawing degree days the following summer. For example, the minimum thaw depth of 36 cm in 1996 followed a previous cold winter with low snowfall through the month of January.

Burned site: Annual maximum thaw depth increased rapidly in the first 14 years following the fire to a maximum depth of 245 cm in 1985. In 1986, however, seasonal frost remained in 3 of the 10 probe sites resulting in an average thaw of 178 cm. An upper layer of frozen soil remained at some of the probe sites for the next 2 years resulting in an average thaw of only 155 cm in 1988. These upper layers melted out completely in 1990 and the depth of thaw continued to increase to 302 cm in 1995. In 1996, following a winter with light snow and cold temperatures, the upper seasonal frost layer remained at all 10 probe sites, giving an average thaw of only 78 cm. This upper layer has remained frozen, except in 1998 when 4 of the probe sites reached the bottom thaw layer of over 300 cm, to give an average thaw depth of 185 cm. From 1998 to 2006, the upper layer has remained frozen, and the thaw depth has ranged from 80 to 105 cm.

Mean annual temperatures and snow depths from the Fairbanks International Airport (Fig. 3) show that the two summers when seasonal frost first remained (1986 and 1996) followed winters of low snowfall. In addition, 1996 had a below average mean annual temperature.

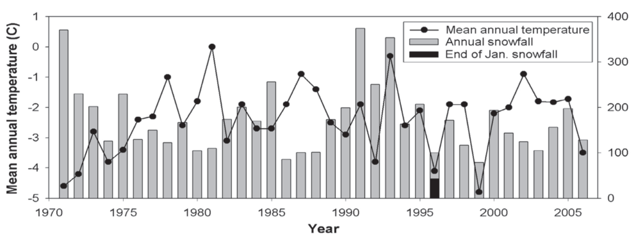

Figure 3. Mean annual temperature and mean annual snowfall for Fairbanks, Alaska from 1971 to 2006.

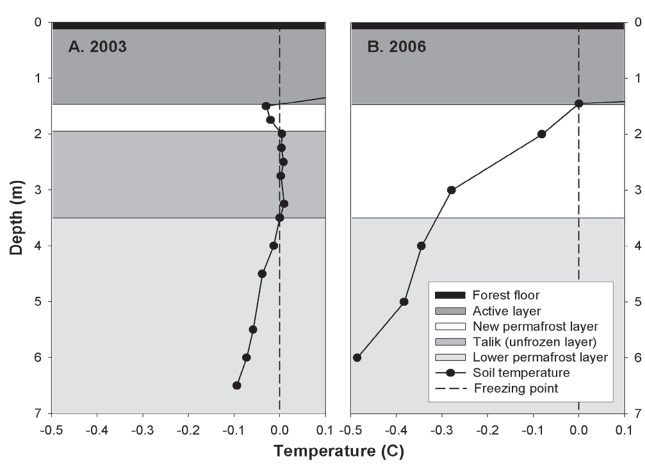

Figure 4. Soil temperature profiles from the burned site borehole, A) 2003 profile shows a new frozen layer approximately 50 cm thick extending from 1.4 to 1.9 m below the active layer, B) 2006 profile shows complete freezing of the talik and new permafrost extending 1.45 m below the present active layer.

Fireline site: For the first 25 years following the fire, the thaw depth under the fireline followed much the same pattern as the burned site. There was an annual increase in thaw depth from 1971 to a maximum of 268 cm in 1985. In 1986, the upper layer of seasonal frost remained frozen across the entire fireline. For the next six years, the upper seasonal frost layer began to thaw, and the number of probe points that penetrated through to the lower frozen layer increased from three in 1987 to all ten of the probe points in 1992, when the thaw depth approached the pre-1986 level. This condition continued until 1995 when a thaw depth of 266 cm was recorded.

In 1996, a winter of light snow and below average temperatures (Fig. 3) resulted in a seasonally frozen layer that persisted throughout the following summer. The average depth of thaw in 1996 was only 69 cm. Unlike the burned area, the shallow layer of frozen soil did not remain along the probe line. From 1997 through 2006, there was an increase in the number of probe points that reached the pre-1996 level. By 2006, only 2 points along the probe line had thaw depths less than 100 cm, and the average thaw depth of all 10 points was 135 cm.

At this time, it is impossible to predict if the upper frozen layer will continue to melt or if a light snow year with cold temperatures, such as occurred in 1996 and 2006, will result in the reestablishment of a continuous upper frozen layer.

Borehole profile

The thickness of the upper frozen layer was impossible to determine using our probing method. In 2002, we drilled a 6.5 m deep borehole in the burned site near the probe line and installed a series of thermistors to obtain temperatures throughout the soil profile.

A temperature profile from the borehole during the period of maximum thaw in September of 2003 (Fig. 4A) shows an active layer of 1.4 m. The new frozen layer was approximately 50 cm thick and extended from 1.4 to 1.9 m below the current active layer. This new permafrost layer divided the active layer and the talik formation. The talik temperatures were very close to 0°C. Below 3.4 m, the temperatures of the original permafrost layer decreased to -0.1°C at the bottom of the borehole (6.5 m). The lower permafrost depth stabilized at 3.5 to 4.0 m, and an unfrozen soil zone (talik) remained between the two frozen layers. However, in September of 2006, the temperature profile (Fig. 4B) shows the disappearing talik layer. The permafrost temperature at 6 m depth is more than 0.3ºC colder after 3 years. The new permafrost development, since 1996, accelerated the refreezing of the talik layer. As a result of the three years of permafrost aggradations, the ground temperature profile is becoming similar to the pre-fire thermal conditions.

Fireline cross section

To better understand the changes in thaw depth across the fireline, cross sections of the fireline were measured

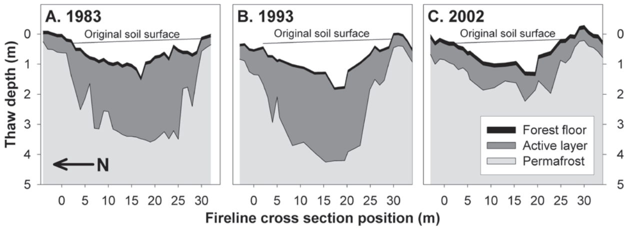

Figure 5. Cross section of the fireline in A) 1983, B) 1993, and C) 2002, showing considerable lowering of the original surface, and the reestablishment of permafrost in an uneven band across the entire fireline.

periodically during the 36 years of the study. Changes prior to 1980 are described by Viereck (1982). Figure 5 shows the cross section in 1983; 1993, when thaw was near the maximum; and 2002, the most recent cross section where the new layer of seasonal frost had persisted.

Surface: Figure 5 shows a considerable lowering of the surface level over time through subsidence and erosion. In 1983 (Fig. 5A), the surface lowered about 1 m through erosion and subsidence with slightly more on the northern side of the fireline. By 1993 (Fig. 5B), a small intermittent stream that formed from water captured upslope in the fireline had created a ditch that was approximately 75 cm deeper than the surrounding surface. The 2003 profile of the surface (Fig. 5C) shows that there has been some filling of the ditch and a slight rise in the surface of the fireline, which may be the result of vegetation buildup, deposition, and expansion due to the refreezing of water into ice in the newly frozen upper layer.

Depth of thaw: The cross sections in Figure 5 show that the depth of maximum annual thaw and the reestablishment of permafrost occur in an uneven band across the fireline. In 1983 (Fig. 5A), the deepest thaw occurs near the middle of the fireline beneath the small stream. There is a very steep rise of the permafrost on the south side of the fireline, due perhaps to the shading of that side of the fireline by trees to the south. The cross section in 1993 (Fig. 5B) shows that the thaw is fairly even across the middle of the fireline and rises sharply on both edges to the level of the active layer in the adjacent undisturbed vegetation. By 2002 (Fig. 5C), the upper surface of the newly developed permafrost is uneven, but in general follows the surface layer.

Estimated fireline cross section: Figure 6 illustrates a conceptual fireline cross section during the late 1990s and early 2000s, when the upper zone of permafrost (newly established in 1996) was intact. It shows the surface of the fireline, lowered through erosion and subsidence, and the uneven surface of the new upper frozen layer. The base of this layer is estimated from the measured thickness in the burn site (approximately 150 cm) at a similar period. Below this is an unfrozen layer of talik that is surrounded above and below by the permafrost in the adjacent unburned area. For the base of the talik, we have used the depth of thaw taken in 1995 when the thaw was at its deepest. Below the talik is the zone of permafrost that was there before the fire and reaches an unknown depth.

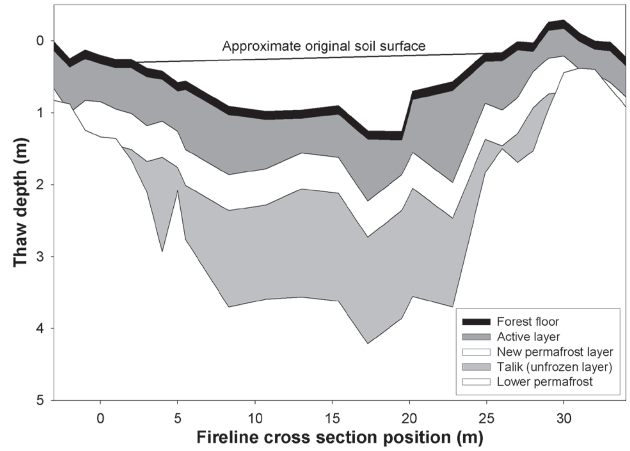

Figure 6. Conceptual fireline cross section during the period (1996–2003) that the upper zone of newly established permafrost was intact.

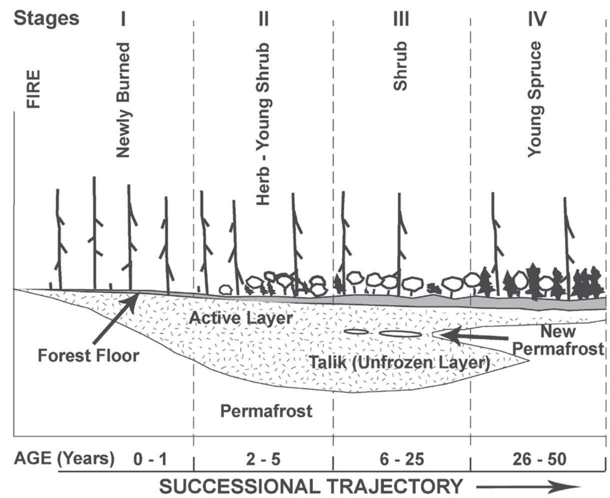

Figure 7: Successional changes observed in vegetation and the active layer at the burned site following the Wickersham fire.

Conclusion

Long-term observations such as those made on active layer and vegetation changes over the last 36 years at the Wickersham fire site are extremely valuable for developing an understanding of the effects of fire and fireline construction in the boreal forest of Alaska. We originally hypothesized that a shallow active layer would return to the burned site by a gradual freezing back from the lower depth (Fig. 1). We expected to observe a continuous increase in the active layer to a maximum depth during the first 30 to 50 years after the fire. Next, a gradual decrease in the active layer was expected to return the active layer to its approximate pre-fire depth 100 years following the fire. Other long-term measurements of active layer recovery following wildfire in the southern Yukon Territory (Burn 1998) and near Inuvik, N.W.T., Canada (Mackay 1995) reported that permafrost aggraded upward in a return to pre-fire conditions.

Surprisingly, a layer of seasonal frost formed at the Wickersham burned site that eventually remained frozen throughout the entire year and continued to remain frozen for the next ten years (Fig. 7). The active layer did increase for the first 25 years following the fire as originally hypothesized. However, an upper layer of seasonal frost remained frozen 17 years after the fire and then became discontinuous for the next 10 years. Since 1996, the seasonal frost layer has remained frozen. This created a new permafrost layer with an active layer of 90 cm and an unfrozen talik layer between the upper and the lower frozen layers. This new permafrost layer accelerated the refreezing of the talik layer, and by 2006, the talik layer disappeared (Fig. 4B) and the permafrost has returned to the pre-fire thermal conditions.

Another important observation of this study is that under present climate conditions, permafrost is reforming at the Wickersham fire site on the burned stand but not on the fireline. The increased maximum thaw depth pattern for the two sites is similar, with a maximum thaw of 266 cm for the fireline and 302 cm for the burned site in 1995 (Fig. 2). Also, the development of an upper frozen zone in 1986 and 1996 was similar. The difference on the fireline is that the upper frozen zone has become intermittent, but it may be rejuvenated by another cold snowless year.

In addition to the permafrost differences at the burned and fireline sites, there is a significant difference in rate of vegetation recovery between the burned area and the fireline. The vegetation of the burned area is beginning to have many features of the original black spruce stand, whereas the fireline has remained very different with few features and species of the original stand.

Investigation of the Permafrost Environment for Pile Installation at Fort Wainwright, Alaska

Ted S. Vinson

Professor (Emeritus), Department of Civil Engineering, Oregon State University, Corvallis, Oregon, USA

Abstract

During 2004, 516 piles were driven to -18 m (59 ft) for housing units on Fort Wainwright, Alaska. Nearly 93% of the piles encountered permafrost compared to the contractor's estimate of 15%. Owing to the substantial difference between the actual and estimated number of piles that encountered permafrost, an investigation was undertaken to determine if the prediction of the percentage of piles that would encounter permafrost could have been improved prior to pile driving. Very limited data was available. No borings within 100 m (330 ft) of the housing units were advanced to a depth of 18 m (59 ft). Notwithstanding this fact, a topographic surface was generated using commercially available mapping software from four borings which encountered permafrost and six borings advanced to 14.5 m (47.5 ft) in thawed material at the project site. When the building footprints were projected on the predicted surface, it was estimated that greater than 80% of the piles would encounter permafrost.

Keywords: degrading permafrost; mapping; pile driving; topographic surface.

Introduction

During the period July 6 to October 16, 2004, 516 piles were driven as foundation elements for four housing units on Fort Wainwright, Alaska. The piles were driven to a design tip elevation of -18 m (-59 ft) on an approximate two hectare (five acre) tract to the west of an existing housing complex on Alsace Loop. A total of 129 piles were driven at each housing unit (i.e., 4 units x 129 piles per unit = 516 piles). The 2-cm (8-in.) diameter piles were driven with a hardened steel driving shoe welded to the pile tip to prevent damage during high driving resistance. Of the 516 piles driven, 479 piles experienced high driving resistance when permafrost (typically frozen sand and/or gravel) was encountered at depths ranging from 6 to > 15 m (19 to > 50 ft). When permafrost was encountered, it required a substantial change in the installation procedure. Specifically, the pile was cut, a tricone (or roller) drilling bit was inserted in the pipe pile, a hole was advanced (i.e., predrilled) to the pile tip elevation or beyond, the cut section of the pile was welded back onto the pile, and the pile was driven through the permafrost to the design tip elevation. Of the 479 piles encountering permafrost, 24 were completed without predrilling, 362 required one predrilling operation and 93 required two predrilling operations.

Nearly 93% of the piles at the four housing units, designated as Buildings C, D, F, and H, encountered permafrost. The pile foundation contractor, based on a "conventional" interpretation of the pre-bid boring logs, estimated 15% of the piles would encounter permafrost. More specifically, the contractor noted "Six of the forty (40) test borings in or near the four buildings where pile foundations were specified indicated the existence of permafrost" Consequently, [6/40] x 100% = 15% of the piles would encounter permafrost.

Owing to the substantial difference between the estimated compared to the actual number of piles that encountered permafrost, an investigation was undertaken to determine if the prediction of the permafrost surface and the percentage of piles that would encounter permafrost could have been improved prior to pile driving. The results of the investigation are reported herein.

Geologic Conditions, History of Surface Disturbance and Modification, Boring Logs

Fort Wainwright is situated in the Tanana River Valley, to the south and east of Fairbanks, on the broad floodplain of the Tanana and Chena Rivers. The Tanana basin was filled through alluvial processes with deposits of silt, sand, and gravel, in excess of 180 m (590 ft) deep near the Tanana River. A mantel of 1–5 m of aeolian silt to silty fine sand may overlie these alluvial deposits in the Fort Wainwright area. At the project, site there is a silt-to-silty sand layer of approximately 1–5 m (3–16 ft) depth overlying clean sand and/or gravel to a depth greater than approximately 16 m (53 ft) (maximum boring depth).

Fairbanks and Fort Wainwright are in a discontinuous permafrost zone. The occurrence and characteristics of permafrost in a discontinuous zone can vary dramatically. On Fort Wainwright moss-dominated black spruce forests on lowlands or lower slopes are generally underlain by permafrost. Romanovsky (2006) reports the typical thickness of permafrost around Fairbanks is about 50 meters (165 ft), but varies between a few meters to 150 m (490 ft) and more.

Removal of the vegetative cover in an area underlain by permafrost will cause the permafrost to degrade. Pewe & Reger (1983) report that past surface disturbances have increased the depth of permafrost in the Fairbanks area by 7–12 m (23–40 ft). Linell (1973) reported that on a research site in the Fairbanks area underlain by frozen silt, when the trees and brush were removed, the permafrost level, initially at -1.1 m (-3.6 ft), degraded to -4.7 m (-15.4 ft) after 26

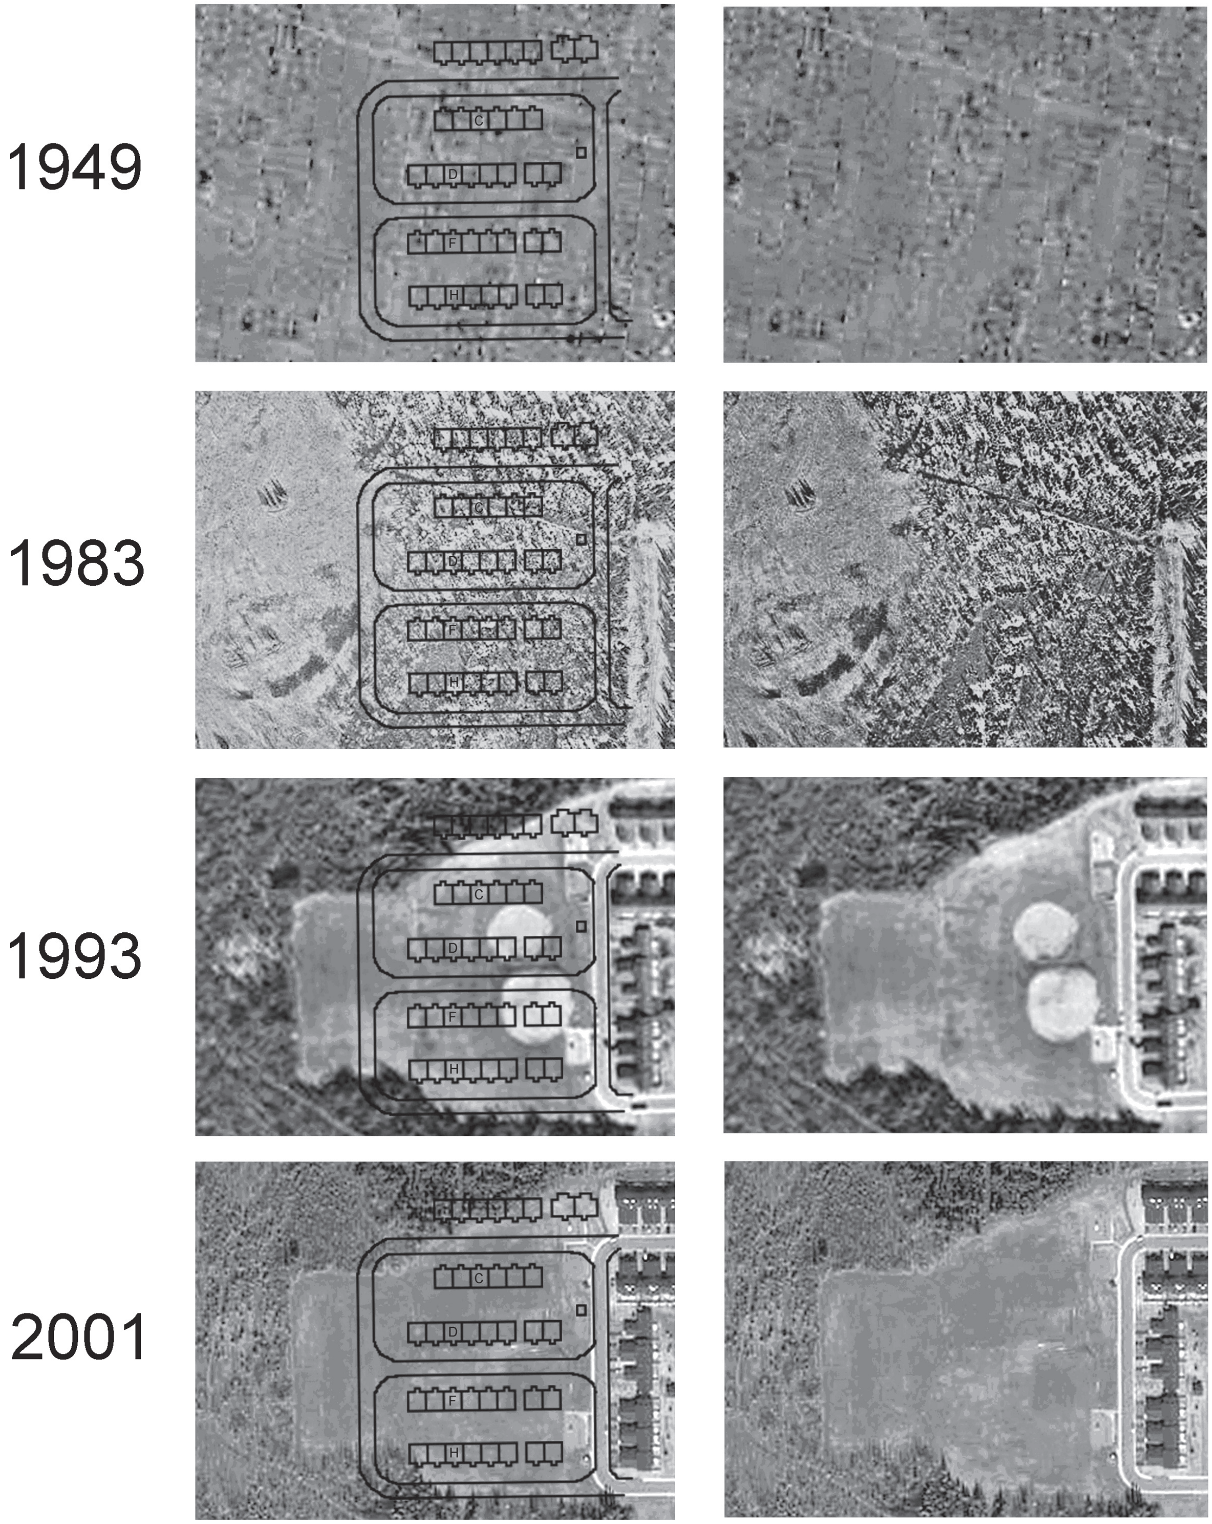

Figure 1. Comparison of 1949, 1983, 1993, and 2001 airphotos of the project site. The left frames show the project site with the building structures and roads superimposed. The right frames are without building structures and roads. North is at the top of the photographs.

years. In the same study, when the trees, brush, and surface vegetation were removed, the permafrost level degraded to -6.7 m (22 ft) after 26 years. Studies by the Defense Mapping Agency Hydrographic/Topographic Center (1978) indicate that permafrost at Fort Wainwright in cleared areas occurs at 8–13 m (26–43 ft) below the ground surface. Cleared areas were defined as areas where surface vegetation has been removed. It is apparent from past studies in the Fairbanks area that the amount and rate of degradation is dependent on a number of factors.

The preceding reported thaw depth estimates are based on conduction as the heat transfer mode. Convective heat transport associated with groundwater flow will cause thawing of permafrost. Conduction and convection heat transfer modes acting in concert have resulted in permafrost thawing in the Fairbanks and Fort Wainwright area greater than the values noted above.

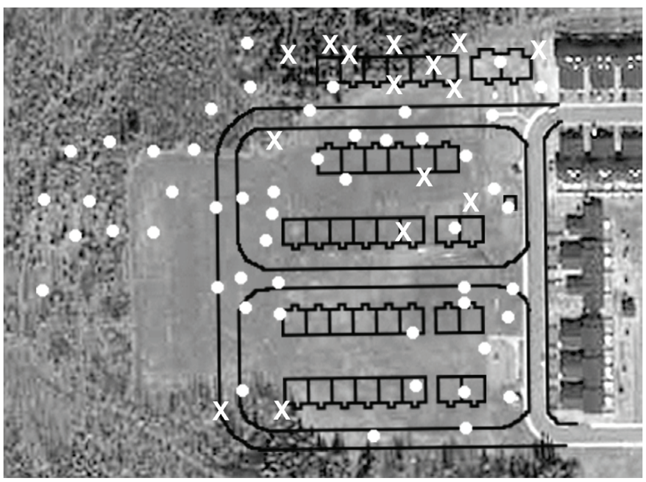

Figure 2. Schematic of borings, buildings, and roads on the 2001 airphoto. Circles indicate permafrost thawed to a depth greater than the boring was advanced; X indicates permafrost was encountered.

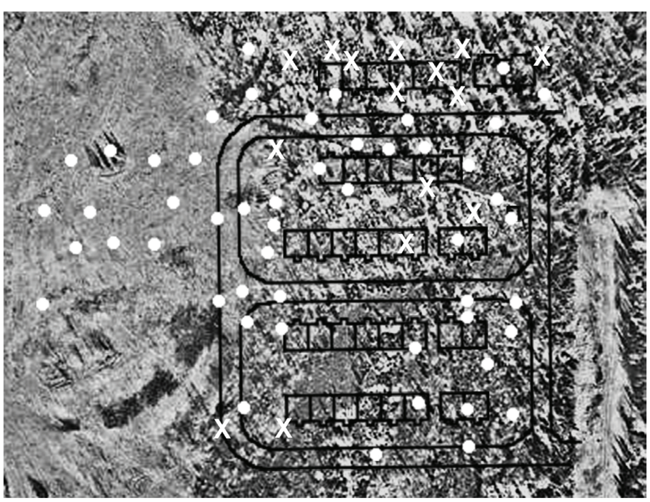

Figure 3. Schematic of borings, building, and roads on the 1983 airphoto. Circles indicate permafrost thawed to a depth greater than the boring was advanced; X indicates permafrost was encountered. The similarity in the surface vegetation over the project site is apparent.

Fort Wainwright (formerly Ladd Field) was established in 1939. Figure 1 shows 1949 and 1983 airphotos of the project site in which the surface vegetation and trees prior to surface disturbance and modification are clearly visible. It is apparent that significant surface disturbance did not occur on the project site prior to 1983. Considering the character of the vegetation, it is likely the project site was completely underlain by permafrost at a relatively shallow depth prior to surface disturbances. Based on boring logs presented in the March 2003 Geotechnical Report for the project, in "Black spruce woods with moss on the ground" permafrost occurred at a depth of less than 1 m (3.3 ft). Evidence of a substantial change in surface cover is shown in the 1993 airphoto taken approximately two years after construction activities were initiated for a housing complex on Alsace Loop to the east of the project site. The 2001 airphoto shows the likely site condition when the geotechnical investigation was conducted at the project site (2002–2003). The central portion of the site was a recreational facility (e.g., softball fields and playground). An old excavation was present at the mid-eastern portion of the site. There was evidence that a large portion of the site was graded in the past. It was reported that the open areas are fill material.

The boring logs for the project site provide evidence of permafrost degradation in the 10- to 12-year period from the early 1990s to 2002–2003. The boring locations are shown in Figure 2 overlain on the 2001 airphoto of the site.

Following a review of the boring logs in the general vicinity of Buildings C, D, F, and H, 17 borings were advanced through thawed material to a depth of approximately 7 m (23 ft). The correct interpretation of the 17 boring logs is that permafrost has degraded to a depth of at least 7 m (23 ft) at the location of the borings. It cannot be assumed that permafrost is absent at these locations or permafrost has thawed to a depth of 18 m (59 ft) (i.e., design depth of pipe pile). Six borings were advanced to a depth of approximately 14.5 m (47.5 ft), indicating that permafrost had degraded to a depth of at least 14.5 m (47.5 ft) at these locations. Three borings which were in the "footprints" of Buildings C, D, and H, indicated permafrost was present at depths of 1.5, 6.5, and 9.5 m, respectively. A fourth boring west of Building C indicated permafrost at a depth of 14.2 m (46.6 ft). Figure 3 shows the boring locations superimposed on the 1983 airphoto. As previously noted, there was very little difference in the character of the surface vegetation

Table 1. Borings in the footprint and close proximity of Buildings C, D, F, and H.

Building	Borings in Building Footprint	Borings within 10 m of Building Footprint	Total Number of Applicable Borings
C	1	5	6
D	1	2	3
F	1	1	2
H	1	1	2

from 1949 (and likely much earlier) up to the initiation of construction activities at the project site in the early 1990s. This implies that permafrost was very likely at a relatively shallow depth over most of the project site prior to the early 1990s.

The number of borings in the footprint and close proximity of Buildings C, D, F, and H is given in Table 1. It is apparent that very limited data is available to estimate the permafrost surface beneath the buildings. Furthermore, and equally significant, is the fact that no borings within 100 m (330 ft) of any proposed building were advanced to the tip elevation of the pipe piles (18 m, 59 ft).

Use of Pile Driving Records to Plot Topographic Map of Permafrost Surface

The driving record for the 479 piles which experienced high driving resistance when permafrost (typically frozen sand and/or gravel) was encountered at depths ranging from 6 to >15 m (20 to >50 ft) may be used to create a topographic map of the surface of the permafrost at the project site. Each pile location was assigned an X and Y coordinate. The Z coordinate is the depth at which permafrost was encountered during pile driving. A topographic surface is produced using a surface generation algorithm. A contour map can be plotted on the topographic surface or projected to the ground surface. The topographic surface and contour map shown in Figure 4 is believed to be an accurate depiction of the actual permafrost environment at the site. The irregular character of the surface and depth of thaw strongly suggests that both conduction and convection heat transport processes are occurring at the project site. Figure 5 presents the contour map together with the footprints of Buildings C, D, F, and H. It is apparent that permafrost at a depth of 18 m (59 ft) underlies all of Buildings C and D, and 85+% of Buildings F and H. This is in excellent agreement with the occurrence of permafrost at a depth of 18 m (59 ft) or less from the pile driving records.

Comparison of Permafrost Surface at Site to the Record provided by Boring Logs

Figure 6 shows a contour map of the depth to permafrost from the pile driving record and the locations of borings advanced in the area. Borings which encountered permafrost and borings advanced in thawed material are shown. The number adjacent to the boring locations indicates either the depth to permafrost or the maximum depth to which thawed material was encountered. By comparing the depths shown adjacent to the borings to the contour intervals it is possible to establish if the boring logs indicated a site condition that was different than the conditions actually encountered. For the fifteen borings that were inside the boundary of the contour map, there are no apparent contradictions. At the locations where 12 borings were advanced to an approximate 7 m (23 ft) depth and thawed ground was reported, permafrost was encountered at a greater depth during the pile driving

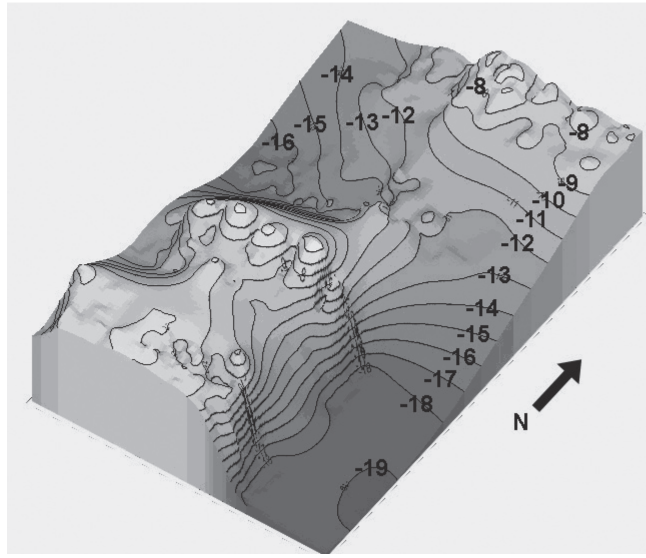

Figure 4. Topographic surface of permafrost based on the pile driving records. The irregular character of the surface strongly suggests that conduction and convection heat transport processes are occurring at the project site. The depth in meters is shown on the contour lines.

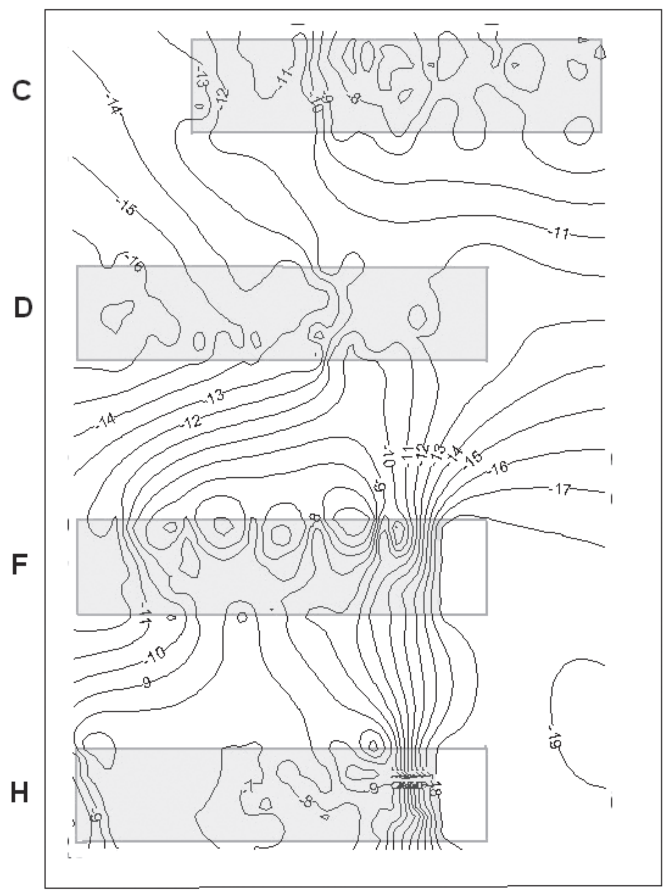

Figure 5. Contour map together with the footprints of Buildings C, D, F, And H. The shaded area represents the occurrence of permafrost at a depth of 18 m (59 ft) or less. It is apparent that permafrost at a depth of 18 m (59 ft) underlies all of Buildings C and D, and 85+% of Buildings F and H. The depth in meters is shown on the contour lines.

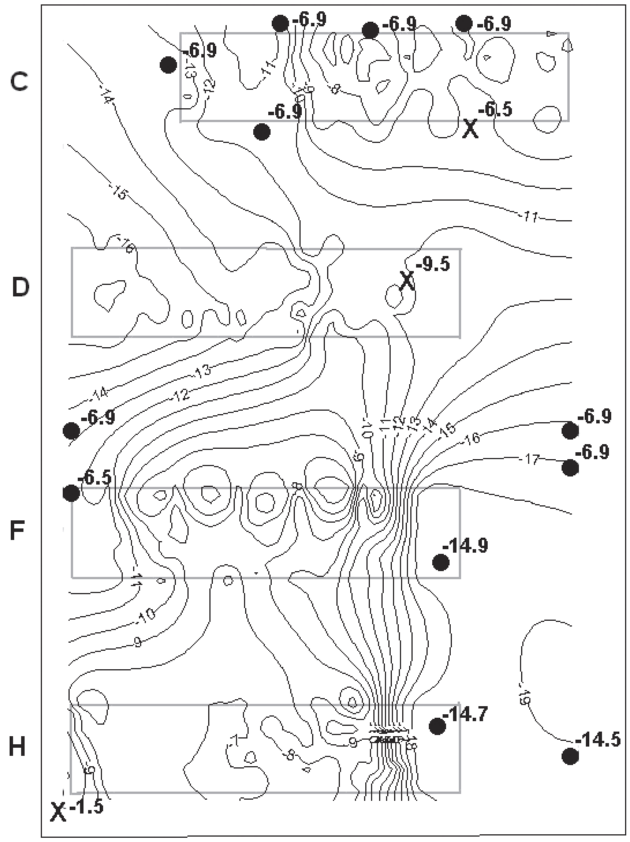

Figure 6. Contour map of the depth to permafrost from the pile driving record. Circles indicate permafrost thawed to a depth greater than the boring was advanced; X indicates permafrost was encountered. The number adjacent to the boring location indicates either the depth (m) to permafrost or the maximum depth to which thawed material was encountered. North is at the top of the figure.

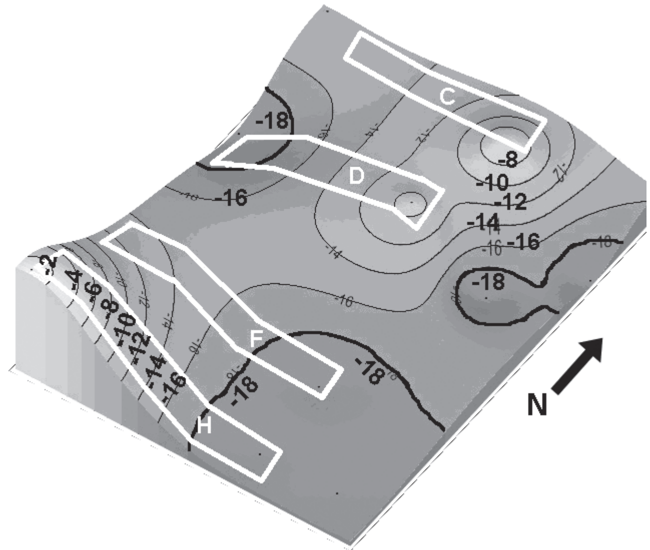

Figure 7. Topographic surface developed from boring logs with the Kriging surface mapping algorithm. The -18 m (59 ft) elevation is shown as a bold contour line. A distortion of the building footprint occurs when it is projected on the topographic surface, and the footprint no longer appears to be rectangular or at the correct distance from adjacent structures.

operation. For the three borings that indicated permafrost would be encountered at a specific location, permafrost was encountered during the pile-driving operation at the approximate depth indicated by the borings. An assertion of a “Differing Site Condition” is without merit.

Use of Boring Logs to Plot Topographic Map of Permafrost Surface

A topographic surface of the permafrost may be predicted from the boring logs provided in the contract documents. Figure 7 shows a surface produced using 4 borings which encountered permafrost at the project site together with 6 borings advanced to approximately 14 m (46 ft) in thawed material. For the borings advanced to approximately 14 m (46 ft), it was assumed that permafrost was at a depth of 20 m (66 ft). The predicted surface is in very good general agreement with the actual surface (see Fig. 4). A very satisfactory topographic surface can be generated from the boring logs with one of three commonly used topographic mapping algorithms considered in the investigation (i.e., Kriging, linear equations, and inverse distance). A fourth method (i.e., triangulation) was less satisfactory. When the building footprint is projected on the topographic surface and the area inside the building footprint with permafrost at a depth of 18 m (59 ft) or less is noted, it represents the area over which permafrost would be encountered during pile driving. To estimate the area it is convenient to display the permafrost surface contour map with the footprint of the buildings (Fig. 8). It is apparent from Figure 8 that all of Building C is underlain by permafrost at a depth less than or equal to 18 m and approximately 90%, 70%, and 70% of the piles in Buildings D, F, and H, respectively, would be underlain by permafrost at a depth less than or equal to 18 m. Based on the results presented in Figure 8, a reasonable estimate of the piles that would encounter permafrost at a depth less than or equal to 18 m would be greater than 80%.

Summary and Conclusions

It is highly probable that the entire housing unit project site was underlain by permafrost at a shallow depth prior to the establishment of Fort Wainwright. Permafrost degradation was initiated when surface disturbance and modification occurred (primarily) in the early 1990s.

It is apparent that very limited data was available to estimate the depth of permafrost beneath the buildings. No borings within 100 m (330 ft) of the housing units were advanced to a depth of 18 m (59 ft). Notwithstanding these facts, it is possible to generate a topographic surface of the permafrost using commercially available software and the 4 borings which encountered permafrost at the project site, together with 6 borings advanced to approximately 14 m (46 ft) in thawed material. For the borings advanced to approximately 14 m (46 ft), it was assumed that permafrost was at a depth of 20 m (66 ft). When the building footprints are projected on the predicted topographic surface, and the

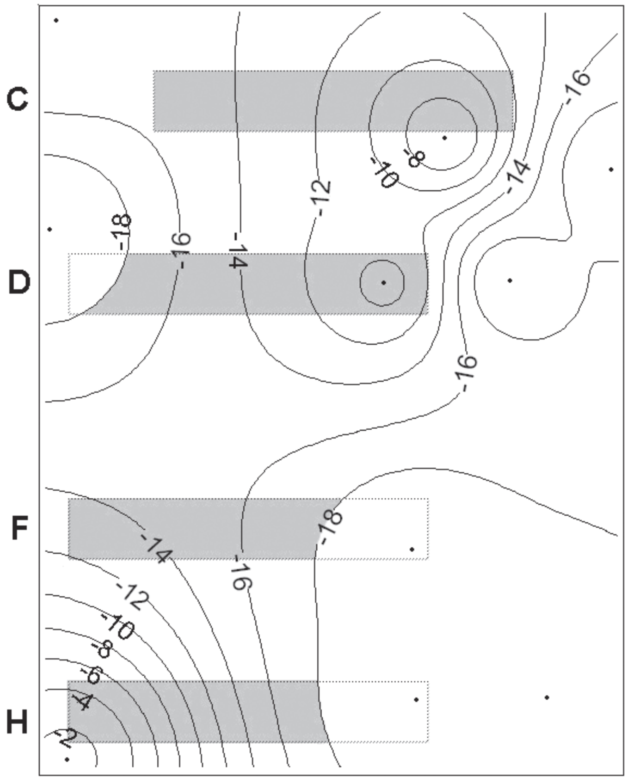

Figure 8. Contour map with emphasis on the -18 m permafrost surface elevation. The shaded area represents the occurrence of permafrost at a depth of 18 m (59 ft) or less. All of Building C is underlain by permafrost at a depth less than 18 m and *approximately* 90%, 70%, and 70% of the piles in Buildings D, F, and H, respectively, would be underlain by permafrost at a depth of 18 m (59 ft) or less. Based on the results, a reasonable estimate of the piles that would encounter permafrost at a depth less than or equal to 18 m would be approximately 80%. North is at the top of the figure.

area inside the building footprints with permafrost at a depth of 18 m (59 ft) or less is noted, a reasonable estimate of the piles that would encounter permafrost would be greater than 80%. The predicted surface compares very favorably with the actual surface plotted from the 479 piles that encountered permafrost.

It is neither logical nor reasonable in the permafrost environment in which the piles were to be installed at Fort Wainwright to conclude that 15% would encounter permafrost. The possibility that permafrost could exist over the entire project site at a depth less than 18 m (59 ft) should have been anticipated. Studies relating to degrading permafrost in the Fairbanks area have been reported in the scientific and engineering literature for more than three decades. Based on available information, it is without precedent that permafrost in the Fairbanks area at an initial depth of 1 m would degrade to a depth of 18 m (59 ft) in 10 to12 years (with conduction as the heat transfer mode; in the absence of convective heat transport, e.g., groundwater flow).

The logs of the borings advanced in the thawed materials do not confirm the *non*existence of permafrost. Prior to surface disturbance and modification, permafrost was present over nearly the entire project site at a very shallow depth. The permafrost did not disappear in the 10- to 12-year period following surface disturbance and modification. To correctly interpret the likely subsurface conditions at the project site the permafrost must be thought of as a surface that is changing with time and not a feature that is present or exclusively absent even in a discontinuous permafrost zone.

Acknowledgments

Steve Young, Corvallis, Oregon, assisted in the data reduction, and executed the software used to perform the topographic mapping. Charles Wilson and Greg Carpenter, U.S. Army Corps of Engineers, Anchorage, Alaska, provided information related to the geotechnical conditions at the site. Miles Illichmann, U.S. Army Corps of Engineers, Fairbanks, Alaska, provided the photographs shown herein and valuable insight into the history of the project site. Steve Pinnell and Blake Marchand, Pinnell Busch, Inc., Portland, Oregon, reviewed the project report written by the author that is the basis for this paper. The contribution of these individuals is gratefully acknowledged.

Abstract

Small stone polygons occupy a depression at 3865 m in the Sangre de Cristo Mountains, southern Colorado, USA. Vertical photographs were collected between 1975 and 2004 to document natural change on the surface of these polygons. Over time, the stones in the core region of these small polygons moved in multiple directions rather than directly toward the edges of the polygons. Clearly, movement results from freeze-thaw forces in three-dimensions within the polygons and from forces generated by water freezing in the stone gutters. Smaller polygons formed within the larger unit. Some stones observed in 1975 disappeared by 2004, essentially moved into the edges of the polygon and rotated such that identification becomes difficult. Measured horizontal displacements reached 29 cm, although the average is 7.4 cm for all stones. Maps of change and vectors of motions reveal the dynamic aspects of three dimensional forms subjected to intense freeze-thaw in an alpine environment.

Keywords: displacement; frost processes; repeat photography; stone polygons.

Introduction

Stone polygons, forms of patterned ground that are common in arctic and alpine areas, are generally attributed to intense freeze-thaw processes (Washburn 1956). In the years since Washburn's comprehensive review, numerous researchers have reported on many aspects of patterned ground in various locations (Washburn 1979, French 1996, Hallet et al. 2004) and attributed them to numerous processes of formation. Additional research will be cited with specific information as this paper is developed rather than simply listing them in this introduction. Vitek (1983) reported on seven years of surficial activity observed on stone polygons found in a small depression in glacial till at 3865 m in the Blanca Massif of the Sangre de Cristo Mountains in south-central Colorado. This paper extends the record of those initial observations to 30 years. In total, observations were made 22 times from 1975–2004. On several occasions, observations could not be obtained because the stone polygons in the 850 m^2 depression in a cirque were underwater from snowmelt and precipitation.

Since the site was first observed in 1975 until the last visit in 2004, standing water during the growing season is a major deterrent to grasses occupying the depression. Occasionally small tufts of grass appear but seldom do they survive the harsh winters. The lack of vegetation suggests that frost processes are not impeded and readily move stones around the surfaces of the polygons. The site is very remote, a five hour hike from the nearest road, and is not on any marked trail, nor would a causal hiker venture into this area because of the lack of access to high peaks, i.e. those above 4300 m .a.s.l. Aside from an occasional small animal print embedded in the center of a polygon, the site has been virtually undisturbed. Every effort was made during photography to retain the site as undisturbed.

This paper presents observations, analyses of these observations, and discusses the forces involved in creating these stone polygons and movements of stones in the center of several polygons. How these observations relate to published research will be described in the discussion section along with suggestions for future research at this site. Whereas these observations represent changes in a surficial plane, stone polygons are three-dimensional phenomena. Within the centers of these small polygons, smaller polygons have been observed; they form either from desiccation drying or are the remnants of frost polygons left over from winter. Movement vectors reveal that motion is possible in many directions rather than just toward the edges of the polygons. We present only total change from 1975– 2004 in this paper rather than the incremental changes that are possible with the data that have been collected. Greater detail will be published in a subsequent paper.

Study Area

The Sangre de Cristo Mountains are located in south-central Colorado (Fig. 1). Extensively glaciated during the Pleistocene, the Blanca Massif portion of the range contains numerous sites with patterned ground. Large stone polygons (Vitek & Tarquin 1984, Berta 1988, Vopata et al. 2006) are

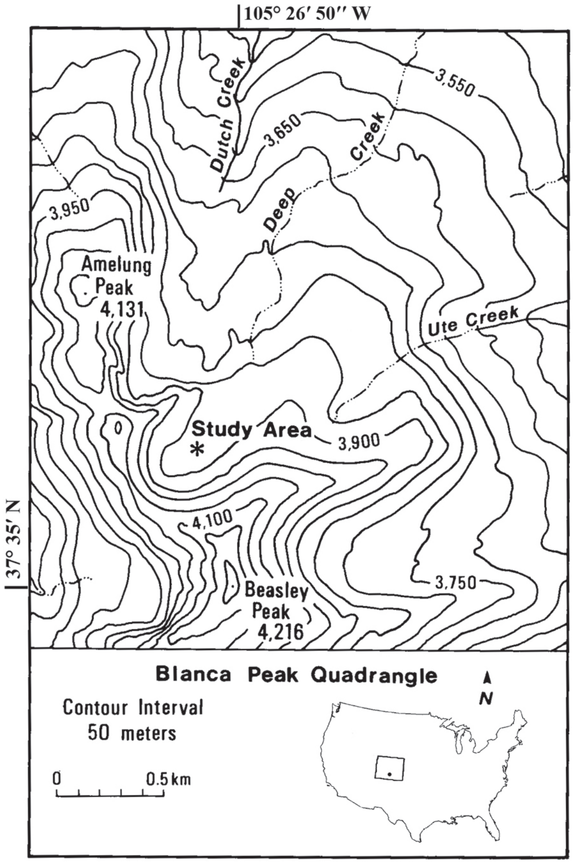

Figure 1. Location of the study area in southcentral Colorado.

Figure 3. July 31, 2004, ground view of the study site with colleagues for scale.

prevalent in numerous locations above the tree line, including sites on ridges above 3900 m .a.s.l. The location of these stone polygons, shown on an aerial photograph (Fig. 2), is precisely 37°36′27.89″N, 105°26′54.51″W, with these values read from an image on Google Earth©. At approximately 180 m above the tree line, the climatic conditions of the site can be classified as alpine tundra, but exact temperature and moisture conditions have not been monitored. When the site was first observed in 1975, it was covered by water. Within several weeks after the initial observation, however, the water evaporated and/or infiltrated through the glacial till (the frost table or permafrost may have lowered sufficiently to allow the water to drain) and revealed the stone polygons that have been photographed since 1975 (Fig. 3).

Methodology

Repeat photography is a viable technique for observing surficial change (Graf 1985, Kull 2005). In some instances changes occur rapidly, but some changes occur so slowly that photographic records can be used to confirm change. Over the years, every effort was made to take these hand-held photographs at approximately the same time of day to keep shadows constant. Colored slides and black-and-white photographs were collected on every trip to the site. The same Pentax camera was used for all black-and-white photography, and two different Nikons were used to record colored slides of the polygons. A 50 mm lens was used on both cameras. In 2004, digital images were acquired of the site in addition to traditional film medium. A steel ruler was positioned in every photograph to provide a consistent scale. J. Vitek took the photographs in every year but one. In this manner, any variation in the distance from the camera to the surface of a polygon was minimized.

The analyses for Vitek (1983) required making maps of the locations of stones from photographic prints and overlaying a map from one year over the photograph of the next year to detect change. The process was slow and only as accurate as the cartographic representation of the photographic image. Minor scale changes were made during the photographic process to create images that could be compared.

Fast forward into the twenty-first century and high speed computing. Digital images can be processed with software and provide a wealth of data about surficial change that occurs between two sets of imagery. ERSI ArcGIS 9.0©

is used to digitize, analyze, and layout the stone polygon images of 1975 and 2004. Identifiable structures and features on the largest stones found around the edges of the polygons were recognized and were used in the geo-referencing process. The structures chosen are mainly mafic inclusions, fractures, stone edges and stone corners. Geo-referencing of the images was done in the same coordinate system (UTM, Zone 13 N) and the same spatial extent. The scales of all the geo-referenced images are defined according to the metal scale placed on a stone polygon and measured during photography in 1975. After geo-referencing, all the boundaries of the stones were mapped as polygons. For each stone in 1975, a point, primarily the edges of the stone, and polygon centroids were marked and tracked to positions in the 2004 image. The magnitudes and directions of the movement of these points are represented by vector lines. The lengths of these vector lines and area of the polygons were calculated. Finally, the stone polygons from both dates and the vectors of movement were overlaid and the layouts of stone movement were created. The position of a stone in 2004 can be visually linked to its position in 1975. We believe that computer-generated and compared images yield results that are significant because images that are compared can be aligned more precisely than with manual mapping.

All images were converted to digital images for these analyses because of the ease of comparing such images. Although the stone polygons were not disturbed during the observation period, individual stones are lost only because we could no longer positively identify them at a new location. For the purpose of this paper, we chose to compare several images from 1975 against the images of the same sites collected in 2004. An initial assumption that the large stones forming the edges of the polygons do not move was easily discredited. Some large stones that formed the edges of the polygons have moved, but the analyses considered such changes in calculating the movement of the stones in the centers of the polygons for this paper.

Observations

We never knew before making the trek from the base camp at 3110 m to the site at 3865 m if the depression in which the stone polygons formed would contain water or would be dry. Water over the stone polygons excluded photographic data being collected on individual stone polygons. Often, water was observed in the gutters between polygons but below the level of the centers. During dry summers, water completely disappeared from this site. We can assume that water was lost to evaporation as well as drainage into the till once it was no longer frozen. The annual depth of frost penetration is unknown and no information exists on permafrost in this area. A trench dug to a meter in depth in August of 1983 revealed a frozen surface. Whether the ice survived until the next summer is unknown.

A site visit in March of 1978 was made to assess the conditions of the depression in late winter. Interestingly, lacustrine ice over the site had already begun to thaw, but needle ice, isolated patches of lacustrine ice, and frozen centers were observed in several polygon centers that were exposed above the level of the lacustrine ice. Stones on the surfaces of the polygons, therefore, are subjected to more forces than the simple freeze-thaw introduced into the till by temperature fluctuations. The variety of forces at work will be evaluated in the discussion section. No effort was made to visit the site during the winter because the depth of snow was impassable in the main valley and the total distance and time to walk to the site doubled in such severe conditions.

Figure 4. Photograph of site D taken on August 6, 1975. Metal scale is 150 mm.

Figure 5. Photograph taken of site D on July 31, 2004. Metal scale is 150 mm.

For this paper, the same four-stone polygon centers presented in Vitek (1983) are re-assessed. Photographic data also exist for 12 additional stone polygons and will be used in conjunction with a complete analysis of this site at a later date. Figure 4 is a photograph of site D collected on August 6, 1975, and Figure 5 is the same sited on July 31, 2004. Scanning and comparing these two images generates Figure 6. Figure 7 shows the vectors of motion for stones in polygon D using the center of each stone as the position of reference.

Results

Observing this site over 30 years reveals how slowly freeze-thaw processes operate in an alpine environment to rearrange the surficial appearance of the polygons. Given that the site has been free of glaciers since the end of the Pleistocene, approximately 11,000 years have been available for various freezing processes to reorganize the till left behind by the glacier. The absence of trees at this elevation and the current absence of grass and other alpine plants in the depression allows frost processes to be active. In close proximity to the depression with active stone polygons, large relict stone polygons (Vitek & Tarquin 1984) probably ceased to develop once grass was able to stabilize the centers of the polygons. Grass was observed growing over some stone gutters between the relict polygons. The frequent presence of water in this depression (probably for a significant amount of time each year), therefore, is the primary reason why the site remains active and free of vegetation.

Stones in the centers of the polygons were identified in 1975 and mapped using the system discussed in the Methodology section. Table 1 is a comparative summary of the observations made in four centers of stone polygons that were photographed in 1975 and 2004. Perhaps the most important observation in Table 1 is the number of stones that could not be easily identified in 2004 compared to the initial positions in 1975. Movement of a stone plus rotation often makes it impossible to conclude the fate of a particular stone. Such stones are reported as "lost" and the amount of movement cannot be calculated. Even if the stone is resting with others along the edges of the polygon, it was considered "lost" if precise identification was not possible. The number of "lost" stones may be minimized when a comparison is made between every photograph available for each site, a total of 22 iterations being possible. Movement of an individual stone ranged from only the slightest degree of movement to 29 cm in one instance (polygon C) with the

Table 1. Summary of measurements for 1975–2004.

Site	N (1975–2004)*	Mean Disp.	SD	Range

B	40 – 27	7.67 cm	5.78	1.8 – 19.9 cm
C	52 – 23	8.65 cm	7.99	1.0 – 29 cm
D	37 – 30	5.59 cm	3.89	1.0 – 15.7 cm

* N is the number of stones observed in 1975 and those relocated in 2004; Mean Disp. is the mean displacement observed; and SD is the standard deviation.

average distance moved for all stones that were re-identified in 2004 being 7.4 cm. Figure 6 shows the position of stones in polygon D in 1975 and 2004, respectively. If all stones could be located, we believe that the average distance moved would significantly increase.

The level of analysis possible is a function of the size of stone selected and whether it can be relocated during the next time period, or in this case, after 30 years. Many stones were deemed too small to trace even yearly because when rotation occurred positive identification was difficult, if not impossible. Moreover, assumptions about the direction of movement (toward the edge of the polygon) are not correct in that stones were moved toward the center of the polygon as observed in every polygon. No stone was physically identified by lifting it from the site. Interpretation to relocate a stone was based on viewing each site in color, and black-and-white images. If one were to continue the study, perhaps some type of marker could be added to each stone without disturbing it.

On a yearly average basis, stone movement is about 0.25 cm. Hence, years of observation really are necessary to detect significant change in the arrangement of stones in stone polygons. Whereas this focus has been on the visual changes in the surface, essentially a plane, the centers of stone polygons are three dimensional because sorting over the history of the feature has concentrated fine material (sand, silt and clay) in the core and stones were noticeably absent in the center of the core of one polygon that was excavated. Other research has shown how stone polygons function as three-dimensional systems such that stones are sorted to the surface and edges of the polygon. This concept is expanded in the discussion section.

Discussion

In the 25 years since the fourth Permafrost Conference was held in Fairbanks, significant contributions have been made to the literature on patterned ground. Detailed measurements by Hallet (1998) of motion within sorted circles demonstrated how frost processes operate. Hallet's instrumented efforts from 1983–1997 on Spitsbergen represent the best effort to interpret change in patterned ground at a low elevation, high latitude location. He measured vertical heave, the rapid settling of fines, a preferential subsidence of borders, and was able to conclude that convection occurred in the sorted circles. He observed that a small residual difference in displacement remains after each full-year cycle and over time pattern evolves. Gleason et al. (1986) demonstrated that sorted patterned ground can arise from density-driven Rayleigh free convection in water saturated soils that are frozen. With the presence of water in the alpine depression that we studied, observations confirmed that a small average yearly displacement is capable of sorting material given sufficient time. An ample supply of water is transformed into ice (needle, lacustrine, and ground), thereby, generating re-occurring forces that transform till into sorted stone polygons.

Kessler & Werner (2003) developed a numerical model to explain how stones and soil self-organize in polar and high alpine environments to create patterned ground.

They demonstrated that frost heave can act in a number of different orientations within the surface based upon the nature of the material encountered. Lateral sorting and stone domain squeezing are the feedback mechanisms that develop stone polygons. They stated that polygons are enhanced by rapid freezing. At our alpine site, the centers of the stone polygons can be squeezed as frost penetration occurs from the surface and through the sides (gutters) given that ample air spaces are prevalent in the stone gutters between centers. If water occupies these gutters, however, the centers will be squeezed by water freezing within the gutter and material in the core of the stone polygons will, therefore, freeze from the surface and the sides. How the water in the stone gutters (and subsequently ice) contacts the core material of the stone polygon will definitely impact how the core freezes and how much heaving occurs. Hence, the presence or absence of water in the depression during the dominant freeze-thaw periods (fall and spring) will have a significant impact on the forces generated in the till. Fowler & Noon (1997) noted that differential frost heave depends on the soil heaving characteristics and the rate of frost penetration. Observations at our site suggests that the rate of frost penetration will be extremely variable because of the variation in the sizes of stones that formed the gutters and the sides of the polygons in addition to the size of stones on the surface and the sediment composition of the core. In actuality, every site will exhibit such variability and, thereby, complicate formulation of models to replicate the processes involved in formation. Without precise temperature and moisture values for the site, including the presence or absence of water during freezing, one can only hypothesize about the frost processes that contribute to stone motion from the forces generated by freezing and thawing.

Fang & Hager (2002) believe that the stones represent large sources of noise in a non-linear reaction-diffusion type of model. Regardless of the model used, the variability of the sizes of stones in the centers and in the gutters of stone polygons complicates any model because nothing is uniform in any setting with stone polygons. The role of differential frost heave (Peterson & Krantz 2003) is dependent upon heat transfer in the system. The variable sizes of the stones in the till in this depression create complexities that would be difficult to model. Penetration of the freezing plane in three dimensions is very irregular and would result in thrusts and heaves in multiple directions. These forces are reflected in the observation of stones moving in the multiple directions in the centers of the polygons not just toward the edges.

Ugolini et al. (2006) assessed how fines were segregated in the development of patterned ground. They mentioned that airborne fines, plus those produced by weathering, contribute to the core of fine material segregated by frost processes. We believe that fines at this site can be attributed, in part, to aeolian transport because sand dunes occur in the San Luis Valley immediately west of the site. Detailed analyses of the silts and clays would be necessary to confirm the source of the fines in the centers of the polygons. Although radiocarbon techniques have been used to date patterned ground (Jeong 2006), no efforts were made to date these stone polygons. The absence of lichens on stones within the depression also provides an indication of the dynamic nature of the site. Vitek & Tarquin (1984) observed and measured lichens found on large inactive stone polygons nearby that indicated the stones in the gutters were stable for at least 2500 years based upon a growth rate curve for lichens from another location in Colorado (Benedict 1979).

Gleason et al. (1986) observed that the depth of the active layer at the onset of convection corresponded to the depth of sorting. Holness (2003) reported similar relationships for sorted circles in the maritime Subantarctic. Convection cells may account for certain features of the circles, including regularity of form morphology, but differential frost heave contributes to movement within the circles. He noted that increasing frost penetration was highly correlated with the distance between fine centers and also the depth of sorting. At our site, the short distances between centers suggests shallow depth of sorting, perhaps a function of the thin till layer over the bedrock surface of this glacial cirque.

Conclusions

Stone polygons are common in arctic and alpine areas in which freeze-thaw processes dominate. Observing one site on 22 occasions over 30 years yields information about the rate at which the surface is changing. Although 30 years is less than 0.27% of the total time since deglaciation, these observations do demonstrate change. For some stones in the system, change is significant whereas it is not for others. We also observed secondary polygons forming within the fines of the cores and we observed stones on the surface moving in directions other than toward the edges of the polygons. Whereas repeat photography of the surface of the centers reflects two-dimensional change, forces acting on these polygons do so in three dimensions – the surface and through the sides (the gutters). Variability between each polygon is a function of how these forces act at each site. Whereas the average total movement of the stones observed was 7.4 cm from 1975–2004, the average yearly rate of motion was only 0.25 cm for stones relocated in 2004. The passage of time, however, makes change easier to detect.

To increase the complexity of the study would require significant resources for instruments and transportation to the site in all seasons. We believe that the data collected thus far provide a unique glimpse of the two-dimensional changes that can occur. Additional research on this unique alpine site in southern Colorado is possible because it has not been disturbed.

Acknowledgments

Friends who made the five-hour hike to the site to assist with data collection include Mark Vitek, Mark Gregory, Marshall Cossman, Phil Ward, Lance Salisbury, Pam Tarquin, and Ellen Rose. Our sincere thanks for your help.

Transformations of Cryogenic Structure of Frozen Clay Soils at Shear

S.S. Volokhov
Faculty of Geology, Moscow State University, Vorobievy Gory, 119899, Moscow, Russia

Abstract

This report presents research results regarding the process of ice segregation in frozen clay soils at shear under creep conditions. It is demonstrated that the process of ice segregation takes place in the shearing area only at the stage of frozen soil failure and is related to crack formation during shear. When soils were subjected to continuous creep deformation, no increase in ice content was observed. It is concluded that the formation of a film of ice within the soil shear surface has a strengthening effect.

Keywords: creep; failure shear; migration; moisture; segregation.

Introduction

Transformation of cryogenic structure of frozen soils at shear is the subject of works by Vyalov (1959), Tsytovich (1975), Roggensack & Morgenstern (1978), Yershov et al. (1981), Chuvilin et al. (1994), and others. It is demonstrated by Roggensack & Morgenstern (1978) that as a result of shear of frozen clay samples at a constant deformation velocity of frozen clay samples at temperatures from -1°C to -1.5°C, ice schliers are formed in the shearing area orientated along the shear planes. Similar results are obtained in Yershov et al. (1981) and Chuvilin et al. (1994) under shear tests of bentonite, polymineral, and kaolinite clays in creep conditions at a temperature of -3°C. Moreover, Savigny & Morgenstern (1986) reported a growth of new ice lenses in ice-rich soils along shear surfaces at triaxial compression. This research is far from being complete. The issue of the nature of unfrozen water migration and of ice segregation in the shearing area is still of present interest.

Scientific literature contains evidence of the fact that unfrozen water migration may result from changing of the pore geometry and the interfacial energy of soil particles at formation of dislocations, microfractures, and other defects (Sakharov 1994, Komarov 1999). This suggests that unfrozen water migration and ice segregation at shear in frozen soils happens due to formation of microfractures when shearing stress exceeds the long-term strength; i.e., in divergent creep conditions, at deformation velocities comparable with unfrozen water migration velocities. Verifying this hypothesis is the subject of the present research.

Research Methods

Kaolinite clay (Chelyabinsk), polymineral clay (Gzhel), and loam (Yamal) were tested. The tests were performed on samples of soils of disturbed structure. The samples of frozen soils were prepared in work rings from a soil paste, consolidated for 2 days under a step load increasing until it reached 0.2 MPa, cooled for 4 h at a temperature of 0°C, and frozen for one day in a low-temperature cabinet (-30°C). They were then maintained at the experiment temperature (-3°C or -1°C) for one day. The values of total moisture content and density of the samples were, respectively, 37%–38% and 1.68 g/cm3 for kaolinite clay, 30% and 1.86 g/cm3 for polymineral clay, and 29%–30% and 1.85 g/cm3 for loam. The samples were of cylindrical form and had a diameter of 71.4 mm and a height of 35–37 mm.

Single-plane shear apparatus PRS (Fig. 1) designed by NIIOSP (Sadovsky 1967) was used for shear tests on frozen soils. The test scheme is shown on Figure 2. The research was carried out at constant shear loads in conditions of convergent and divergent creep. In convergent creep cases the duration of the experiments was up to 30 days, and in divergent creep cases the samples were brought to failure. The tests were carried out at normal load of 0.1 MPa with double replication. The experiments were performed in a refrigerating chamber NKR at temperatures -3°C and -1°C maintained within the accuracy of ±0.1°C. One of the two tested samples was used for studying the transformation of cryogenic structure, the other one for studying the changes in the total moisture content of the frozen soil.

Research on cryogenic structure of soil samples was performed by means of an optical microscope. Distribution of the total moisture content along the height of the samples was determined by division into 12 layers, each about 3 mm thick. Each layer was then divided by two cutting rings of different diameter into three areas: the edge area, the intermediate area, and the central area (Fig. 3). For

each of them, a curve of total moisture content distribution according to sample height was plotted. Comparison was made between the tested samples and of samples which had not undergone shear.

Research Results

In order to verify the hypothesis stated above regarding the nature of ice segregation in the shearing zone, analysis was undertaken of transformation of cryogenic structure and of moisture content in frozen soils which had undergone constant loads, both being under the value of the limit of long-term shear strength and exceeding this value. Thus, the tests were performed under convergent creep and divergent creep conditions. In the latter case, the samples were brought to failure.

The results of this research are demonstrated with the kaolinite clay example. Tests of polymineral clay and loam samples had similar results.

An example of the initial cryogenic structure of frozen kaolinite clay samples at a temperature of -3°C before the shear test is demonstrated in Figure 4. In general, the samples had a massive cryogenic texture, with ice pocket and air bubble inclusions. Increase of ice content from the centre of the samples to their peripheral areas is indicated. The soil in the centre of the samples was more solid, almost without ice inclusions. Detached ice schliers parallel to the exterior surfaces of the samples could be seen in the edge areas. The patterns of the initial total moisture content distribution are demonstrated on Figure 5. The diagrams show that moisture content increased from the central part of the sample towards the edges. It was connected with moisture migration at soil freezing.

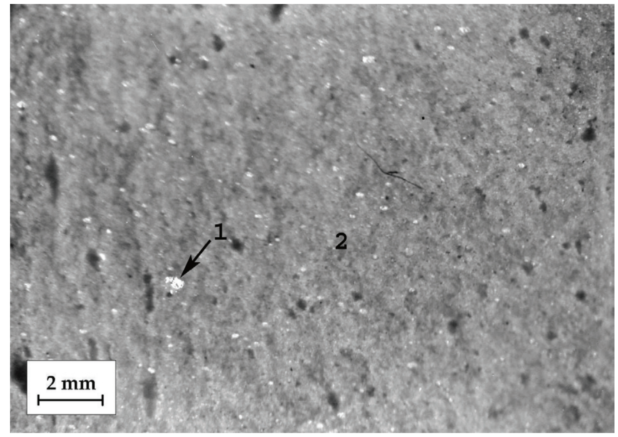

Figure 4. Initial cryogenic structure of cross section of frozen kaolinite clay samples before the shear test. Temperature -3°C. 1 – ice, 2 – mineral skeleton.

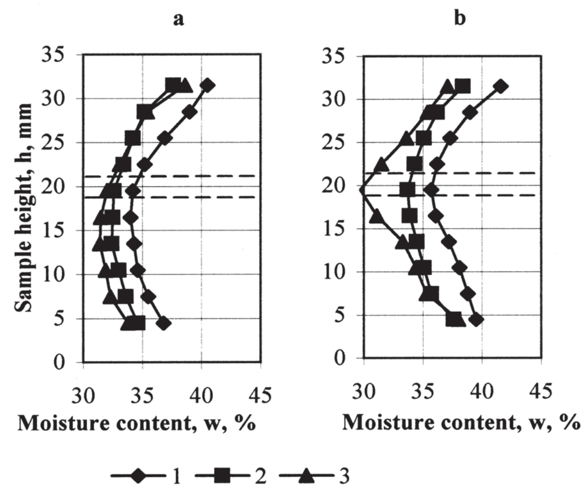

Figure 5. Initial total moisture content distribution in the samples of frozen kaolinite clay. 1 – in the edge area, 2 – in the intermediate area, 3 – in the central area. Dashed lines show a position of apparatus clearance.

Tests were performed on frozen kaolinite clay samples at the temperature -3°C, by means of constant shear loads of 0.5 and 0.45 MPa. The shear load of 0.5 MPa corresponded to the limit of long-term shear strength achieved by step-stress tests. When a shear load of 0.5 MPa was applied, sample failure was achieved in 29 days. At that load, the transient creep stage lasted for about 7 days. When the load of 0.45 MPa was applied, convergent creep was observed for 29 days. A duplicate test of the samples under the load of 0.5 MPa was carried out, with an interruption after 7 days, i.e., in the end of the transient creep stage.

The results showed that increase of the total moisture content (Fig. 6c) and formation of ice schliers in the shearing area (Fig. 7c) was observed only in the samples brought to failure. In this case, the schliers originated at the lateral surface, in the zone of apparatus clearance, and had an angle to it equal to approximately 45°. The moisture increased by 3%–5% in the upper edge area of the samples.

In convergent creep conditions, and at the transient stage

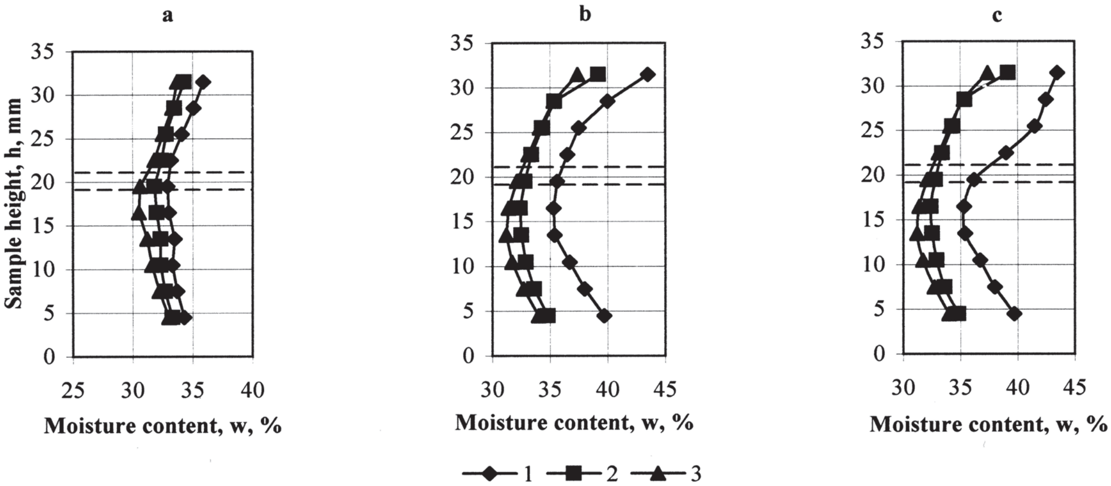

Figure 6. Total moisture content distribution in frozen kaolinite clay samples after shear tests under shear loads: a – 0.45 MPa (29 days), b – 0.5 MPa (7 days), c – 0.5 MPa (29 days). Temperature -3°C. 1 – in the edge area, 2 – in the intermediate area, 3 – in the central area. Dashed lines show a position of apparatus clearance.

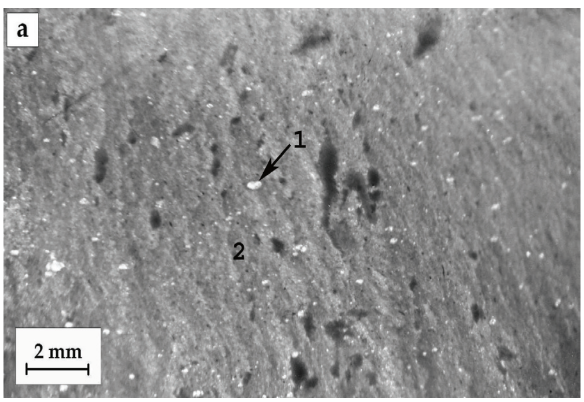

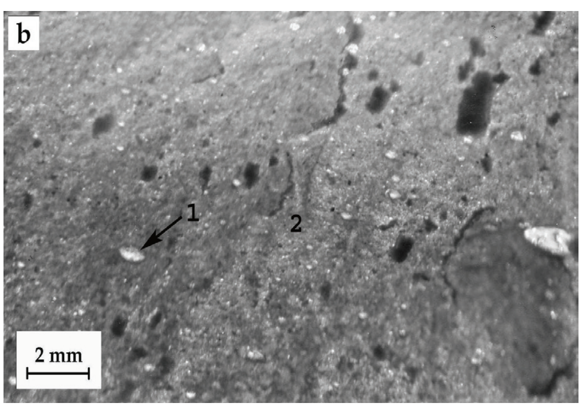

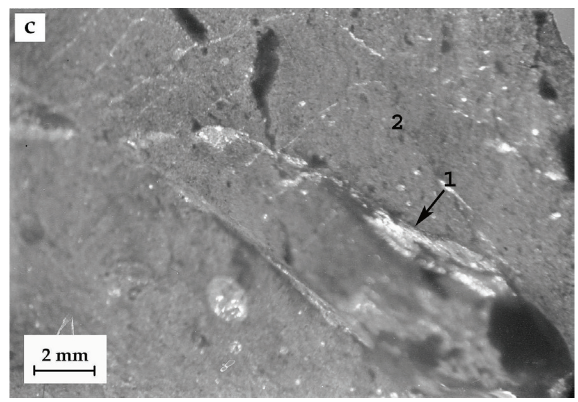

Figure 7. Cryogenic structure of cross section of frozen kaolinite clay samples after shear tests under shear loads: a – 0.45 MPa (29 days), b – 0.5 MPa (7 days), c – 0.5 MPa (29 days). Temperature -3°C. 1 – ice, 2 – mineral skeleton.

at divergent creep, no changes in the moisture distribution along the height of the samples (Fig. 6a, b) or in the cryogenic structure (Fig. 7a, b) of the frozen soil occurred. Thus, redistribution of moisture and formation of schliers in the shearing area took place only at the stages of steady-state creep and progressing flow; i.e., at the stage of sample failure.

The tests of frozen kaolinite clay were also done at the temperature of -1°C, under constant shear loads of 0.1, 0.3, and 0.4 MPa, and under a step load increasing until it reached 0.4 MPa. The tests lasted for 18 to 21 days. Failure of samples was achieved only under constant shear load of 0.4 MPa. In this case, increase of moisture occurred in the edge area (by 6%) and in the intermediate area (by 1%–2%), in the shear zone defined by apparatus clearance. A reduction in moisture content (Fig. 8d) was observed in the layers adjacent to the zone of shearing. Apparently, the unfrozen water migrated from those areas to the soil shear surface where a nearly solid layer of ice (Fig. 9) was formed. At lower loads (0.1 and 0.3 MPa) and at a step load increasing up to 0.4 MPa, convergent creep was observed and no changes in the cryogenic structure or total moisture content were recorded (Fig. 8a, b, c). As the work of Volokhov (2005) demonstrates, under shear tests of kaolinite clay at the temperature of -3°C, the shear surface does not coincide with the plane of the shear apparatus clearance but has an angle of gradient to it equal to about 45°, originating at the lateral surface of the samples and reaching their frontal surface. Here, displacement of a cuneal-shaped part of the sample takes place, overthrusting the other part of the sample (Fig. 10a). At the temperature of -1°C, the soil shear zone is arc-shaped confined to the clearance of the apparatus (Fig. 10b). It appears from this

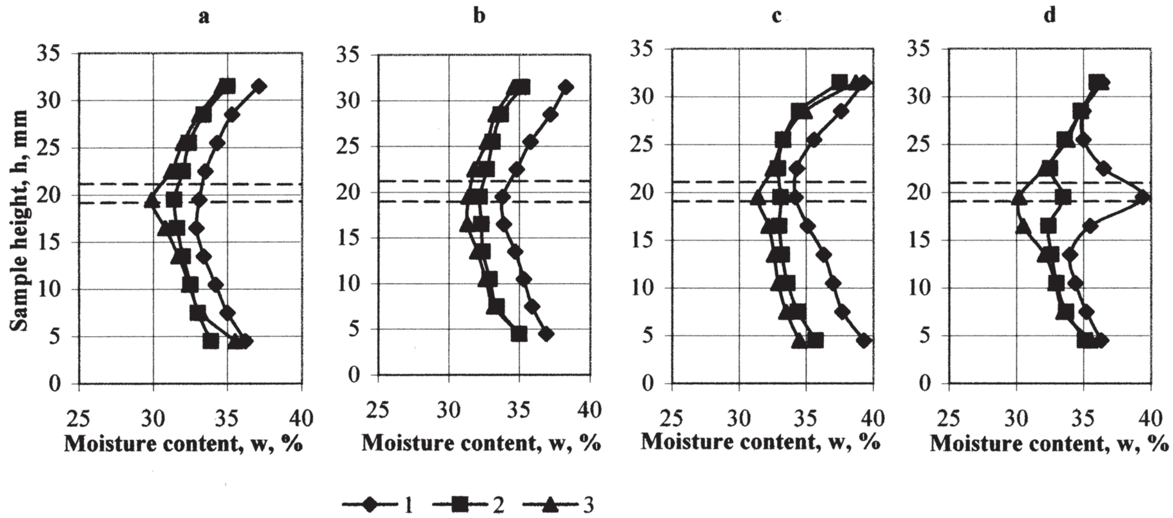

Figure 8. Total moisture content distribution in frozen kaolinite clay samples after shear tests under shear loads: a – 0.1 MPa, b – 0.3 MPa, c – a step load increasing until it reached 0.4 MPa , d – 0,4 MPa. Temperature -1°C. 1 – in the edge area, 2 – in the intermediate area, 3 – in the central area. Dashed lines show a position of apparatus clearance.

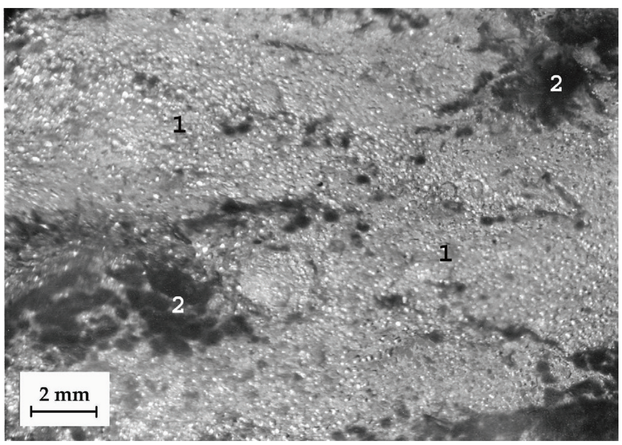

Figure 9. Cryogenic structure of soil shear surface of the frozen kaolinite clay sample. Temperature -1°C. 1 – ice, 2 – mineral skeleton.

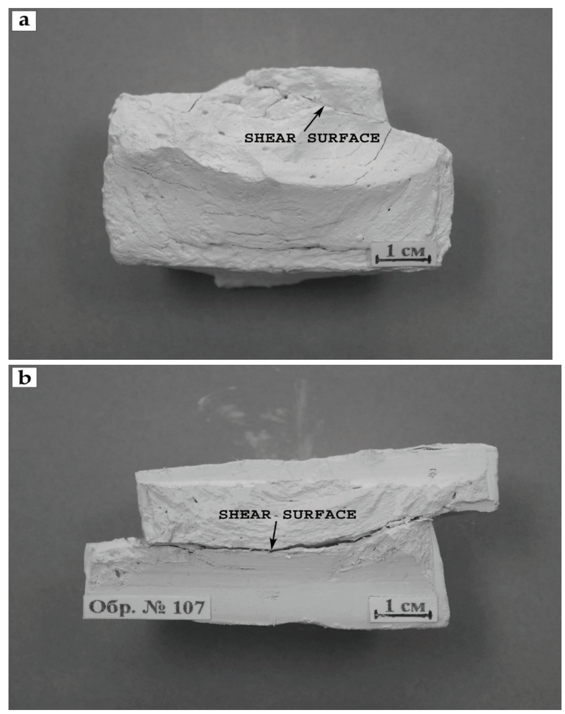

Figure 10. Character of failure of frozen kaolinite clay samples at temperatures: a – 3°C, b – 1°C.

that the aforementioned changes in the cryogenic structure and in moisture content of frozen kaolinite clay occur in the zone of soil shear dislocation.

Thus, this research has provided the following results.

1. In convergent creep conditions, no changes in the cryogenic structure or in distribution of the total moisture content occur. Ice segregation and an increase of total moisture content happen only in divergent creep conditions; i.e., under failure of samples.

2. In divergent creep conditions, ice segregation occurs in the shear area only at the stages of steady-state creep and progressing flow; i.e., at the stage of frozen soil failure. It is not recorded at the transient creep stage.

3. In all of the cases, ice segregation is confined not to the clearance plane of the shear apparatus, but to the shear surface within the soil, irrespective of its alignment in relation to the clearance of the shear apparatus. In this soil shear surface, an ice film develops.

4. Maximal increase of the total moister content of frozen soils and formation of ice schliers at shear is characteristic for the edge area of the samples. As for the central area of the samples, such changes are not present.

Analysis of Results

The results achieved allow conclusions to be drawn concerning the nature of unfrozen water migration and of ice segregation in the shearing area. Changes in the cryogenic structure and in moisture content of frozen clay samples occurred only at the failure stage and their confinement to the sample shear surface suggests that processes of unfrozen water migration to the shearing area and ice segregation in it are related to formation of microfractures at the failure stage. Formation of cracks in the soil is accompanied by formation of new surfaces and increase of interfacial energy of the mineral or ice components of frozen soil. It can cause unfrozen water migration from the areas having lower specific interfacial energy to the microfractures with high values of specific interfacial energy; i.e., under the effect of thermodynamic water potential gradient. Continuous deformation of frozen soil under steady-state creep and progressing flow, and the formation of new microfractures must provide for inflow of unfrozen water to the shearing area from adjacent areas of soil. Freezing of excessive water in the microfractures results in formation and growth of ice schliers there.

Apparently, the described process can go on provided that the unfrozen water migration velocity and the velocity of microfracture formation are commensurate. This is possible at rather low strain rates during frozen soil failure stages, provided that the duration of the stages is significant.

Verification of the hypothesis on the leading role of crack formation in the process of ice segregation at shear is based on the fact that this process occurs mainly in the edge area of the samples and does not affect their central area. This may be related to the fact that shearing of samples begins at the lateral surface at low crack formation velocities. The central area of the samples remains unaffected by the failure process. Therefore, unfrozen water has time to migrate to the shearing zone, filling the cracks in the edge area and freezing there. Advance of the cracks to the central area of samples occurs at high strain rates so that moisture has no time to migrate into them; therefore no changes in the cryogenic structure and in moisture content of the samples takes place in this area of the samples. This process is possible only within a certain range of strain rates at the stage of frozen soil failure.

The conclusion can be made regarding the role of ice segregation in forming of frozen soil strength. Ice schliers appearing in the cracks serve to bond cracks, preventing their advancement and decelerating frozen soil failure. If this process did not occur, frozen soil would be destroyed faster. Consequently, it plays a strengthening role.

Abstract

Permafrost Monitoring in Switzerland (PERMOS) has been built up since the early 1990s. After a 6-year pilot phase starting in 2000, PERMOS has taken root. In 2007, all potential PERMOS elements were evaluated based on the criteria and categorised into (A) approved element, (B) element subject to verification in the next two years, and (C) no PERMOS element. The concept "PERMOS 2007" was updated and adapted accordingly. All approved elements will fulfill defined technological and methodological standards. Hence, in 2010, PERMOS will be a sound, sustainable observation network with two types of PERMOS stations: (1) drill sites building the basis of the monitoring network, and (2) kinematic sites, where systematic observations of permafrost geomorphodynamics are performed, allowing for an integral assessment of the permafrost state in the Swiss Alps. PERMOS is presently active in four regions: Upper Engadine, Bernese Oberland, Matter Valley, and "Quatre Vallées."

Keywords: active layer; monitoring; mountain permafrost; permafrost temperature; rock glacier creep velocity.

Introduction

PERmafrost MOnitoring Switzerland (PERMOS) has taken root and passed from first steps in the 1990s (Haeberli et al. 1993) through its pilot phase (2000–2006) (Vonder Mühll et al. 2001, 2004) and has now reached its implementation phase (2007–2010).

Low-latitude high-altitude mountain permafrost is governed mainly by climate conditions, in particular mean annual air temperature but also snow precipitation. Climate change therefore has an impact on mountain permafrost that is also an important indicator for environmental changes. According to IPCC assessments (IPCC 2007), circumpolar but also mountain regions will be affected much more strongly than the global average. Therefore, the Global Terrestrial Network for Permafrost (GTN-P) that is currently being established within the worldwide climate-monitoring program (GCOS/GTOS) of the World Meteorological Organization (WMO) and others (FAO, UNEP, UNESCO, ICSI) increases in importance. PERMOS is one early component of GTN-P. Moreover, it complements the glacier monitoring network in Switzerland, which was already established towards the end of the 19th century.

In contrast to glaciers and snow, systematic scientific investigation of Alpine permafrost only was started in the early 1970s by the Barsch group of the University of Basel. Since the late 1980s and after the drilling through the Murtèl-Corvatsch rock glacier in 1987 (Haeberli et al. 1988; Vonder Mühll & Haeberli 1990), a number of Swiss institutes started performing research on low-latitude mountain permafrost. An important and valuable contribution was the EU-funded project PACE (Permafrost and Climate in Europe; Harris et al. 2003). These various activities formed the basis for establishing PERMOS, which officially started in 2000 under the umbrella of the Swiss Academy of Sciences (SAS) with support of the Federal Office for Environment (FOE) for a pilot-phase which ended in 2006.

As for the four years from 2007 to 2010, the Federal Office for Environment, the Swiss Academy of Sciences, and the Federal Office for Meteorology signed a contract to implement PERMOS within the responsible federal monitoring structures in Switzerland. This means that after an evaluation, the PERMOS-approved sites will be updated to a technological and methodological standard, and a 50% position is financed for coordination and reporting.

Goals and Strategy

The main goal of PERMOS is to document the state of permafrost in the Swiss Alps on a long-term basis, and hence, temporal permafrost variations. In fact, this is perfectly complementary to the glacier monitoring network. The Cryosphere Commission of the Swiss Academy of Sciences is presently setting up an integral cryosphere monitoring concept which includes all relevant parts of the Alpine cryosphere: snow, glaciers, and permafrost.

As simple as this task is to formulate, as difficult it is to implement. In contrast to glaciers and snow, permafrost is invisible. Moreover, permafrost characteristics change within short distances in low-latitude mountain regions such

as the Alps. The observed parameters were chosen according to the “Priorities for Global Geocryological Database (GGD),” released by the IPA resolution in August 1995 (Hegginbottom 1995, Table 1). The strategy has been set up in a pragmatic way; PERMOS is based on infrastructure (equipped drillings, ground surface temperature sites, and observation of permafrost creep at various rock glaciers) that was established within research projects. New and explicit PERMOS sites will be placed only after available and existing stations are updated to a common standard. New stations will be located in regions where gaps occur. Ideally, each climate region of the Alps is covered by four PERMOS stations.

Pilot Phase (1990s–2006)

The pilot phase aimed to (1) ensure continuation of established time series, (2) check, improve, and adapt observations, and (3) propose a monitoring concept that allows maintenance over decades.

Initial PERMOS observations

In 1999, three items were defined to be observed during the pilot phase:

(1) borehole measurements (temperature, deformation)
(2) lower boundary of permafrost distribution (BTS)
(3) aerial photographs to document surface characteristics

After three years, first corrections were made based on gained experiences of the monitoring and ongoing research projects: (a) drill sites will be complemented by permanent electrodes to regularly record Electrical Resistivity Tomographies (ERT) following the principles according to Hauck and Vonder Mühll (2003); (b) it turned out that the annual lower boundary of permafrost distribution could not be determined by combining the bottom temperature of the snow cover (BTS) and ground surface temperature (GST). Consequently, permafrost pattern is determined in few areas every 10 years only. In addition, GST sites were complemented with a number of single-channel-temperature-loggers mounted in steep walls (Gruber et al. 2003); (c) Creep processes and behaviour of alpine rock glaciers are only poorly understood so far. However, recent studies (Kääb et al. 2006, Roer 2003) indicate that creep velocities vary considerably (see Fig. 1). Arenson et al. (2002) report even annual variations. Therefore, creep velocity of selected rock glaciers shall be determined by photogrammetry and geodetic surveys.

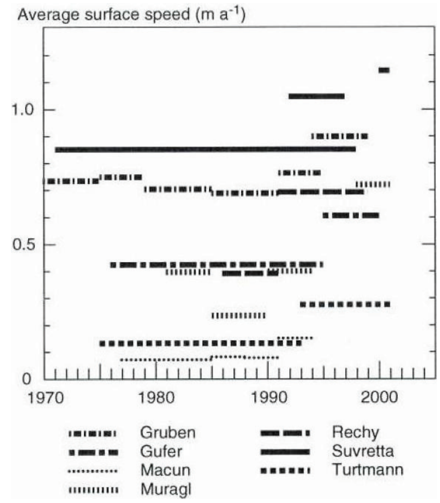

Figure 1. Creep velocities of seven rock glaciers determined by photogrammetry (Kääb et al. 2006). Note the marked variations, e.g., of Muragl rock glacier.

Types of PERMOS Sites

Following the adaptations and in discussing the monitoring results, it was decided to focus on two types of PERMOS sites: drill sites and kinematic sites.

Drill sites

Each drill site of PERMOS shall be composed of:

- One or several borehole(s) that is (are) at least some 15 m deep, equipped with a thermistor string attached to a data logger. Sensors are recommended to be at the following depths [m]: 0.0, 0.4, 0.8, 1.2, 1.6, 2.0, 2.5, 3.0, 4.0, 5.0, 7.0, 9.0, 11, 13, 15, 20, 25, 30, 40, 50, 60, 70, 80, 85, 90, 92, 94, 96, 98, 100 with temporal interval of 6 hours down to 5 m depth, farther down, once every day.
- Snow thickness and air temperature shall be measured as a minimum for climate parameters.
- Geophysical monitoring consists of at least 20 fixed installed electrodes to regularly record ERTs.
- Single-channel-temperature loggers recording ground surface temperatures in at least 15 spots with (flat and oblique) and without (steep rock walls) a snow cover in winter in the region (distributed at various altitude, exposure, locality within a few kilometers).

Kinematic sites

Rock glacier creep is observed either by photogrammetry using aerial photos, by geodetic survey, or differential GPS. Each rock glacier is equipped individually according to the applied methodology and movement pattern.

PERMOS 2007–2010

The updated concept was discussed, elaborated, and approved by the PERMOS community. A comprehensive evaluation of each potential PERMOS element was conducted in 2007.

Evaluation and applied criteria

During the pilot phase, each potential monitoring element was included and, to a limited amount, financially supported. While at the beginning of the pilot phase only few sites were available, the number increased. Consequently, each potential element was evaluated according to various criteria. Approved elements shall be recorded for the next several decades. The base line was to continue rather few elements on a standardized high quality and technology level and to omit redundancies.

The following set of criteria was elaborated within the expert Cryosphere Commission SAS:

(a) Relevance towards the overall aim to document the permafrost state in the Swiss Alps;
(b) Importance towards society and politics; i.e., contribution to understanding issues related to environment, climate change, and natural hazards;
(c) Importance for research and academic education;
(d) Feasibility in terms of accessibility.

In addition, time series were assessed according to length and temporal resolution, quality (accuracy, gaps), site characteristics, representativeness, accessibility, contribution to the GHOST tier structure (Cilhar et al. 1997), additional parameters available, and particular remarks.

The evaluated elements were allocated to one of the following categories:

(A) PERMOS approved: the element will be recorded for the next several decades, and a large part will be funded by PERMOS. The site will be updated to the technological and methodological standard.

(B) Retention: the element is part of PERMOS. Particular requirements and open questions are addressed. The element will be re-evaluated in 2009.

(C) Rejected: the element is rejected and no longer financially supported by PERMOS. It is up to the institution to continue the time series.

Network in 2007

In the evaluation, all drill sites that are not fully equipped according to the above-mentioned composition were B-rated, and similarly most "GST sites." Within the updated concept, these two elements will be merged into one "drill site" until 2010. Presently, PERMOS consists of 9 A-rated drill sites, 9 A-rated GST sites, which will be updated and transferred into "standard PERMOS drill sites." All B-rated elements (6 drill sites, 3 GST sites, and 5 kinematic sites) are subject to additional installation or further strategical aspects and a re-evaluation in 2009 (see Table 2). Figure 2 shows the geographical distribution of the elements in 2007.

PERMOS Partners

A comprehensive monitoring network must be set up among interested partners from academia and administration. Academia provides the permafrost know-how and the link to ongoing research projects, while administration is responsible for monitoring and provides political links.

The pilot phase allowed for setting up a concept with parameters and elements that could be adapted according to gained experiences and new research results. After some 15 years, PERMOS complements the Swiss glacier monitoring network and Swiss snow observation, data of which all are being complied to contribute to cryological monitoring.

In general, funding institutions are skeptical to invest in monitoring programs, since they cannot fund "infinite" long-term projects. Also, universities cannot carry such programs, since their core activities are research and education. However, both research funding institutions and universities were key to setting up PERMOS. Research projects funded by the Swiss National Science Foundation (SNSF) and the European Commission, and from ETH Zurich and SFISAR Davos also, have established important milestones without which PERMOS would not exist. Still, the maintenance of the elements is being carried by the university institutes and has been supported since 2000 by the financing partners.

In fact, the success of PERMOS is based on a go-together of the academic institutions involved in permafrost research in Switzerland and the financial support of the SAS: University of Zurich (coordination), ETH Zurich, SFISAR Davos, the Universities of Berne, Fribourg, Lausanne, and the Academia Engadina Samedan.

This, in turn, triggered the commitment of the authorities, which are officially in charge of climate and environmental monitoring: the Federal Office for Environment (FOE) and the Federal Office for Climatology (MeteoSwiss).

Monitoring Results

Most important results from monitoring consist of comparing elements from one time interval to another. However, many details of involved processes that are modeled are based on data provided by monitoring sites. In particular, numerical and statistical models are calibrated using one part of monitoring data. It is therefore neither possible nor intelligent to distinguish or separate permafrost monitoring and research.

PERMOS drill sites are located in different terrain and lithologies. Murtèl-Corvatsch is a rock glacier site with a coarse, blocky surface layer and permafrost below the active layer consisting of almost pure ice. The Schilthorn drill site is on schist bedrock with a shallow weathered clay-rich debris layer of some decimeters in thickness. The same climate

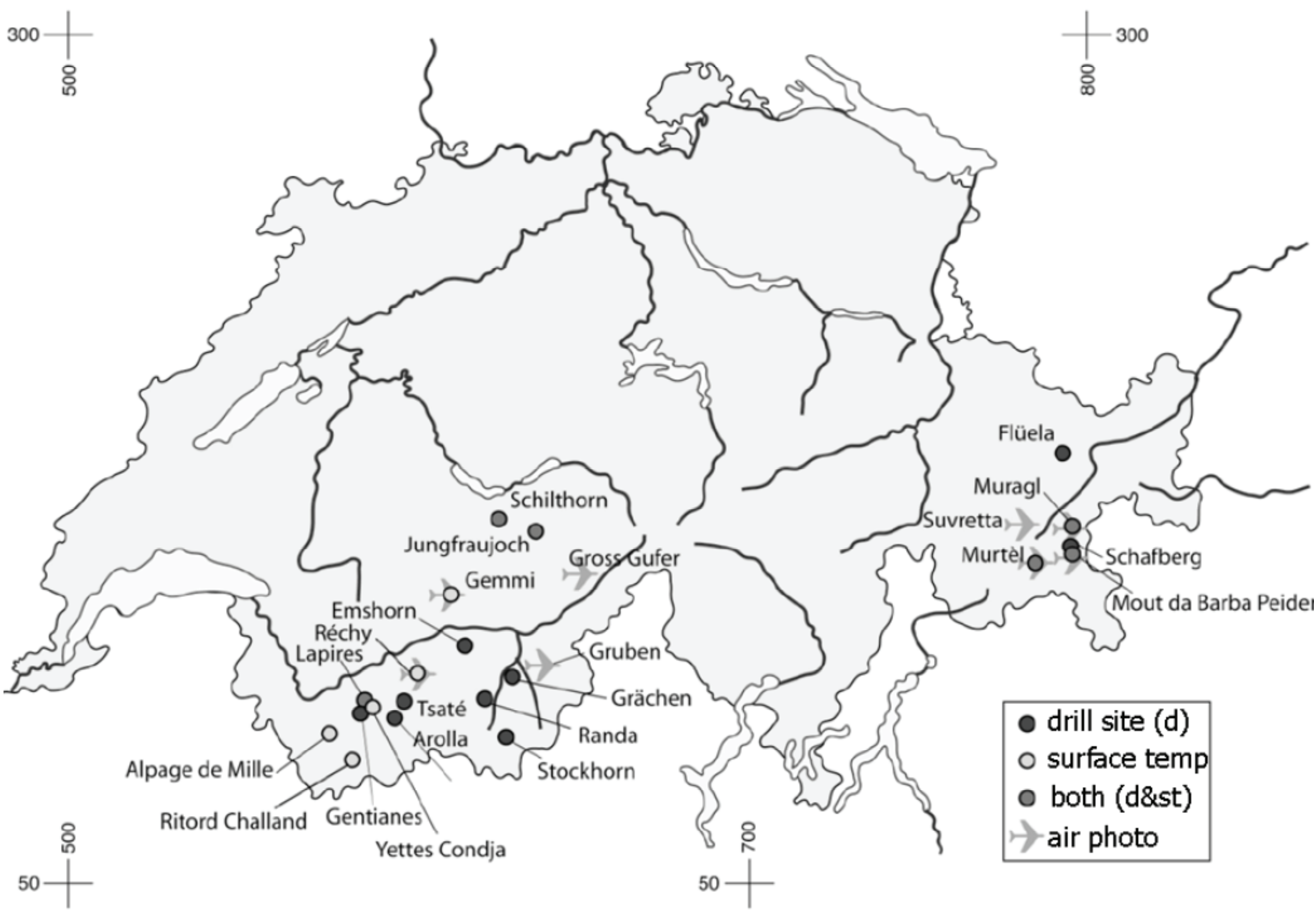

Figure 2. PERMOS sites in 2007 where different parameters are measured.

signal causes different reactions of the thermal regime at such different locations.

Process understanding

In winter 2006/2007, snow cover was only thin, and mean monthly temperatures were 1°C to 3°C warmer than normal. Permafrost temperatures were influenced differently: in steep walls where snow cannot accumulate, air temperatures caused a warming. At permafrost sites with usually a significant snow cover, lacking snow led to a cooling of subsurface temperatures.

Active layer

The thickness of the active layer is mainly influenced by summer weather conditions. Recorded in summer 2003 was an active layer almost twice as thick as in the years before and afterwards (Fig 2). Within PERMOS, maximal active layer thicknesses and the corresponding date are recorded. Several PERMOS sites are integrated into the CALM network (Brown et al. 2000).

Permafrost temperatures

Permafrost temperatures at about 10 m depth are

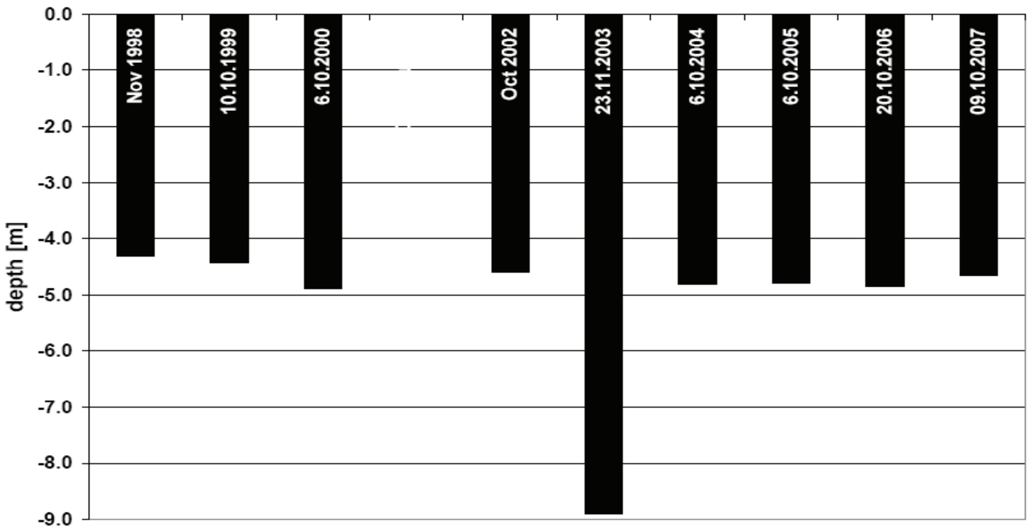

Figure 3. Depth and date of the active layer thickness at borehole Schilthorn 51/1998. In the extremely warm summer 2003 permafrost thawed down to almost 9 m.

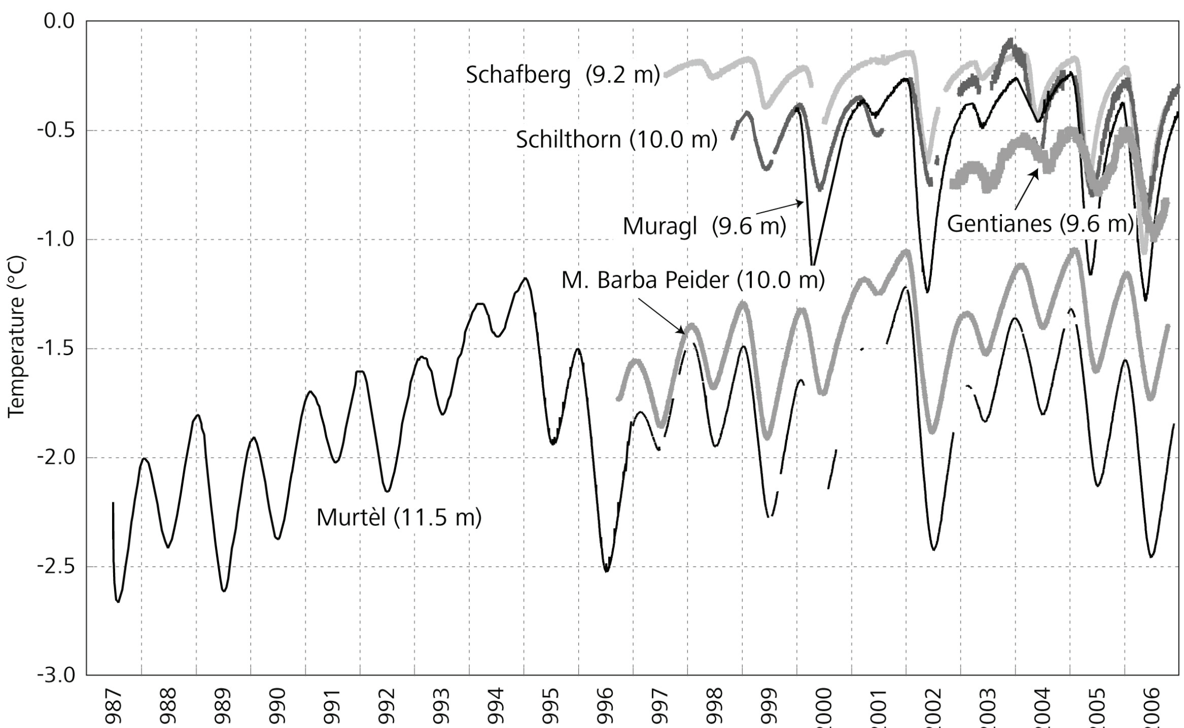

Figure 4. Permafrost temperature of a number of PERMOS elements at about 10 m depth.

characterized by a nice sinusoidal shape and a phase lag of about half a year. High frequency “noisy” parts of the temperature signal are largely filtered out, and differences of the various localities are damped as well. Therefore, these graphs are used for comparison of the various drill sites and also to determine region-specified trends.

Figure 4 shows a compilation of temperatures at about 10m depth from a number of drill sites, all located on flat or oblique terrain with a snow cover in winter. At these sites, snow characteristics govern mainly thermal regime.

Conclusions

A comprehensive monitoring network must be set up among interested partners from academia and administration. Academia provides the permafrost know-how and the link to ongoing research projects, while administration is responsible for monitoring and provides political links.

The pilot phase allowed for setting up a concept with parameters and elements that could be adapted according to gained experiences and new research results. After some 15 years, PERMOS has found its place by complementing the Swiss glacier monitoring network and Swiss snow observation, data of which all are being complied to contribute to cryological monitoring.

Acknowledgments

Obviously, PERMOS as a monitoring program involves many contributors and depends on key persons that support the efforts, and on financial support. The Swiss Academy for Sciences (SAS), the Federal Office for Environment (FOE), and the Federal Office for Climatology (MeteoSwiss) finance PERMOS based on a signed contract. Equally important are the contributions of the academic institutions, providing synergies from research and education projects.

Abstract

Permafrost environments within the Siberian Arctic are natural sources of the climate-relevant trace gas methane. In order to improve our understanding of present and future carbon dynamics in high latitudes, we studied the activity and biomass of the methanogenic communities in terrestrial and submarine permafrost deposits. For these investigations, permafrost cores of Holocene and Late Pleistocene age were drilled in the Laptev Sea region. A high CH_4 concentration was found in the upper 4 m of the Holocene deposits, which correlates well with the methanogenic activity and biomass. Even the incubation of core material at -3°C and -6°C showed a significant CH_4 production (range: 0.04–0.78 nmol CH_4 h^{-1} g^{-1}). The results indicated that the methane in permafrost deposits originated from modern methanogenesis by cold-adapted methanogenic archaea. Microbial-generated methane in permafrost sediments is, so far, an underestimated factor for future climate development.

Keywords: Laptev Sea; methane; methanogenesis; permafrost deposits; phospholipid biomarker; psychrophiles.

Introduction

The Arctic plays a key role in Earth's climate system, as global warming is predicted to be most pronounced at high latitudes and because one third of the global carbon pool is stored in ecosystems of the northern latitudes. Global warming will have important implications for the functional diversity of microbial communities in these systems. It is likely that temperature increases at high latitudes will stimulate microbial activity and carbon decomposition in Arctic environments, and accelerate climate change by increasing trace gas release (Melillo et al. 2002, Zimov et al. 2006). Currently, the functioning of microbial communities and their impact on changing environmental conditions are not adequately understood, and the potential methane release from frozen sediments is not adequately quantified.

Methane is chemically very reactive and more efficient in absorbing infrared radiation than carbon dioxide. Estimates of methane emissions from arctic and sub-arctic wetlands range between 10 and 39 Tg a^{-1}, or between 2.2 and 8.6% of global methane emissions (Bartlett & Harriss 1993, Cao et al. 1998). Methane, as a powerful greenhouse gas, contributes to about 20% of global warming (IPCC 2001).

In general, temperature is one of the most important variables regulating the activity of microorganisms. The growth potential, as well as the molecular, physiological and ecological aspects of microbial life at low temperatures, has been investigated in many studies (e.g., Gounot 1999, Wagner 2008). Certain key processes of the methane cycle are carried out exclusively by highly specialised microorganisms such as methanogenic archaea and methane oxidising bacteria. The microbial methane production (methanogenesis) in the active layer of permafrost is the terminal step during the anaerobic decomposition of organic matter, while the methane oxidation is the primary sink for methane in Arctic wetlands (Wagner et al. 2005).

However, there are only a few studies investigating the geochemistry and microbiology of permafrost deposits, which were mainly done in Siberia and Canada. Direct bacterial counts in the order of 10^7 to 10^8 were reported for permafrost deposits from Northeast Siberia (Rivkina et al. 1998). Shi and colleagues (1997) found viable bacteria in permafrost sediments up to 3 million years in age in the Kolyma-Indigirka lowlands. Most of the isolated bacteria showed mesophilic growth characteristics. In contrast, the minimum temperature for growth of permafrost bacteria was recently calculated to be -20°C (Rivkina et al. 2000). Furthermore, molecular life markers and low numbers of methanogens were found in the Mallik gas hydrate production research well (Colwell et al. 2005, Mangelsdorf et al. 2005). However, methanogenic activity could not be detected in the permafrost sediments using radiolabelled ^{14}C-substrates.

For the understanding and assessment of recent and future carbon dynamics in high latitudes, we have to answer the question: "What will happen to the carbon stored in permafrost, in the event of a climate change?" From this view point, we studied the methane concentration, the quantity and quality of organic matter, and the activity, biomass and diversity of methanogenic communities in permafrost deposits of the Laptev Sea region.

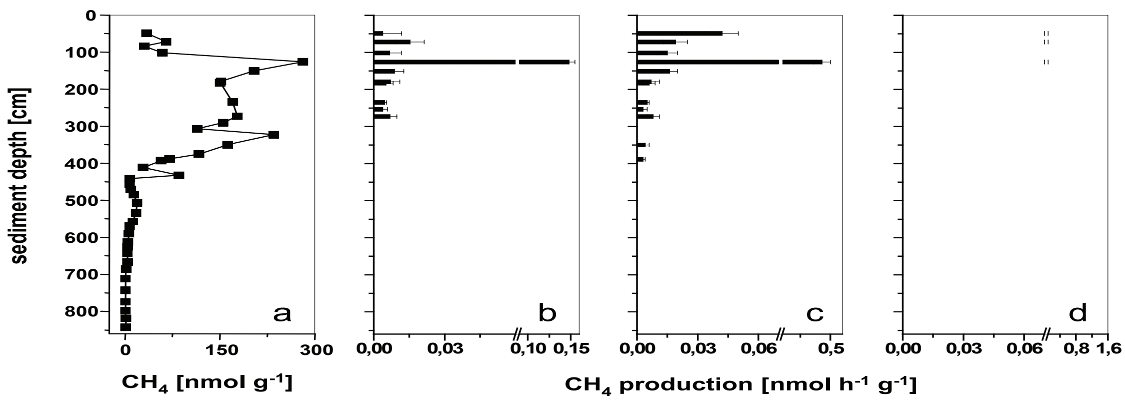

Figure 1. Vertical profiles of methane concentration (a), and methane production rates determined at 5°C without any additional substrate (b), with acetate (c) with hydrogen (d) as methanogenic substrates.

Study Sites

Within the scope of long-term studies on carbon dynamics in the Siberian Arctic, several expeditions were carried out by the Alfred Wegener Institute for Polar and Marine Research.

The Holocene permafrost core was drilled during the LENA 2001 expedition on the main study site Samoylov Island (72°22′N, 126°28′E, Pfeiffer & Grigoriev 2002). Samoylov, with the Russian-German Research Station, is located in the active part of the Lena Delta (Hubberten et al. 2006). The Lena Delta lies at the Laptev Sea coast between the Taimyr Peninsula and the New Siberian Islands. Continuous permafrost, which occurs throughout the investigation area, extends to depths of about 100–300 m (Yershov 1998), with active layer thicknesses between 30 and 60 cm depth.

The submarine permafrost cores of Late Pleistocene age were recovered in the framework of the COAST expedition from the western Laptev Sea along a transect running perpendicular to the coastline (Rachold et al. 2007). The Laptev Sea region is characterised by an arctic continental climate with low mean annual air temperature of about -15°C and low summer precipitation of <198 mm. Further details of the study sites were described previously in Wagner et al. (2003) and Rachold et al. (2007).

Drilling of Permafrost Deposits

The drilling of an 850 cm long core was carried out with a portable gasoline powered permafrost corer without using drilling fluid to avoid microbiological contamination of the permafrost samples. A mixing of the permafrost sediments was not observed due to the frozen state of the core material. The individual core segments, which were up to 50 cm in length, were placed immediately after removal from the corer into plastic bags and stored at about -8°C in the permafrost cellar of the Research Station Samoylov. After drilling of the core, the borehole temperature was monitored with a string of 9 thermistors. The cores were transported in a frozen state to Potsdam, Germany. During transport, the temperatures in the containers were monitored by micro data loggers. The storage temperature in the Potsdam laboratory was -22°C.

Core segments were split along their long axis into two halves under aseptic conditions with a diamond saw in an ice laboratory at -22°C. Afterwards, one half of the core was cleaned with a sterile knife for lithological and geocryologically descriptions. Subsequently, one half was cut into segments of about 10–30 cm length according to the lithology and the geocryology. Small pieces (approx. 10 g) of each sub-sample were taken for analysing the methane concentration in the frozen sediments. The remaining material of each sub-sample was thawed at 4°C and homogenized under anoxic and sterile conditions for analysis of the sediment properties and the microbial activities and biomarkers. Sub-samples for the different analyses were placed into sterile plastic Nalgene boxes. Separated samples were used directly for the experiments (methane concentration, methane production rates, and biomarker analysis) or were freeze-dried for the organic carbon analyses. The second half of the core is kept as an archive in the ice core storage at the Alfred Wegener Institute.

Methanogenesis in Terrestrial Permafrost

Our results show significant amounts of methane in the first four meters of frozen sediments (up to 282 nmol CH_4 g^{-1} sediment, Late Holocene, 5000 yr BP until today) and only trace amounts of methane in the bottom section of the core (0.4–19 nmol CH_4 g^{-1} sediment; Middle Holocene, 9000–5000 yr BP; and Early Holocene, 11500–9000 yr BP; Fig.1a). Different amounts of methane in different aged permafrost deposits from northeastern Eurasia were reported by Rivkina & Gilichinsky (1996). They detected methane in modern (Holocene) and old permafrost deposits (Middle and Early Pleistocene, 1.8–0.78 mill. yr BP), but not in Late Pleistocene ice complexes (ice rich permafrost, 130000–11500 yr BP). They concluded from their findings that methane cannot diffuse through permafrost sections. If methane is unable to diffuse through permafrost from deeper deposits, it must either be entrapped during the deposition of the sediments or originate from recent methane production by methanogenic archaea (methanogenesis) in the frozen ground.

The analyses of methane production in selected sediment samples at 5°C, revealed activity only in permafrost layers with significant concentrations of methane (upper 4 m of the sediments; Fig. 1b). An important finding from the activity analyses is that no methane production was detectable in the bottom part of the permafrost section (>4 m) characterized only by traces of methane. This was also the case after addition of acetate or H_2/CO_2 as energy and carbon source (Fig. 1c, d). This indicates that the absence of methanogenesis does not depend on deficiency of methanogenic substrates in the Middle and Early Holocene deposits. Methane was only found in permafrost sediments with verifiable methane production activity.

The investigation of phospholipids as molecular biomarkers for *Bacteria* (PLFA) and *Archaea* (PLEL) shows a vertical profile with the same trend as the methane concentration. Specifically, significant amounts of phospholipids were determined in the upper Late Holocene deposits (<4 m sediment depth), which correlates ($r = 0.632$, $P = 0.05$) with the highest amount of methane (Fig. 2). In contrast, the biomarker concentrations in the Middle and Early Holocene permafrost sediments (>4 m sediment depth) drastically decreased to values below 10 nmol g^{-1} sediment, which corresponds with the detected traces of methane. Phospholipids are compounds of cell membranes that rapidly degraded after cell death (Harvey et al. 1986, White et al. 1979). They are regarded as appropriate biomarkers for viable microorganisms (e.g., Ringelberg et al. 1997, Zelles 1999). Therefore, the positive correlation of methane concentration with viable bacteria and archaea gives us the first strong evidence of recent methanogenesis under in situ conditions in permafrost deposits.

Although only a few psychrophilic strains of methanogenic archaea have been isolated, there are some indications of methanogenic activity in cold permafrost environments (Kotsyurbenko et al. 1993, Ganzert et al. 2006). However, the incubation of permafrost samples from 45–63 cm depth at sub-zero temperatures with acetate and hydrogen as methanogenic substrates, indicated a relatively high methane production rate under permafrost temperature conditions. At a temperature of -3°C, a significant increase in methane production was found, which rose linearly to headspace concentrations of about 1000 ppm (with acetate) and 2500 ppm (with hydrogen) during 300 h after the initiation of the experiment. At a temperature of -6°C, methanogenesis was lower; however, after a lag phase of about 300 h, a significant increase to 200 ppm (with acetate), and 500 ppm (with hydrogen) within 200 h, was observed. The calculated activity of methanogenic archaea with hydrogen reached values of 0.78 ± 0.31 nmol CH_4 h^{-1} g^{-1} and 0.14 nmol CH_4 h^{-1} g^{-1} at incubation temperatures of -3°C and -6°C, respectively. This was 2.5 and 3.5 times higher compared to the activity with acetate (0.31 ± 0.04 nmol CH_4 h^{-1} g^{-1} and 0.04 ± 0.01 nmol CH_4 h^{-1} g^{-1}) at the corresponding temperatures.

The quality of organic carbon is a limiting factor in the microbial metabolism process. Our results reveal a high organic carbon content (on average 2.4%) for the Holocene permafrost deposits (Table 1). However, the quantity of organic matter in permafrost ecosystems provides no information on the quality, which determines the availability of organic compounds as energy and carbon sources for microorganisms (Hogg 1993, Bergman et al. 2000). For this purpose, the humification index (HIX), which is a qualitative parameter, can give suitable information with regard to microbial metabolism. Wagner and colleagues (2005) demonstrated that the availability of organic carbon in permafrost soils decreased with increasing HIX. This is in agreement with the present study. It was shown for the permafrost sequence that the HIX increased continuously with depth. This indicates that the organic carbon is less available for microorganisms with depth because of the higher degree of humification. Consequently, at this point, we can summarize that the zone with significant concentrations of methane and activity of methanogenic microorganisms is characterized by the highest concentration of high quality organic carbon.

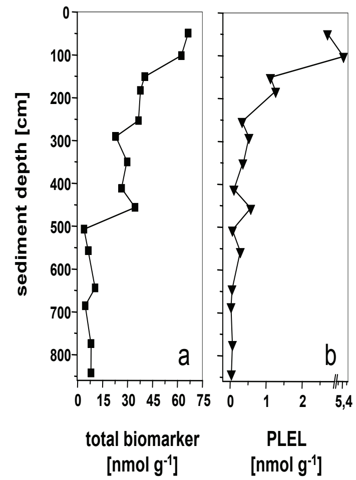

Figure 2. Vertical profiles of total lipid biomarkers (a) and phospholipid ether lipids (PLEL, b) within the Holocene permafrost core.

In contrast to the results of the soil-ecological variables (methane production activity, PLEL biomarker concentration, TOC, HIX), we do not achieve any hint for a possible entrapment process of methane during sedimentation, which was deduced from data of paleoclimate research carried out in the same study area (Andreev et al. 2004, Andreev & Klimanov 2005).

More than 20 percent of the terrestrial Arctic is characterized by ice rich permafrost (Zhang et al. 1999). Large areas, mainly dominated by continuous permafrost, exist in Siberia with thicknesses up to 900 m (Yershov 1998). The present study revealed that considerable parts of these cold habitats are recent sites of methane production, probably catalyzed by specific cold-adapted methanogenic archaea. This increasing reservoir of climate-relevant trace gases becomes of major importance against the background of global warming which could result from a thawing of permafrost area up to 25% until 2100 (Anisimov et al. 1999) and subsequent disposal of the methane reservoirs into the atmosphere. Additionally, the results show that an increase of the permafrost temperature would lead to substantial rise in microbiologically-produced methane in the frozen ground. This would further strengthen the contribution of permafrost to the atmospheric methane budget.

Methanogenesis in Submarine Permafrost

Coastal erosion and sea level rise created the shallow shelf of the Laptev Sea whose bottom is formed by the formerly terrestrial permafrost (Rachold et al. 2007). Flooding of the cold (-5 to -15°C) terrestrial permafrost with relatively warm (-0.5 to -2°C) saline sea water changed the system profoundly and resulted in a warming of the permafrost. Therefore, we consider submarine permafrost as a natural laboratory for studying the impact of environmental changes on permafrost habitats.

First results obtained from submarine permafrost deposits of the Laptev Sea shelf revealed methane concentrations of up to 284 nmol CH_4 g^{-1} sediment (Fig. 3a). Highest methane values were found in the layers with the highest amount of organic carbon (up to 9%). Extremely low $\delta^{13}CH_4$ values of -75 ‰ indicated active methanogenesis in this zone (Knoblauch, pers. com.). According to the studies of Rivkina & Gilichinsky (1996), who did not find any significant amounts of methane in Late Pleistocene permafrost sediments, it can be concluded that our findings in submarine permafrost are also a result of recent methanogenesis. This interpretation is supported by first data of DNA-based analyses of methanogenic communities in the sediments, which revealed a higher diversity and abundance of methanogens within the core segment with the highest amount of methane (Fig. 3b).

Conclusions

This work shows, for the first time, that methanogenic archaea do not only survive in permafrost habitats, but also can be metabolicly active under in situ conditions. Due to the sub-0°C experiments and the in situ temperatures of permafrost sediments, we can conclude that the methanogenic community is dominated by psychrotolerant or even psychrophilic microorganisms. Despite this adaptation to cold environments, we show that a slight increase of the temperature can lead to a substantial increase of methanogenic activity. In the event of degradation of terrestrial or submarine permafrost sediments, this would lead to an extensive expansion of the methane deposits with subsequent impacts on total methane emissions. A future in-depth characterization of the metabolism of these cold-adapted methanogens will reveal biotic and abiotic factors which influence the methane production activity of these organisms.

Methane of microbial origin in perennially frozen deposits probably represents an unconsidered source for the global methane budget. Methane release to the atmosphere from frozen ground is mediated by ongoing permafrost degradation through enhanced thermokarst formation and accelerated coastal erosion in the Arctic. Although the change in permafrost conditions by global warming is examined in the framework of several international projects (e.g., ACD: Arctic Coastal Dynamics, CALM: Circumpolar Active Layer Monitoring), these investigations should be linked more closely with microbiological process studies and biodiversity research. Microbial parameters important

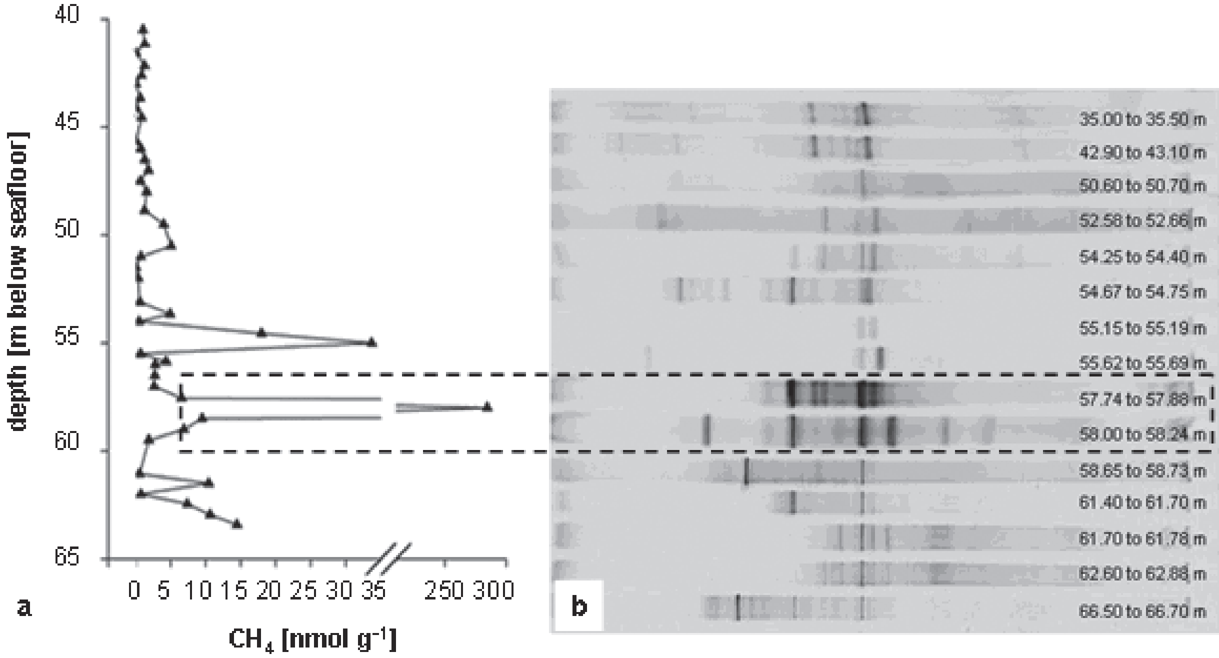

Figure 3. Vertical profiles of methane concentration (a), and DGGE fingerprinting of 16S rRNA genes (b) amplified from the submarine permafrost sediments (between 35.0 and 66.7 m depth).

for the assessment of the carbon turnover (e.g., cell numbers, activities, biodiversity and stability of microbial communities) should be analysed at observation areas in the Arctic, where long-term ongoing monitoring programs are undertaken. The evaluation of microbiological data and their correlation with climatic and geochemical results represents the basis for the understanding of the role of permafrost in the global system, in particular feedback mechanisms related to material fluxes and greenhouse gas emissions in the scope of a warming Earth.

Acknowledgments

The authors wish to thank the Russian-German field parties during the expeditions LENA 2001 and COAST, especially Dimitri V. Melnitschenko (Hydro Base Tiksi), Dimitry Yu. Bolshiyanov (Arctic and Antarctic Research Institute) and Waldemar Schneider (Alfred Wegener Institute for Polar and Marine Research) for their logistic support as well as Volker Rachold (IASC, formerly AWI) and Eva Pfeiffer (University of Hamburg, formerly AWI) for their leadership of the expeditions COAST and LENA 2001, respectively.

Abstract

Fountain Glacier is hydrologically unique in the Canadian Arctic for the large perennial icing in its proglacial valley. It is hypothesized that the icing holds information on the glacier hydrology and the role permafrost has on the overall hydrological system. A spring first observed in 1991, down valley from the glacier, is thought to be supplied by pressurized subglacial water. Aerial and geophysical surveys have been used in conjunction with thermal-hydrological modeling to study the spring's stability and longevity of the icing. Results indicate that there is a well established temporal relationship between changes experienced by the glacier and the icing. It is suggested that the relationship between glacier and permafrost, is an unstable equilibrium, where the glacier drives the system out of equilibrium by altering the proglacial hydraulic conditions as it retreats, whereas the growth of permafrost restores the system back to a new hydro-thermal balance.

Keywords: Bylot Island; glacial hydrology; glacier; GPR; icing; naled.

Introduction

A major issue in glacial hydrology is to determine the way water flows in the glacial environment and the interactions it has with the surrounding ground, which are mainly controlled by the local hydrology, geology and topography.

However, in the High Arctic, where the permafrost is continuous, the interaction between the flow of glacial meltwater and the surrounding ground is mainly governed by temperature. Subzero temperature regimes promote the formation of permafrost and cold glacier ice fringes which, frozen to the glacial bed, act as effective water barriers, enabling the storage of pressurized subglacial flow.

Icings and associated features are often observed on proglacial floodplains in the High Arctic. These occur where water, flowing through a network of subglacial and intra-permafrost passages, comes to the surface and freezes in layers. Studies have pointed out that water could mainly come from two sources: (1) subglacial long-term storage; or (2) interconnected supraglacial or marginal ice dammed lakes (Pollard et al. 1999, Hodgkins 2004). It has been commonly accepted that the formation of some icings are related to polythermal glaciers, such as Fountain Glacier on Bylot Island, that have a temperate base, under which water can be stored in a network of interconnected cavities (Pollard et al. 1999, Yde & Knudsen 2005). However recent research by Hodgkins et al. (2004) has presented evidence supporting the existence of icings in front of Scott Turnerbreen Glacier in Svalbard, believed to be a cold based glacier.

Field observations suggest that the icing in front of Fountain Glacier is a perennial feature that partially degenerates throughout the melt season as a result of thermal and hydraulic erosion. However, once the ablation season is over and air temperatures become negative, a delicate hydrostatic and thermal balance enables its regeneration by allowing an uninterrupted liquid water supply throughout the winter.

This paper describes the glacier-permafrost interactions that lead to the preservation of a proglacial icing on Bylot Island, Canada; and proposes that subglacial water storage is responsible for supplying water to the icing through a proglacial talik. Additionally, it is suggested that the slow overall thinning of the proglacial icing is directly related to the retreat and thinning of Fountain Glacier.

Study Area

Bylot Island (Fig. 1a) is located at the eastern margin of the Canadian Arctic, north of Baffin Island, at approx 73°N, 78°W. It is roughly 180 km in length and 100 km in width; with a 4,500 km^2 icefield covering the centre of the island.

Even though the island has been studied by a few authors (e.g., Zoltai et al. 1983, Moorman 1998, 2000a, b, 2003, Irvine-Fynn 2004, Fortier & Allard 2004) it is still considerably unexplored.

Mountain areas are composed mainly of crystalline Canadian Shield bedrock, while the lowlands that receive the flowing glaciers mainly consist of poorly consolidated sandstone and mudstone of Cretaceous-Tertiary age.

The climate of Bylot Island can be considered as an arctic desert. It has a mean annual temperature of -15°C, a mean annual precipitation of 225 mm and the average local snow depth was measured to be less than 80 cm near the terminus of Fountain Glacier (Moorman & Michel 2000a, b,

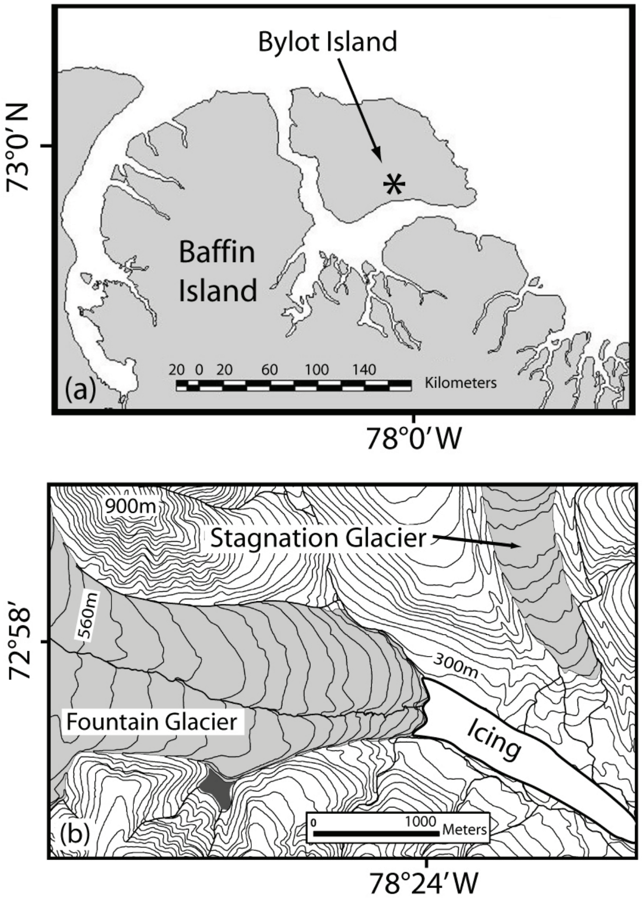

Figure 1. (a) Location of Bylot Island on the northern edge of Baffin Island, Canadian Arctic and (b) topography of the study area in the region of Fountain and Stagnation Glaciers.

Moorman 2003). The island is located in a zone of continuous permafrost (Zoltai et al. 1983) with estimated thicknesses being between 200 and 400 m (Moorman 2003). The coupled action of the strong presence of permafrost and the low precipitation makes the hydrology highly dependent on glacial conditions (i.e., ice melt and dynamics). The island's air and ground temperature regimes directly influence the preservation of hydrologic features in ice, ice cored moraines and proglacial plains. Klassen (1993) and McCuaig (1994) have presented evidence suggesting that Bylot Island has not experienced glacial advances in more than 40,000 years. Its glaciers currently show signs of retreat from their Neoglacial maximum at the end of the Little Ice Age.

Field observations were carried out on the lower ablation zone of Fountain Glacier and the adjacent section of the icing located on its proglacial plains (Fig. 1b).

Methodology

Glacial retreat and thinning

The quantification of the retreat and thinning of Fountain Glacier was obtained through the comparison of the following images and Digital Elevation Models (DEM):

- Aerial photographs obtained in 1958 and 1982 were georeferenced using a second order polynomial, and resampled to a standard pixel size of 5 m.
- A CV580 radar image was acquired over the area of interest in May 1995 by the Canada Centre for Remote Sensing. This image was already terrain-corrected and had a pixel resolution of 5 m.
- A 15 m-resolution orthorectified panchromatic Landsat ETM image was obtained in 2001.

All four images were re-sampled to UTM zone 17X, NAD 83 and given a pixel size of 5 m. Vectors were then drawn representing the position of the glacier snout on each of the four dates.

- A 5 m gridded DEM was generated for the lower part of Fountain Glacier from 20 m contours available as a vector layer from the 1:50,000 Canvec vector coverage, derived from the 1982 photography.
- A second DEM was generated from DGPS positions obtained in the summer of 2007.

The 2007 DEM was then subtracted from the 1982 DEM to establish the amount of thinning which has occurred over the ablation zone of Fountain Glacier over the last 25 years.

Icing thinning

Ground Penetrating Radar (GPR) surveys were carried out on the proglacial icing in front of Fountain Glacier during the summer of 2007. Transverse survey lines were established all over the extent of the icing following a zigzag pattern. Additionally, a longitudinal line was surveyed through the middle section of the icing in order to tie the transverse profiles together.

Survey lines were conducted using a Pulse Ekko Pro GPR System (Sensors and Software) with 200 MHz antennas in parallel broadside configuration. The profiles were acquired in continuous mode using a 400V transmitter and a stacking of 16, which allowed an average step size of 12 cm. A Garmin GPS receiver was connected to the GPR unit allowing the continuous acquisition of positional data while the radar profile was collected. Radar data was then filtered for low frequency signal saturation and enhanced with an Automatic Gain Control (AGC).

A Common Mid Point (CMP) survey was also acquired in order to determine the wave propagation velocity for the icing ice and convert time-based profiles to depth.

The base of the icing was delineated using ReflexW software and a contour map of the icing showing ice thickness was then generated.

Based on GPR surveys conducted in 1993 with a Pulse Ekko IV System (200MHz antennas), Moorman & Michel (2000) produced an ice thickness map of the proglacial icing. Both maps were compared and a contour map was generated showing the changes in ice thickness over the period from 1993 to 2007.

Spring activity and location

The spring activity and location was determined through the comparison of:

- Image extracted from an aerial video shot in 1991.

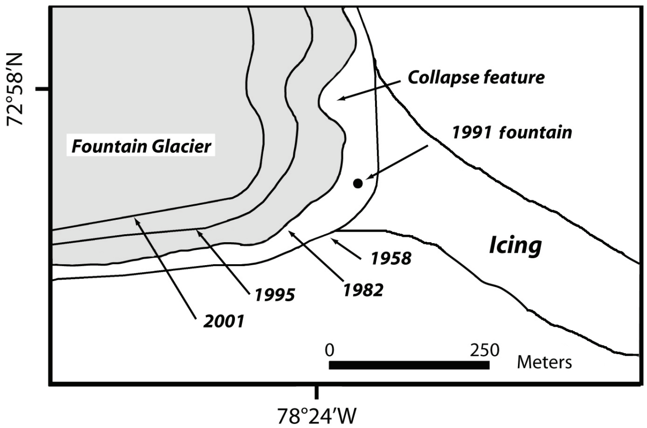

Figure 2. Temporal variation of Fountain Glacier's terminus. The retreat rate has increased considerably since 1982 when a collapse feature on the northern half of the snout was first observed.

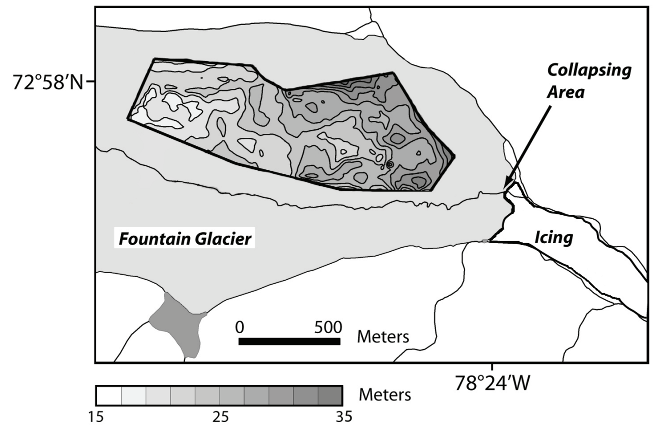

Figure 3. Contour map showing the thinning experienced by Fountain Glacier during the last 25 years (1982–2007). Contour interval is 2 m. The glacier's outline corresponds to its 1982 position.

- Georeferenced aerial photograph acquired in 1982.
- Icing map created by Moorman & Michel (2000) in 1993.
- Field observations conducted in 1991, 1993, 1994, 1995, 1999, 2001, 2003 and 2007.

Glacial Behavior

Fountain Glacier (Fig. 1b) has a total catchment area of 72 km^2 (Walter 2003). The glacier is 16 km long, its elevation ranges from 255 m a.s.l. to 1758 m a.s.l. and its average surface slope is 5.5° (Walter 2003).

The snout of Fountain Glacier terminates in a 20–30 m cliff face overlooking the proglacial plain where the icing is situated. It is flanked by vegetated moraines which tend to be considerably smaller than the ones surrounding neighboring glaciers, such as Stagnation Glacier.

The glacier's surface is generally smooth, with few moulins and crevasses, characteristic of polythermal glaciers subjected to subzero temperature regimes. As such, the superficial hydrology of Fountain Glacier mainly consists of marginal streams and a deeply incised meandering channel in the lower 3 km of the ablation area that discharges a large percentage of the supraglacial meltwater. This deeply cut and strongly meandering supraglacial stream is an indication that some hydraulic features are reoccupied annually (e.g., Moorman & Michel 2000a).

Although the glacier's englacial and subglacial hydrology has not been thoroughly studied, signs of preserved englacial conduits have been observed by Ground Penetrating Radar (GPR) surveys and corroborated with field observations on the glacier's margins. Radar profiles have also shown areas of higher concentration of noise, interpreted as water-rich temperate ice towards the base of the glacier. Although there were no observations of subglacial channels flowing from Fountain Glacier in 2007, continuous water chemistry measurements showed that water turbidity considerably increased towards the end of June, suggesting the beginning of the emergence of subglacial flow.

Even though the proglacial plains are reworked seasonally by meltwater erosion, there are a few signs of high water pressure events. A roughly 5 m-high, water-transported boulder was deposited on the southern side of the proglacial plain between field observations made in 1996 and 1999. These observations support the hypothesis that Fountain Glacier may sporadically exhibit water outbursts as a result of the sudden release of subglacially stored pressurized water. This affects the area's morphology, including the permafrost that surrounds the glacier terminus.

Until recently (since the Little Ice Age) the glacier has not presented marked retreats, slowly losing mass via ice melting and sublimation only during the short ablation summer period. However, this appears to have changed in the last few years. The terminus has shown important signs of activity, retreating about 60 m between 1958 and 1982, giving an average retreat rate of about 2.5 m per year over this period (Fig. 2).

Between 1982 and 1995, it retreated about 80 m, which gives an average retreat rate of about 6 m per year. On average, the retreat rate has more than doubled in speed over a period of 13 years. Between 1995 and 2001 the glacier receded 60 m more at an average rate of 10 m per year. Although imagery is not yet available for 2007, preliminary field observations support the hypothesis that this trend will continue and that the rate of retreat is still increasing.

During the period 1958 and 1982, a collapse feature began to develop in the northern half of the glacier's snout very close to the effluent point of the incised supraglacial stream shown in Figure 1b. Before the collapse, the glacier's snout showed a mild slope ramp, characteristic of undisrupted termini. The collapse feature is clearly shown by a distinct curve in the contour lines representing the glacier's position in 1982. The collapse feature has become more predominant throughout the years, severely increasing the snout's slope.

The long-observed equilibrium of Fountain Glacier has not only been disrupted by recession but also by thinning (Fig. 3).

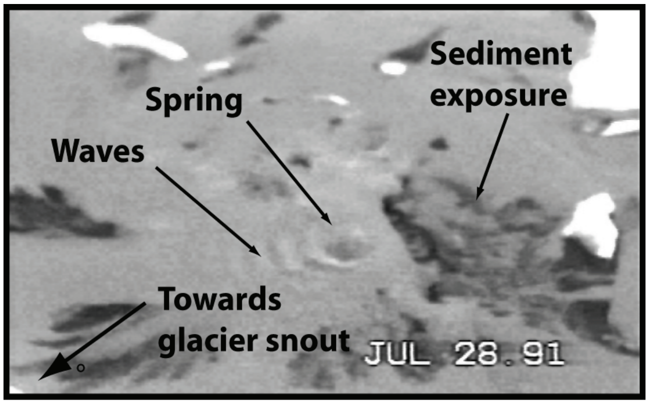

Figure 4. Image extracted from a video shot during a helicopter flight over the proglacial plains of Fountain Glacier in 1991. Note the spring activity shown by the presence of concentric waves on the water surface.

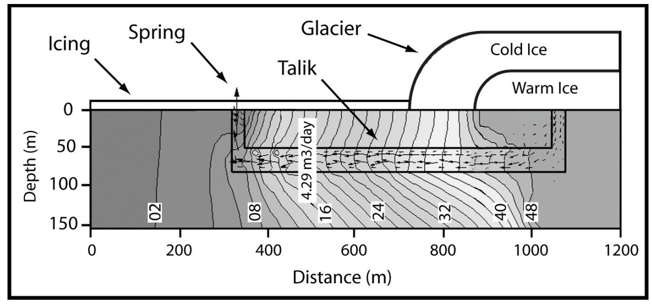

Figure 5. Thermal hydrological modeling of the generation and preservation of the proglacial icing. The model shows a stable liquid water flow through the proglacial talik after 10 years of modeling iterations. The talik is 30 m thick and the spring is located at approximate 300 m from the glacier terminus which is the maximum attainable distance for the talik to be preserved. Contour lines represent hydraulic head with an interval of 2 m.

Although there is insufficient data to determine the thinning rates over the last 50 years, the comparison of the 1982 DEM and field observations collected during 2007 shows that the upper surveyed area had thinned by around 15–20 m, while the section nearest the snout showed the greatest thinning, typically between 25 and 30 m. On average Fountain Glacier appears to have thinned between 0.6 and 1.2 m per year over the last 25 years.

Icing and Spring Activity

Fountain Icing is a proglacial icing located at an elevation of approximately 260 meters above sea level. It presents well developed candle ice and is considerably debris free. The icing extends for over 11 km from the terminus of Fountain Glacier down valley until the margins of Sirmilik Glacier; although aerial photographs show that only the section closest to Fountain Glacier (500 m wide by 1.2 km long) has had perennial ice cover since 1948 (Moorman & Michel 2000b). This last section presents a valley bottom profile characteristic of outwash plains, with some areas emerging through the icing surface. The sub-icing topography varies considerably and is continuously being reworked by water erosion during the melting season.

As in glaciers, field observations show that meltwater tends to concentrate in channels that grow bigger at the expense of smaller ones. As such, the icing has historically presented a main supra-icing channel that drains the majority of the meltwater. Aerial and field photographs show that this channel was located on the north side of the icing until the glacier collapse feature began to develop. Some time before 1999, when the collapse feature was big enough and the glacier's terminus ramp had become steepened, this main drainage channel shifted towards the southern side of the icing. The prevalence of drainage channels on the margins of the icing has promoted a dome shape surface recognized by Moorman & Michel (2000b).

During the fall and winter, when freezing temperatures prevail, the icing is rebuilt. Field observations conducted during early June and late August show that even though the icing is significantly eroded by the end of one melting season, it is totally replenished by the beginning of the subsequent one. By the end of the ablation season, superficial water flow rapidly decreases leaving only groundwater sources as an option for the icing to regenerate.

Fountain Glacier, originally named B26, got its unofficial name from the presence of a fountain, first observed during over flights in 1991(Fig. 4). The spring emerged strongly at a distance of roughly 50 meters from the glacier's terminus, flooding the proglacial plains, which at that time promoted the partial erosion of the icing that covered the proglacial valley.

It is hypothesized that pressurized subglacial storage is responsible for supplying water to the icing through a proglacial talik that connects the glacier to the spring, promoting the regeneration of the icing during the freezing winter. Simplified finite element thermal-hydrological models support the hypothesis that liquid water may indeed flow, even under harsh arctic winter conditions, by means of a proglacial talik, which is preserved unfrozen by the heat produced by pressurized flowing water. Although the model shows that the talik begins a slow freeze-back process after some time, high water pressure episodes such as the one that occurred in 1991 cause a thermal enlargement of the talik (Fig. 5).

Aerial photograph comparison suggests that the icing did not extend all the way to the terminus of the glacier before 1991 (Moorman & Michel 2000) when the spring was first observed. However, field observations conducted in 1993 determined that the area flooded by the spring activity in 1991 had become covered by icing ice, and that an ice blister had developed in the former location of the fountain. Marks of small supra-icing streams radiating out were observed (Fig. 6). The ceasing of the spring activity, the development of the collapse feature on the glacier snout and an increasingly consistent glacial retreat appear to have occurred around the same time. From this time onwards the icing has thinned considerably.

The thinning of the icing allowed the exposure of what is

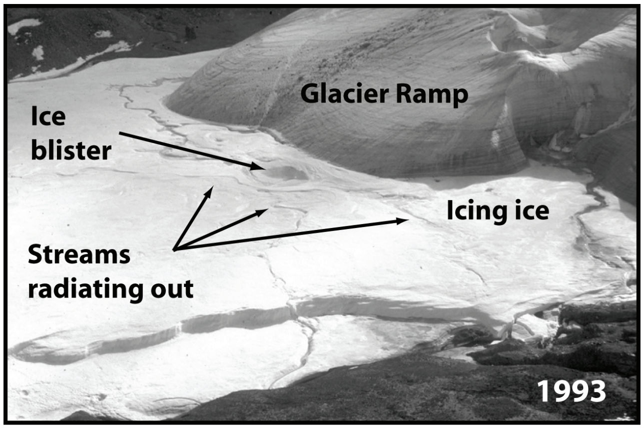

Figure 6. Oblique aerial photograph showing the ice blister adjacent to the terminus of Fountain Glacier. A series of radiating streams have been presumably fed by water flowing from a spring under the blister.

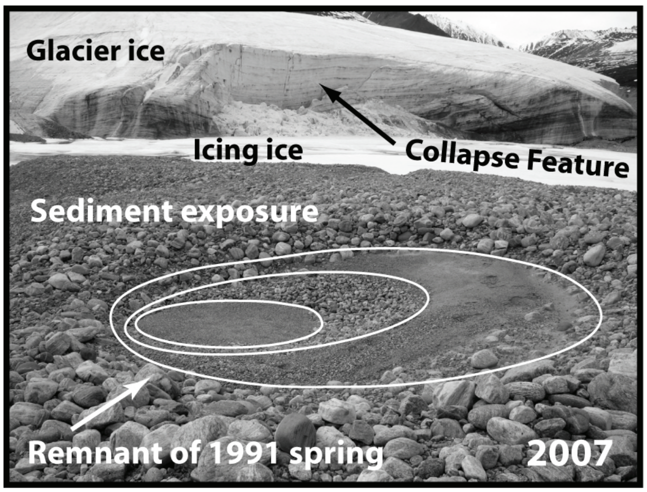

Figure 7. Circular feature embedded in a sediment exposure in front of Fountain Glacier. The feature has been interpreted as the remnants of the spring observed in 1991 which resulted in the icing blister observed in 1993.

inferred to be the remnants of the spring observed in 1991. Figure 7 shows a circular sediment feature embedded in a sediment exposure located in the same area where the spring was observed. In fact, its position taken by GPS closely aligns with the position presented by the map created in 1993 by Moorman & Michel (2000b). The remnant feature consists of three well-sorted sediment rings devoid of fines. Additionally, marks of incipient channels radiating out from the circular feature were observed. As such, based on its location, sediment characteristics and morphology, it has been concluded that the feature is in fact the remnants of the spring observed in 1991.

The subtraction between the ice thicknesses measured by Moorman & Michel (2000b) in 1993 and those obtained in the summer of 2007 reveals a considerable thinning of the icing, by almost 10 m in some areas (Fig. 8). These areas are included within the zones of perennial ice, and as such it is suggested that the icing's thinning is the result of the closure of the spring that once supplied liquid water year

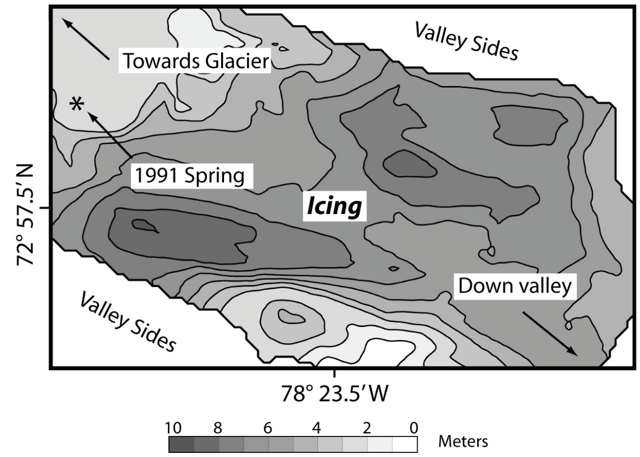

Figure 8. Contour map showing the thinning experienced by the Fountain Glacier Icing during the last 15 years (1993–2007). Contour interval represents 1 m of change in the ice thickness.

round. The total volume lost is 507,075 m^3 over a surveyed area of 94,813 m^2, giving an average thinning of 5.3 m.

It is worth noting that even though the icing has experienced a considerable overall thinning, it is still being rebuilt every winter. This supports the idea that another routing for groundwater has been established, presumably closer to the glacier.

Discussion and Conclusions

The growth and preservation of the Fountain Glacier icing depends on the balance between the glacial system and the surrounding permafrost. Field observations show there is a well established temporal relationship between changes experienced by the glacier and the icing.

The cold impermeable margin of Fountain Glacier results in the year round pressurized storage of liquid water used in the regeneration of the proglacial icing. It was observed that after the collapse of the terminus, the winter spring flow was dramatically reduced, resulting in the thinning of the perennial icing.

The hydrology and dynamics of Fountain Glacier have a considerable effect on the characteristics and response of the proglacial talik responsible for connecting the subglacial environment with the proglacial plain. Figure 9 illustrates a conceptual model that links the reaction of the icing and permafrost systems to the retreat and collapse of Fountain Glacier. It is suggested that the icing is rebuilt by water running through a proglacial talik which needs to remain unfrozen in order to deliver the necessary water year round.

Preliminary results from thermal-hydrological modeling of the proglacial talik suggest that there is a maximum distance between the glacier snout and the point of water expulsion (spring) that can be attained if the talik is to remain unfrozen. The talik is kept unfrozen as a result of a balance between the energy extracted by the subzero air temperature regime and the incoming energy produced by the friction of the pressurized water flow through the sediments (Fig. 5).

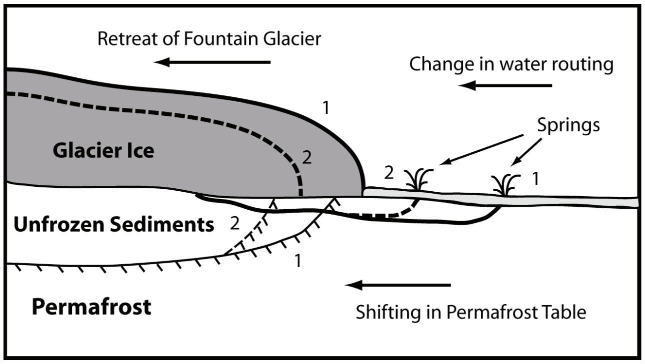

Figure 9. Schematic diagram showing changes in icing and permafrost table as a result of variations in glacial dynamics. (1) Shows the old equilibrium position whereas (2) is the new equilibrium attained.

As such, the retreat and collapse of the glacier terminus exposes a new portion of the proglacial plain to cold air temperatures, altering the talik energy balance, resulting in freeze back and reduction of the spring activity. However, field observations show that the icing is replenished every winter; supporting the hypothesis that a new water routing is readily established as the system attains a new equilibrium position.

It is suggested that the relationship between the two systems, glacier and permafrost, is an unstable equilibrium, where changes in the behavior of either of the two will have considerable effects on the characteristics of the icing. The glacier is considered the dominant factor able to drive the icing out of equilibrium by altering the hydraulic conditions needed to maintain an open talik. Permafrost is the secondary factor that promotes talik freezeback upon the retreat of the glacier, leading to a decrease of water flow through the talik. This hydro-thermal disturbance results in abandonment of the portion of the talik furthest from the glacier terminus. It appears that the closest portion of the talik is preserved, enabling the establishment of a new spring. As such, glacier retreat will promote the up-valley movement of the spring, maintaining a constant distance between the point of water emergence and the glacier snout.

The remotely-sensed data, field observations and finite element modeling demonstrate how the preservation of the icing is a function of the balance between hydrological and thermal regimes that change over a number of time scales. In the short term, seasonal variations in water pressure result from changes in summer temperatures and glacial discharge; that subsequently control the seasonal accretion and erosion of the icing. Over the longer term, glacial retreat and thinning affects the glacier's hydrology and the proglacial subsurface thermal regime. This alters the talik thermal equilibrium at the decadal scale and results in shifts in the spring equilibrium location and discharge.

Finally, steady state thermal disequilibrium (resulting from the gradual talik freezeback) and short high-water pressure events results in intermittent hydrological changes that can affect the icing over the short, medium or long-term.

Abstract

Permafrost microbiology is important for understanding biogeochemical processes, paleoecology, and life in extreme environments. Within the Fox, Alaska, permafrost tunnel, fungi grow on tunnel walls despite below freezing (-3°C) temperatures for the past 15,000 years. We collected fungal mycelia from ice, Pleistocene roots, and frozen loess. We identified the fungi by PCR, amplifying the ITS region of rRNA and searching for related sequences. The fungi within the tunnel were predominantly one genus, *Geomyces,* a cold-adapted fungi, and has likely "contaminated" the permafrost tunnel from outside. We were unable to obtain DNA or fungal isolates from the frozen loess, indicating fungal survival in permafrost soils can be strongly restricted. *Geomyces* can degrade complex carbon compounds, but we are unable to determine whether this is occurring. Results from this study suggest *Geomyces* may be an important colonizer species of other permafrost environments.

Keywords: Fox tunnel; fungi; *Geomyces*; ice wedge; loess; permafrost.

Introduction

The permafrost tunnel near Fox, Alaska, was constructed in the early 1960s to examine mining, tunneling, and construction techniques in permafrost. The tunnel was constructed, and continues to be maintained, by the U.S. Army Cold Regions Research and Engineering Laboratory. The tunnel consists of ice-cemented loess, massive ice, and ice wedges that have been dated from 12 kbp to 40 kbp. The permafrost present in the tunnel is syngenetic with multiple exposures of primary and secondary ice features (Bray et al. 2006, Shur et al. 2004). Fungal growth has been observed on the interior walls. The interior walls, ice wedges, and hanging roots within the tunnel are covered with white fungal mycelia all year. Although the temperature in the permafrost tunnel has remained below freezing (approximately -3°C) for at least the past 15,000 years (Katayama et al. 2007) microbial activity is still present. The tunnel is also very dry and there is no evidence of liquid water. As a consequence, the organisms that grow in the tunnel must be adapted to cold and dry environments.

Observational evidence, such as fungal growth appearing from drilled holes and nails, suggests that the fungal organisms were contaminants brought in from outside the tunnel either from air contamination or on sampling equipment. Fungal growth was observed not only on the loess-rich interior walls, but mycelia often completely carpeted ice wedges. The widespread nature of the fungi throughout the tunnel suggests that it can be transported by air currents. It may also be possible that the fungi occurs on ice surfaces and around drill holes because it is moisture-limited. When a hole is drilled, ice-cemented material is exposed and immediately starts to melt and then sublimate. Therefore, when a hole is drilled, moisture is liberated, and fungal growth at these sites should be possible.

Our research objective was to determine the identity of the fungal organism(s) covering the interior walls and ice wedges of the permafrost tunnel. Understanding their taxonomy could help us understand the microbiology of permafrost environments and determine the range of environmental parameters in which the some fungi can grow. A secondary objective was to determine whether the identified organisms have important characteristics related to biogeochemical processes or human health.

Methods

Soil sampling

To determine the identity of the fungal organisms throughout the permafrost tunnel and on different substrates, five samples were collected from interior walls, hanging roots, and ice wedges. Three samples were taken from the interior walls by scraping the fungus gently with the end of a sterile plastic centrifuge tube. When doing this it was common for loess particles to enter the tube (Figs. 1a, b, d). One sample was taken from an ice wedge in the ceiling in the side corridor (winze) of the tunnel (Fig. 1c). The mycelial "mat" was covering the ice wedge and was easily collected with tweezers and placed in a sterile centrifuge tube (Fig. 1c). The fourth sample was taken from a root hanging from the ceiling of the main adit where the adit and winze separate near the entrance (Fig. 1e). The root was covered in mycelia and the root was broken off with tweezers and placed in a sterile centrifuge tube. The tubes were frozen that same day and later transported to the USGS in Menlo Park for isolation and molecular characterization. We also sampled loess samples from the wall using a serrated metal drill corer (keyhole corer) that had been sterilized using ethanol. In the lab, we further attempted to minimize any potential contamination by scraping of the exterior of the core with sterile razor blades and sampling the interior of the frozen loess core. Carbon and nitrogen concentrations of loess were quantified on oven-dried material (105°C, 48 h) on a Carlo Erba C/N analyzer.

Soil preparation

Soil or fungal flocs were weighed out into 2 ml microcentrifuge tubes (Eppendorf Inc., Westbury, NY) in 0.5 g increments. Under sterile technique, 1.5 ml of DNase/RNase free water (Eppendorf Inc., Westbury, NY) was added to the soil samples or fungal mat. The soil slurry was vortexed for 10 minutes. The slurry was then centrifuged at 10,000 rpm for 1 minute. The supernatant was then serially diluted 10-fold, 100-fold and 1000-fold. These serial dilutions were then plated onto standard potato dextrose agar plates (Difco Inc., Lawrence, KS). As a control the wet soil from the previous step and the dry soil from the original sample were also plated onto potato dextrose agar plates (Difco Inc., Lawrence, KS).

Growth conditions

Plates of each dilution were grown at 0, 4, 20, and 37°C in the dark for 28–31 days. Fungal growth did not occur at 20 or 37°C but did occur at 0 and 4°C. Fungal isolates that appeared on the 4°C plates were isolated onto fresh potato dextrose plates. This step of removing isolates from plates took another 2–3 months of replica plating until there was no difference in isolate morphology. Pure cultures were tested for pH sensitivity at various pHs ranging from 2–8 on potato dextrose agar (Difco Inc., Lawrence, KS) over a period of one month. Growth was only observed at pH 5 and 6.

DNA isolation

Single isolates were removed from agar plates by scraping, placed in liquid nitrogen, and homogenized with a mortar and pestle. DNA was isolated from the homogenized samples following gram-positive bacteria DNA isolation protocol from a Purelink Genomic DNA mini kit (Invitrogen Inc., Carlsbad, CA). There was no fungal protocol with this kit. The isolated DNA was quantified using a standard Picogreen dsDNA assay (Invitrogen Inc., Carlsbad, CA). We also attempted to extract DNA from loess samples in bare (no mycelia) areas using a Powersoil DNA extraction kit (Mo Bio, Inc.), but agarose gel electrophoresis and the picogreen dsDNA assay showed that there was no measurable DNA in the extract. PCR was also tried but was not successful.

PCR conditions

Fungal DNA from isolates was amplified using ITS1-ITS4 primers in a PCR reaction using 0.5 to 1.0 µl of genomic fungal DNA. BSA at a final concentration of 1µg/ml was used to bind to common PCR inhibitors. Thermocycler parameters were an initial melting step 95° (10 minutes one cycle), followed by 40 cycles of 95° (1 minute), 53° (30s), and 72° (1 minute. PCR was concluded with a long extension step of 72° (10 minutes), and then the PCR reactions were placed in the -20°C freezer.

Sequence analysis

Amplified DNA was sequenced at a commercial lab (MClab, San Mateo, CA), and results were imported into Geneious software (Biomatters Ltd., New Zealand). Sequences were examined for quality and Blast searched on the NCBI database. The three best matches were recorded.

Restriction analysis

Restriction analysis was performed on the PCR products in order to determine if the sequences were of the same or different organisms. PCR products were digested overnight with the enzyme CFO1. BSA was added at a concentration of 10 µg/µl to aid in enzymatic digestion. Digests were then run on a 3% gel for 90 min at 75 volts, with a 100 bp ladder (NEB Inc, Ipswich, MA), and negative controls. The gel was stained in ethydium bromide, rinsed for 20 min, and digitally photographed on a UV light table.

Results and Discussion

White mycelia are present on tunnel walls, ice wedges, and plant roots within the permafrost cave near Fox, Alaska, (Figs. 1a–f). The fungal organisms sampled and isolated from multiple locations within the Fox permafrost tunnel were all of the same genus, *Geomyces*. Two of the organisms were identified as *Geomyces pannorum*, while three other samples were closely associated with *Geomyces* strain FMCC-4 (Table 1). Restriction digests of the PCR products produced different restriction patterns for most of the organisms (Fig. 2). The restriction patterns for sample FG1 and FG2 were the only two samples to be identical to each other. Except for FG1 and FG2, all samples had unique restriction patterns, indicating that they had slightly different DNA sequences. Therefore, although they were all the same genus, they differed at the species or strain level.

The physiology of *Geomyces* is such that it is very well adapted to growth in the cold, dark, and dry conditions of the permafrost tunnel. Fungi are generally well suited for growing in dry habitats due to their hyphal growth form an unique forms of osmoprotection. Additionally, *Geomyces* is one of only a few fungal organisms known for growth below freezing, which would be a necessity for any organism living within this frozen environment (Ozerskaya et al. 2005, Panikov & Sizova 2007). *Geomyces* was not capable of growth at 20°C or above, but grew well, albeit slowly, at 4°C. *Geomyces* is considered to be a psychrotrophic fungi, which is an organism that can grow at 0°C, but its optimum growth rate is above 20°C. (Gilichinsky et al. 2005, Robinson 2001). Our results indicate that our isolates could not grow at 20°C or above, and therefore they should be considered psychrophilic fungi.

Geomyces is a commonly observed fungi in boreal and arctic ecosystems that can survive in permafrost environments due to its ability to grow at cold temperatures, its ability to withstand moisture stress and high salt tolerance (Lydolph et al. 2005, Robinson 2001). *Geomyces* has the ability to break down keratin, a compound contained within hair and nails, as well as cellulose, present in plant tissues (Freiedrich et al.). Because *Geomyces* is a kerinatinolytic fungi, it has been used as an indicator of the presence of ancient megafauna (due to the presence of hair and nails in some permafrost). The use of *Geomyces* as an “indicator species” is supported by this study because of the visible presence of ancient megafauna (generally bones) contained within the Pleistocene loess deposits (Willerslev et al. 2004). Cellulose may also be present in this permafrost environment due to the visible presence of plant roots, although *Geomyces* appeared no more dense on plant roots than on the loess tunnel walls.

Geomyces appeared to be capable of much more extensive growth on ice wedges compared to either roots or ice-cemented loess walls (compare Fig. 1c with others). The growth forms of *Geomyces* differed between the ice wedge and the permafrost tunnel walls. *Geomyces* often formed thin brittle mycelial sheets over the entire surface of the ice wedge that could be easily sampled with a small metal instrument. The ice wedges were dark in color and exhibited elevated DOC dissolved organic carbon concentrations (18.4 to 68.5 ppm; Douglas & Cai, unpublished data) which is probably a strong source of carbon substrate for the fungi.

Table 1. Identification of four fungal isolates taken from the interior of the Fox permafrost tunnel. BLAST results matched with the 18S rRNA gene, partial ITS1, 5.8S rRNA, ITS2, and 28S partial sequence.

Sample	Source	Colony Description	Best Identity	Homology	E score	Accession number

			2. *Geomyces pannorum* strain VKM	94%	0.0	DQ189228
			3. *Geomyces* sp. BC-7	94%	0.0	DQ317337

On ice-cemented loess walls, *Geomyces* tended to have a spotty distribution. Growth was generally circular emanating from previously sampled areas, and the mycelia could not be easily sampled without breaking off loess particles from the walls. The growth of *Geomyces* on loess walls tended to be associated with disturbance or points of contamination, where people would, for example, place nonsterile sampling instruments on their surface. The loess walls had carbon and nitrogen concentrations of 2.75% and 0.25%, respectively, and had moisture contents ranging from 18 to 55%. Root samples were not examined for nutrient content, but organic tissues can generally range from 40 to 50% carbon and 1 to 5% N. Therefore, these substrates had enough C and N for microbial growth.

Surprisingly, no other genus of organism except *Geomyces* was isolated from the tunnel. It is possible that given our growth conditions for isolation, we selected for this organism, although we attempted isolation at multiple pH and temperature ranges. This does not preclude other organisms from being present in the tunnel, but it is a strong indication that all of the organisms visible within the tunnel are *Geomyces*. Restriction analysis showed that we isolated several species or strains of *Geomyces*. Although all of our isolates were of the same genus, restriction analysis showed that there were slight differences in their ITS or ribosomal sequences (Fig. 2). It is likely the fact that the isolated *Geomyces* fungi is common in boreal soils, can grow well at cold temperatures, and can be easily dispersed in air that allows it to be the dominant (or only) fungal organism visibly present on the walls of the permafrost tunnel.

We also attempted to isolate DNA from the ice-cemented loess walls in order to compare the fungal DNA present within the loess to the isolates. However, we were either unsuccessful at extracting DNA or the concentration of DNA within the ice-cemented loess walls was so low that we could not measure it, even using sensitive fluorometric techniques. We have been successful at extracting DNA from surface permafrost loess samples (1 m below the soil surface in boreal forests), which leads us to conclude that DNA concentrations within the tunnel loess walls were so low as to be unquantifiable. Our inability to extract DNA from loess in the Fox tunnel may have been due to the fact that few organisms survive frozen conditions for long periods of time (Panikov & Sizova 2007), and DNA quality in frozen soils is reduced over millennia (Willerslev et al. 2004).

We suspect that *Geomyces* in the Fox tunnel is a contaminant from outside the tunnel, rather than an organism that was present in the extant permafrost that has begun to grow on disturbed tunnel walls. *Geomyces* is a common soil organism associated with black spruce (Filion et al. 2004) and therefore is probably very prevalent in the surrounding environment. *Geomyces* growth is observed primarily around sampling holes, metal nails, and areas where the soil has been disturbed by human activity. This could have been caused by using nonsterile tools during sampling. Alternatively, small amounts of soil moisture that are released upon sampling the frozen walls (heat produced by friction between sampling equipment and wall) would permit water-limited fungi to grow rapidly in disturbed areas. The door to the Fox permafrost tunnel is often open and there is good air circulation through the tunnel. Therefore, it would be possible for organisms to contaminate the tunnel from outside.

There are some minor human health aspects to consider with regard to *Geomyces*. It is considered an indoor mold that reduces the air quality within some buildings. It is also found

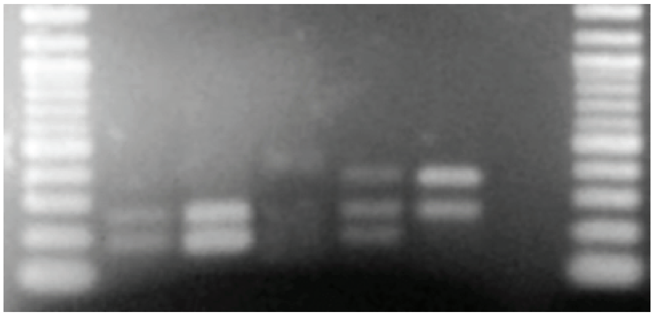

Figure 2. Restriction analysis of PCR products of the four isolates. Lanes 1 and 8 are 100 bp ladders. From left to right the samples in each lane are FG1, FG2, FG3, FG5, FG6, and a negative control.

in household dust, damp walls, and archived paper such as in libraries. It is not considered dangerous. However, one variety of *Geomyces, Geomyces pannorum var pannorum* is suspected in creating slight skin and nail infections (Bloom et al. 2007).

Cold-adapted fungi and biogeochemical cycling

Carbon and nitrogen cycling within thawed permafrost soils is an important area of global change research (Zimov et al. 2006). This study highlights two factors that make permafrost environments unique microbiologically which, in turn, are important for biogeochemical cycling.

First, results from the permafrost tunnel and permafrost studies at the ground surface indicate that fungal abundance in permafrost soils is very low (Gilichinsky et al. 2005, Waldrop et al., unpubl.). Microbial diversity in permafrost soil is also likely to be restricted because fewer organisms are able to withstand frozen temperatures for long periods of time. Therefore, as permafrost soils thaw, what will be the fungal organisms that enter into this new biological niche? Likely it will be cold-adapted organisms not unlike *Geomyces* in this study. Therefore, the study of cold-adapted fungi in C and N cycling is an important area of future research.

Secondly, the temperature response of microbial activity in cold permafrost environments with low fungal diversity may have to be carefully evaluated. Normally, microbial activity increases with temperature, but cold-adapted fungi, such as *Geomyces*, may have faster growth rates and enzyme activities at low temperatures than at higher temperatures (Robinson 2001). An area of further study will be to determine the fungal organisms that act as primary colonizers of permafrost soils as they thaw. Could low microbial diversity in permafrost soils affect the efficiency or rate of biogeochemical processes as permafrost soils thaw? Given that soil microorganisms mediate biogeochemical cycles and the lack of data on permafrost microbiology, there is certainly a strong research need in this area.

Acknowledgments

I would like to acknowledge the U.S. Army Cold Regions Research and Engineering Laboratory for sampling assistance.

A Web-Based Arctic Geobotanical Atlas and a New Hierarchy of Maps of the Toolik Lake Region, Alaska

D.A. Walker, H.A. Maier, and E.M. Barbour
Alaska Geobotany Center, Institute of Arctic Biology, University of Alaska Fairbanks, AK 99775, USA

Abstract

Accurate maps of arctic terrain at multiple scales are needed for spatial analyses, modeling and monitoring of permafrost responses to a changing climate. A new *Arctic Geobotanical Atlas* (AGA) is a web-based multi-scale (plant-to-planet) collection of geobotanical maps and supporting data. A new set of geobotanical maps focuses on the area around the University of Alaska's Toolik Lake Research Field Station in the vicinity of Toolik Lake Alaska, and includes the Upper Kuparuk River region (published at 1:63,360 scale), the Toolik Lake area (published at 1:20,000 scale), and a map of a 1.2-km^2 intensive research grid on the south side of the Toolik Lake (published at 1:5000 scale). We present an overview of the AGA and descriptions of the new maps and mapping methods.

Keywords: GIS; geomorphology; NDVI; remote-sensing; tundra; vegetation.

Introduction

Vegetation distribution is a key variable for predicting the thickness of the active layer and other properties related to permafrost. Most importantly the vegetation mat acts as an insulating blanket above the mineral soil and prevents deep heat penetration in the summer (Walker et al. 2003). Vegetation maps of CALM grids are being used for modeling active layer depths at local scales within 1-km areas (Nelson et al. 1998), and a vegetation map of the entire Kuparuk River basin was used to model regional scale patterns of active layer depth (Nelson et al. 1997, Hinzman et al. 1998). The vegetation is also strongly related to snow distribution (Evans et al. 1989), another variable that strongly influences permafrost temperatures (Zhang et al. 1997). Maps of vegetation at several scales would be highly useful for monitoring and modeling active layer and permafrost temperatures at site and regional scales.

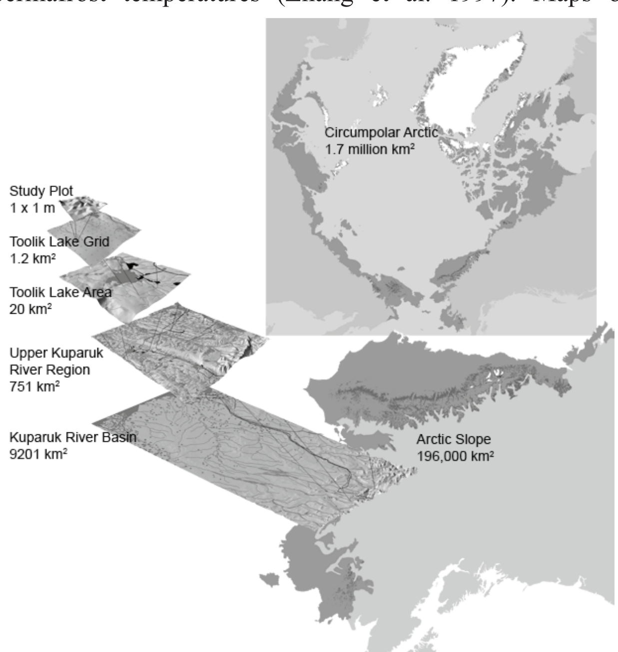

Figure 1. Hierarchy of digital elevation models for the Toolik Lake region in the AGA. Geobotanical maps of the upper Kuparuk River, Toolik Lake area, and Toolik Lake grid are presented in this paper.

The Arctic Geobotanical Atlas

The Arctic Geobotanical Atlas (AGA) is a web-based archive of geobotanical maps that is being developed to aid such studies and other studies that require detail spatial information of the vegetation and other geobotanical information at several scales. The term "geobotany" refers to the science of the relationship of plants to the Earth (Rübel 1927).

The AGA contains a hierarchy of maps and supporting data at seven scales ranging from 1:10 scale (1 m^2 plots) of local areas near Toolik Lake and Imnavait Creek, Alaska to 1:7,500,000 scale for the entire Arctic (Fig. 1). Diverse geobotanical themes include vegetation, geology, topography, landforms, lake cover, and surficial geomorphology. Students and researchers can view thematic maps and download the data by several methods including a map server and SwathViewer software developed at the Geographic Information Network of Alaska (GINA), or they can explore the Arctic using Google Earth. They can also view and print out pdf versions of the original published maps. The map legends are linked to extended descriptions and photographs of the map units.

Other features of the AGA include: (1) an *image library* with photos of the various map units and plant species mentioned in the atlas; (2) a *map catalog* whereby users can select maps according to region of interest, scale of interest, theme or topic of interest, or year of interest; (3) a *glossary* with links to scientific terms used in the atlas; (4) a *bibliography* linked to pdf versions of the references; and (5) a *supporting data* section with links to the original plot-level vegetation and soils data used to describe the map units. The AGA currently includes maps and data from the following projects:

Circumpolar Arctic Vegetation Map (CAVM)

The CAVM covers the global region north of the arctic treeline. It contains maps and descriptions of the vegetation, bioclimate subzones, floristic provinces, topography, landscapes, lake cover, substrate pH, and plant biomass. This section also contains an area analysis of the map by bioclimate subzones and countries (CAVM Team 2003, Walker et al. 2005).

Alaska Arctic Tundra Vegetation Map (AATVM)

The AATVM is a plant community-level map of Arctic Alaska derived from the CAVM. It portrays the dominant plant communities across all of Arctic Alaska, in contrast to the physiognomic-level mapping of the CAVM (Raynolds et al. 2006).

Toolik Lake/upper Kuparuk River basin hierarchy of maps

The Toolik Lake Field Station is a flagship US Arctic Observatory. The upper Kuparuk River basin is a key region for terrestrial arctic research associated with the station. Numerous maps have been prepared to support the research in the area, including that of the Arctic Long-Term Ecological Research (LTER) program and the Department of Energy's R4D studies at Imnavait Creek (Reynolds & Tenhunen 1996). Several maps in the region have been published previously, including geobotanical maps of the Imnavait Creek study areas (Walker & Walker 1996), a Landsat-derived vegetation map of the entire Kuparuk River watershed (Muller et al. 1998) and a Star3i digitial elevation model of the entire Kuparuk River watershed (Nolan 2003). Here we present the maps of upper Kuparuk River region, the Toolik Lake area, and the Toolik Lake research grid (see Fig. 1).

New Maps of the Toolik Lake Area

A new set of geobotanical maps of three areas in the vicinity of the Toolik Lake Research Station have been added to the AGA. A portion of the maps will also be published as a map sheet in the Biological Papers of the University of Alaska (Walker & Maier 2008 in review). The new maps include the Upper Kuparuk River region (Fig. 2, 3) (published at 1:63,360 scale), a map of the 20 km^2 area surrounding Toolik Lake (Fig. 4) (published at 1:20,000 scale), and a map of a 1.2-km^2 intensive research grid on the south side of the Toolik Lake (Fig. 5) (published at 1:5000 scale).

Maps of the upper Kuparuk River region

The 751-km^2 upper Kuparuk River region has terrain typical of the southern Foothills of the Brooks Range, including landscapes affected by three major glacial events

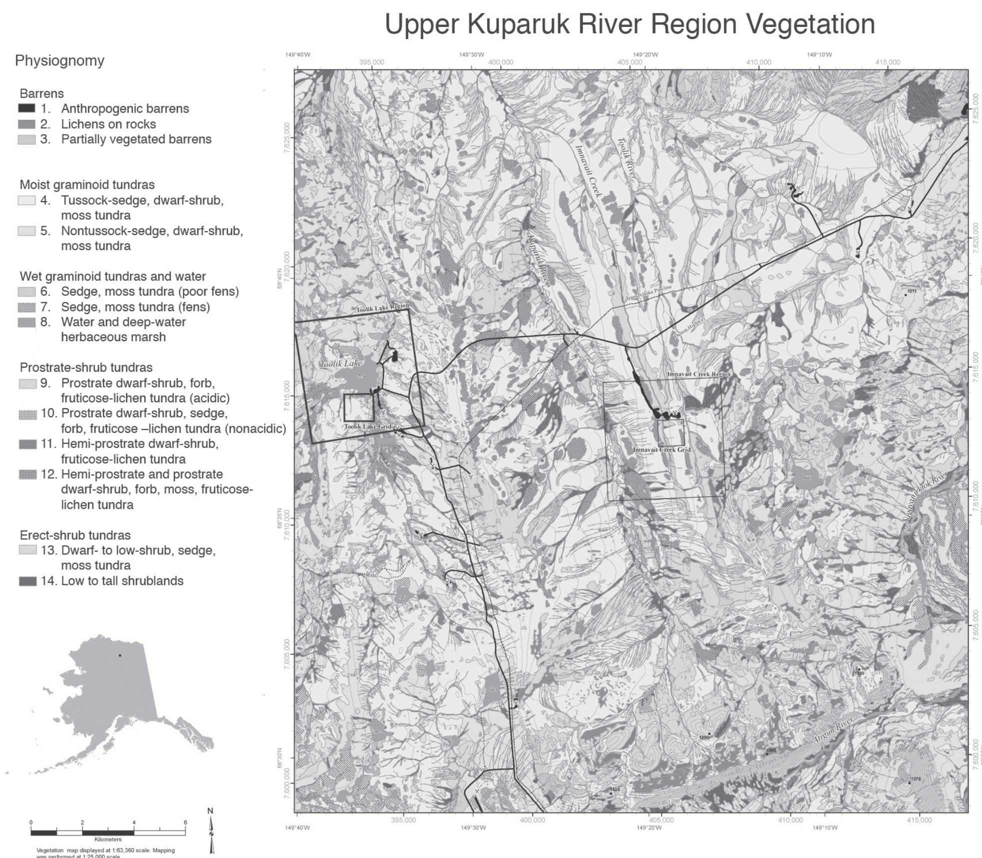

Figure 2. Vegetation of the upper Kuparuk River region. The color version of the map published at 1:63,360 scale has an expanded legend that includes dominant plant communities with GIS codes, typical microsites where each vegetation map unit is found, and area summaries for each map unit (Walker and Maier 2008). A color version also can be found at http://www.arcticatlas.org/. The black rectangles on the vegetation map delineate the boundaries of the Toolik Lake Area, and Toolik Lake Grid (Figs. 4, 5). The location of the mapped area is shown at actual scale as the small black rectangle on the inset map of Alaska.

(Hamilton 2003). The region includes the Toolik Lake and the Imanvait Creek research areas and a stretch of the Dalton Highway and Trans-Alaska Pipeline from the Galbraith Lake airstrip to Slope Mountain. A black and white rendition of the vegetation map of this region is shown in Figure 2.

The vegetation portrayed on the map is derived from a geobotanical database of the region. The base map for the geobotanical map was a 1:25,000-scale black-and-white orthophoto-topographic map that was prepared especially for the mapping project by Vexcel Corp., Denver, CO, in 1994 from stereo pairs of 1:60,000-scale 9 x 9-inch color-infrared aerial photographs that were obtained by NASA in 1982. The base map was prepared without ground-control points, but was registered as closely as possible to the 1:63,360 USGS map of the region. Vegetation and other geobotanical features were mapped by photo-interpretation onto 1:25,000-scale enlargements of the 1982 NASA aerial photographs.

No formal accuracy assessment was performed, but 320 of the map polygons representing 3.2% of the total map polygons, and about 16% of the total map area were checked on the ground during helicopter-assisted transects in 1994.

Geobotanical variables coded for each map polygon included: primary vegetation, secondary vegetation, tertiary vegetation, landform, surface deposit, primary surficial geomorphology, and secondary surficial geomorphology. (Secondary and tertiary types are subdominant types that cover more than 30% of a map polygon.) The geobotanical map was made using methods and legends specially developed for northern Alaska (Walker et al. 1980, 1986, 1989). The geographic information system (GIS) was developed using Arc/Info software and followed the integrated terrain-unit mapping approach (Dangermond & Harnden 1990). The resulting geobotanical maps were presented at conferences in 1996 (e.g., Walker & Walker 1996), but remained unpublished until now. In 2007 the map boundaries were modified to register with a recent digital elevation model (DEM) of the Kuparuk River region (Nolan 2003) and a 1989 SPOT image of the region. The legends were also modified to better fit the hierarchy of maps in the *Arctic Geobotanical Atlas*.

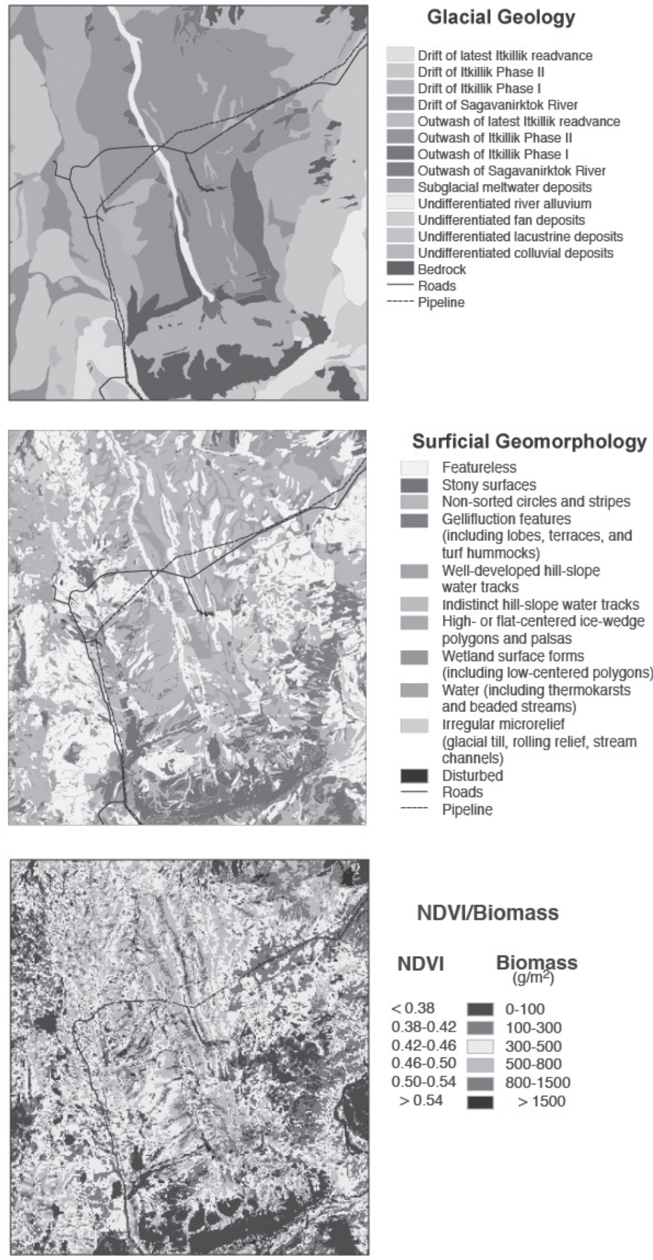

Figure 3. Glacial geology (derived from Hamilton 2003), surficial geomorphology, and NDVI/biomass (derived from Shippert et al. 1995) maps of the upper Kuparuk River region. Color versions can be found at http://www.arcticatlas.org/.

The vegetation of the region was studied and mapped as part of the Arctic Long-Term Ecological Research (LTER) project at Toolik Lake (Walker et al. 1994, Walker & Walker 1996), and the Department of Energy R4D (Response, Resistance, Resilience and Recovery of vegetation from Disturbance) project at Imnavait Creek (Walker & Walker 1996).

Fifty-seven plant communities and land-cover types were recognized during the mapping of the upper Kuparuk River region and are designated by the numeric GIS codes that are included in the expanded legend (not shown here). These were grouped into the 14 physiognomic map units shown on the map, which are compatible with the Circumpolar Arctic Vegetation Map (CAVM Team et al. 2003) and the Alaska Arctic Tundra Vegetation Map (Raynolds et al. 2006). Photos and explanations of the geobotanical mapping units and the supporting field data and metadata can be found on the AGA web site http://www.arcticatlas.org/.

The other maps on the front side of the published map sheet include a false color-infrared satellite image derived from the French SPOT (Système Probatoire d'Observation de la Terre) satellite (not shown), glacial geology (Hamilton 2003), surficial geomorphology, and a map of greenness and biomass as portrayed by the Normalized Difference Vegetation Index (NDVI) (Shippert et al. 1995) (Fig. 3), all published at 1:226,576 scale.

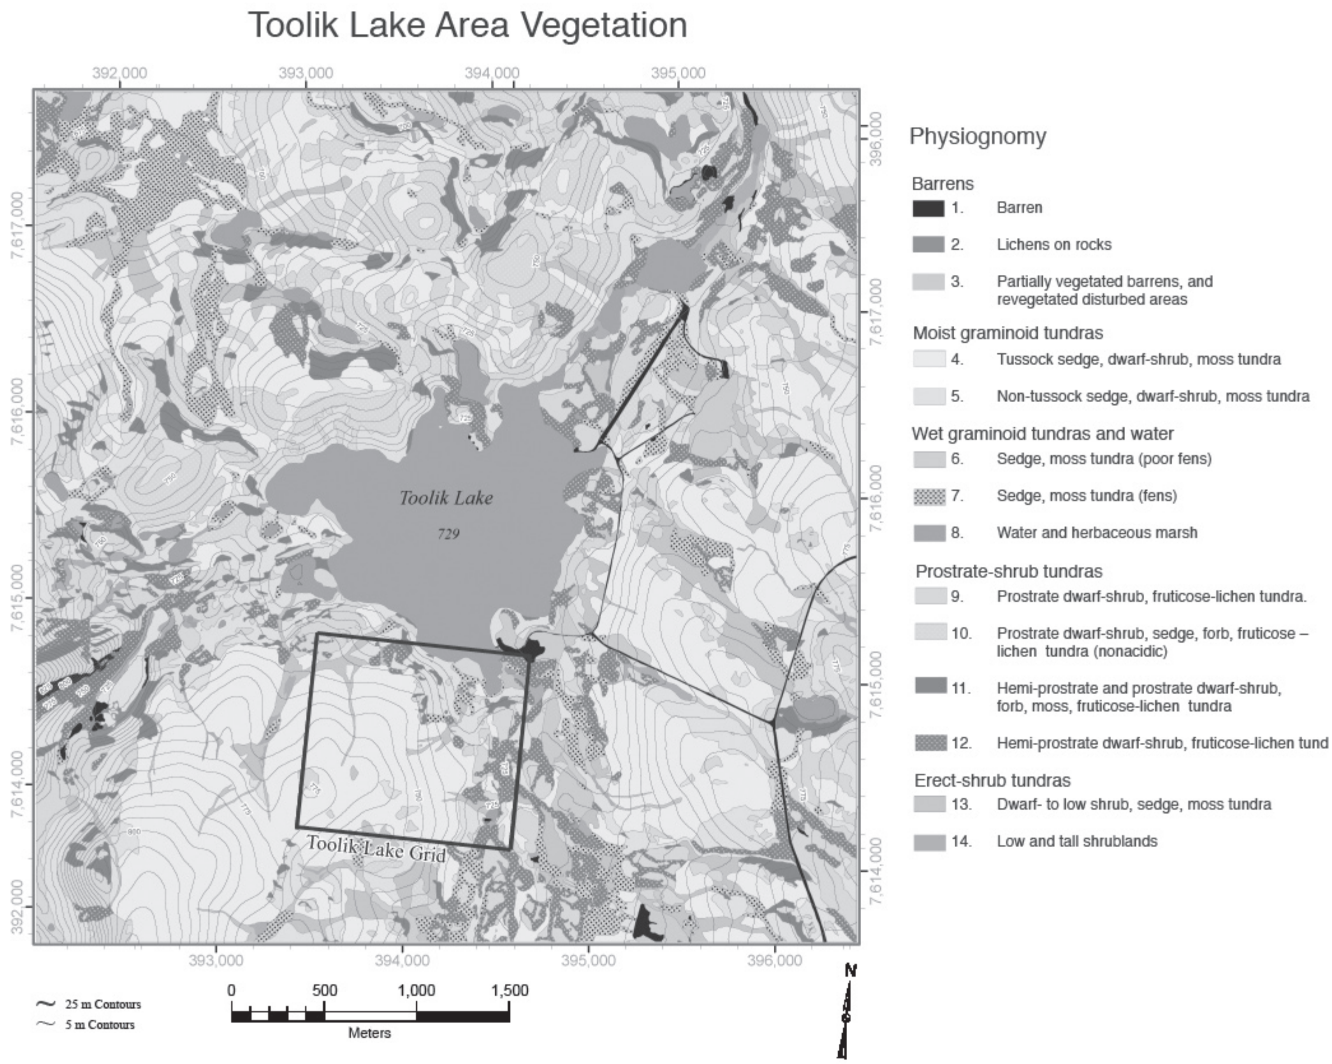

Figure 4. Vegetation map of the Toolik Lake region. The black rectangle delineates the boundary of the Toolik Lake Grid (Fig. 5). A color version can be found at http://www.arcticatlas.org/.

Maps of the Toolik Lake area and grid

The reverse side of the published map sheet shows more detailed vegetation maps of the 20 km^2 area centered on Toolik Lake (Fig. 4) and a 1.2 km^2 intensive research grid on the south side of Toolik Lake (Fig. 5). The Toolik Lake map includes terrain that stretches from the Dalton Highway on the east side of Toolik Lake to Jade Mountain on the west. It includes the Toolik Lake Field Station, the old pipeline construction camp pad and airstrip on the northeast side of the lake, and the primary terrestrial research areas on the south, west, and east side of the lake, as well as several smaller research lakes in the immediate vicinity of Toolik Lake. The area contains surfaces that were glaciated during the Late Pleistocene during the Itillik I and Itillik II glaciations.

The vegetation legend for the Toolik Lake area (Fig. 4) is essentially the same as for the map of the Upper Kuparuk River region but the map shows more detail corresponding to the variations in terrain. Fifty-one landcover and vegetation types were recognized in the field and later grouped into the 14 physiognomic units on the map. The units portray the physiogonomy (dominant plant growth forms) of the major plant communities in each mapped polygon.

The map of the Toolik Lake Grid (Fig. 5) focuses on the 1.1 km^2 research grid on the south side of Toolik Lake. This area is one of the principal intensive research areas at the Toolik Lake Field Station. It includes many experimental research sites where long-term measurements are being made, such as snow-fence study sites and greenhouse experimental sites. The grid was constructed in 1989 to provide geographic referencing for the experimental plots and to provide a sampling scheme for periodic measurements of snow, active layer, and the plant communities.

Sixty-five plant communities were recognized in the field and were then grouped into the 25 units appearing on the map. The vegetation units are primarily at the plant-community level (compared to the physiogonomic level for the maps of the Upper Kuparuk River Region and the Toolik Lake region).

Details of the methods for both maps, including sources for aerial photos, orthophoto topographic map, and the other geobotanical variables that were mapped are in the Arctic Geobotanical Atlas http://www.arcticatlas.org/.

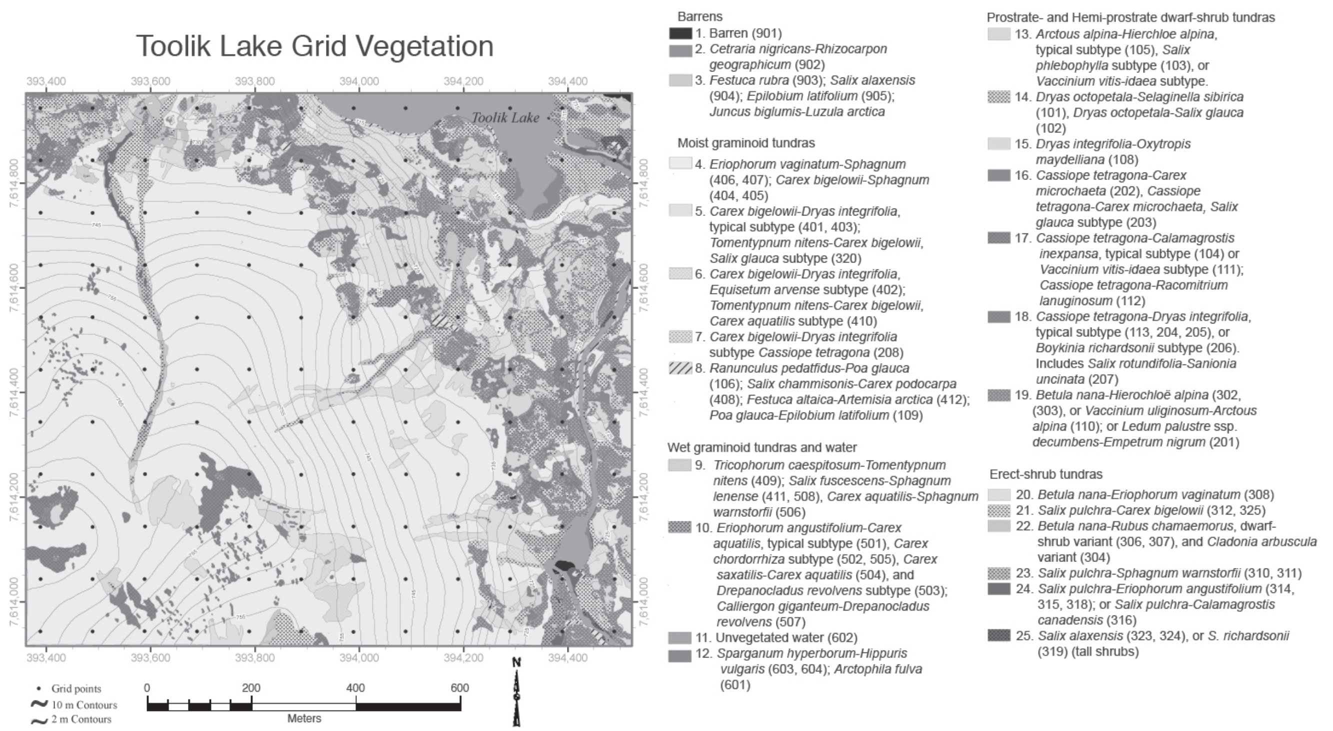

Figure 5. Vegetation map of the Toolik Lake grid. The grid points are spaced at 100-m intervals. A color version can be found at http://www.arcticatlas.org/. The grid is also a component of the Circumpolar Active Layer Monitoring (CALM) program (Brown et al. 2000).

Conclusion

The maps presented here lend themselves well to permafrost-related studies because of the long history of permafrost and active-layer studies in the Toolik Lake region (e.g., Osterkamp 2003, Raynolds et al. 2008 in press, Romanovsky et al. 2008, Walker et al. 2003, 2008 in press) and the clear need to conduct such studies in areas with detailed maps of vegetation, topography, and other terrain information at a variety of scales. Maps at similar scales to those presented here have been extensively for active layer studies and modeling in northern Alaska (Nelson et al. 1997, 1998, Hinzman et al. 1998). The hierarchic nature of the map legends allows results of plot-level studies conducted at Toolik Lake to be extrapolated to much broader regions up to and including the circumpolar tundra region.

Acknowledgments

The maps and website were developed at the Alaska Geobotany Center in the Institute of Arctic Biology and in collaboration with other groups at the University of Alaska Fairbanks, including: Water and Environmental Research Center, Geographic Information Network of Alaska, and Toolik Lake Field Station. Many people have helped in the production of the AGA including Nancy Auerbach, Andrew Balser, Jason Grimes, Tom Heinrichs, Julie Knudson, Leanne Lestak, Corinne Munger, Martha Raynolds, Lael Rogan, Dan Stahlke, and Scott Vockeroth. Funding for the mapping and the AGA came from the Toolik Lake LTER project, the DOE R4D program, and NSF Grants ARC-0425517, ARC-0225517, and ARC-0531180.

Lake Modification in a Permafrost Region, the Colville River Delta, Alaska

H. Jesse Walker
Louisiana State University, Baton Rouge, USA

Abstract

The Colville River Delta, like most deltas of the world, contains a variety of lakes. They range in size from small ponds (less than 0.0125 km^2 in area) that occupy low-centered ice-wedge polygons to large lakes (five of which are larger than 2.0 km^2) that occupy abandoned river channels. As the delta's distributaries migrate, they not only destroy ice wedges and the polygons the ice wedges helped create, but also tap lakes causing them to drain. After tapping, lakes become sedimentary traps and subject to rapid fill. Not all tapping is the result of the river, because the lakes themselves (especially the larger ones) tend to expand with time due to the physical and thermal erosion of their banks. Lake expansion into an ice-wedge polygonal field results in the melting of adjacent ice wedges, the production of an inverted relief and a serrated lake border.

Keywords: delta; erosion; flooding; ice wedge; lakes; permafrost

Introduction

The North Slope of Alaska extends from the crest of the Brooks Range northward to the Arctic Ocean. It is a part of the area dominated by continuous permafrost and has a surface much of which is covered with lakes and ice-wedge polygons. It drains into the Arctic Ocean via a number of rivers, the longest of which is the Colville River (Fig. 1). At its mouth the Colville has constructed a delta that is about 600 km^2 in area (Fig. 2). The delta supports a variety of forms many of which are similar to their counterparts in more temperate regions. However, most of these deltaic forms are impacted by snow, ice, and permafrost in addition to the typical processes, such as those caused by wind and river flow, dominating elsewhere.

The Delta's Lakes

Unlike on the general tundra surface of the North Slope where oriented lakes are common, the delta has a highly varied lake system. The delta's lakes range in size from small ponds to those that are more than 2 km^2 in area (Fig. 3) and in shape from circular and rectangular to sinuous and elongated. They vary in depth from a few centimeters to more than 10 m. Those that are deeper than 2 m usually do not freeze to the bottom during winter and have a permafrost-free zone (talik) beneath them. The delta's lakes vary in age from newly formed to some that have lasted hundreds of years, and they also vary in genesis from those formed in association with ice-wedge polygons and sand dunes to those resulting from river channel migration.

Basically all of the delta's lakes are ephemeral because of the continuous migration of the delta's distributaries which not only aids in the creation of lakes but inevitably leads to their destruction.

The types and distribution of lakes within the Colville Delta

The lakes and ponds of the delta exhibit a variety of types including ice-wedge polygons, abandoned channels, terrace flank depressions, and ice-scour holes (Dawson 1975). The most common are those ponds that occupy low-centered polygons. They are present on most surfaces except newly deposited areas such as sandbars and mudflats. Many of the delta's lakes fit into the thaw-lake category in that they

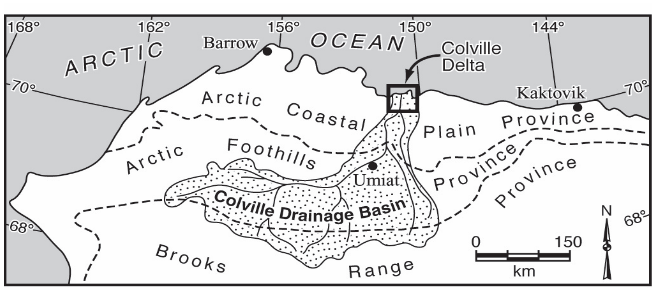

Figure 1. Regional map of the North Slope, Alaska, showing the Colville River Basin and Delta.

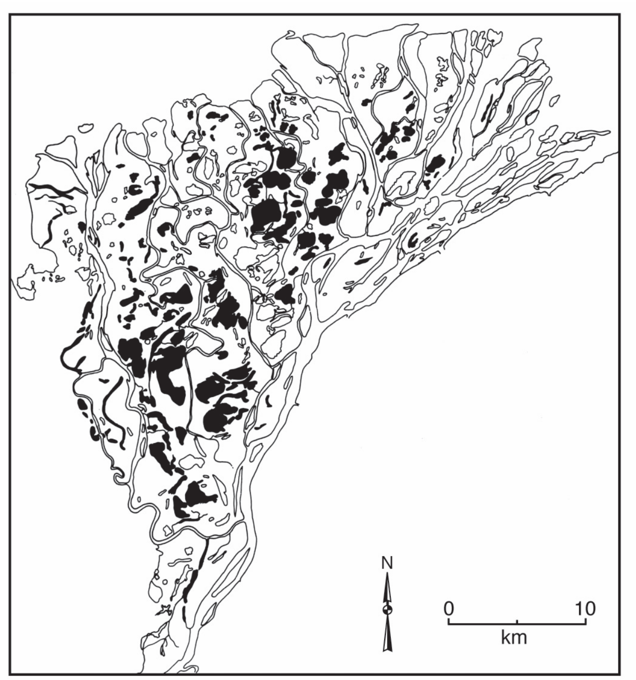

Figure 2. The Colville River Delta showing lake distribution Those lakes subject to flooding are in black.

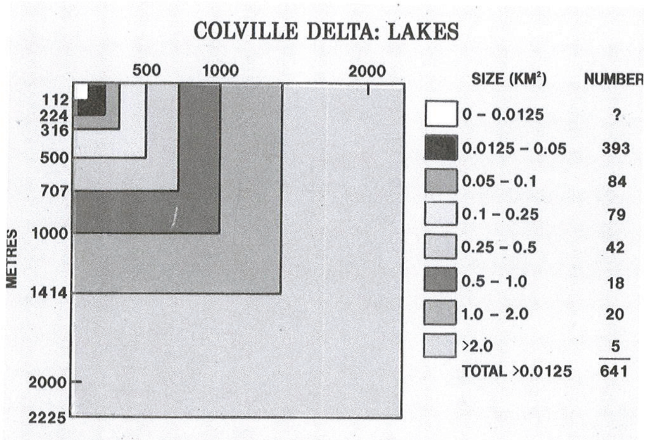

Figure 3. The numbers and sizes of lakes in the Colville River Delta.

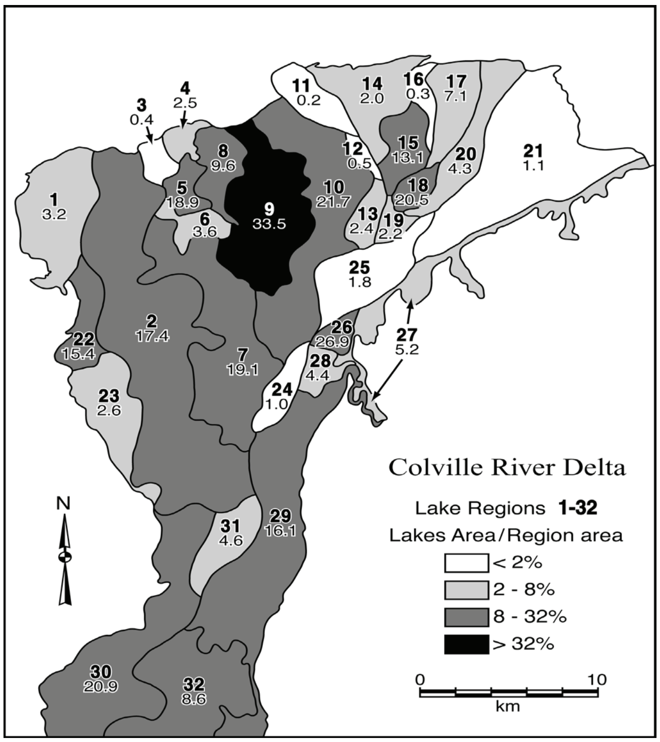

Figure 4. A regional map of the Delta's lakes with percentage of surface area occupied by lakes with areas more than 0.0125 km^2.

exhibit subsidence following the thawing of permafrost (Hopkins 1949, Jorgenson & Shur 2007).

Although the most distinctive characteristic of the delta is often considered to be its lakes, there is great variation in their occurrence within the delta (Fig. 4). The area with the most lake coverage is a north-south band through that part of the delta impacted by meandering distributaries, whereas the least coverage is especially in the northeast part of the delta which is characterized by braided drainage.

Perched Ponds and the Active Layer

One of the characteristics of permafrost is that it prohibits percolation and thus, under the right conditions, can serve as an aquiclude. The Colville River Delta with its varied relief provides a number of situations where perching can occur. The best examples are found within sand dune complexes throughout much of the delta. However, in a sense, the ponds present in low-centered polygons (especially those near a river channel) are perched in that they are perennial lakes with a surface level lying at an elevation above what would be the normal level of the water table in a permafrost-free environment.

Within the Colville Delta, local relief is more varied within sand dune complexes than elsewhere. Further, the delta is an ideal location for the formation of dunes because of the extensive sandbars that form along its channels. This is especially true of the main channel on the east side of the delta. Because the prevailing wind is from the northeast, dunes are best developed in left-bank locations. Dunes nearest the river channel tend to be active, whereas those away from the bank are usually stable and are covered with vegetation. Stabilized dunes, over time, become rounded and smooth, a type of relief that does not favor pond formation. Active dunes on the other hand have a varied relief that often provides ideal conditions for pond formation.

The dunal systems of the delta provide two types of perching: inter-dune and intra-dune ponds. Inter-dune ponds form between dune ridges, whereas intra-dune ponds form within dune ridges. During several field seasons in the 1960s and 1970s, detailed studies of inter-dune ponds were made (Walker & Harris 1976).

The pond selected for repetitive measurements (including active layer thickness and water stage and temperature) is near a field camp on Putu Channel, 3 km north of the head of the delta (Fig. 5). Putu Pond, as we named it, lies in an elliptical basin that is about 96 m long and 31 m wide (Fig. 6, 7). The pond at its maximum extent, which occurs during the snowmelt period, has an area of about 300 m^2 and a depth of 1.3 m. The lowest edge of the basin is about 6 m above the mudflat of Putu Channel, an ideal perching situation. The vegetation in the basin includes a variety of aquatic plants, moss, grasses, flowering plants, and willows that are up to 2 m tall. However, the steep sides of the dune are vegetation free and composed of coarse-textured sand.

During most of the year the area is blanketed with snow, which in the basin itself is several meters thick. The lake freezes to the bottom, and the active layer is frozen for some 7 to 8 months. Although wind, even during winter, removes snow from the crest of the dune, the snow in the basin remains intact until snowmelt begins. The rate of snowmelt varies; snow in the willows lasts much longer than it does elsewhere in the basin. Measurements indicated that active layer thaw began almost immediately after snowmelt exposed the surface. The actual deepening of the active layer varied mainly because of the nature of the vegetation cover (Fig. 8).

Once the active layer begins to thaw, percolation occurs through the coarse sand that makes up the riverbank. Thus during the short summer period, the lake not only lost water to evaporation but also to percolation. However, the lake was sufficiently deep so that it has never dried up.

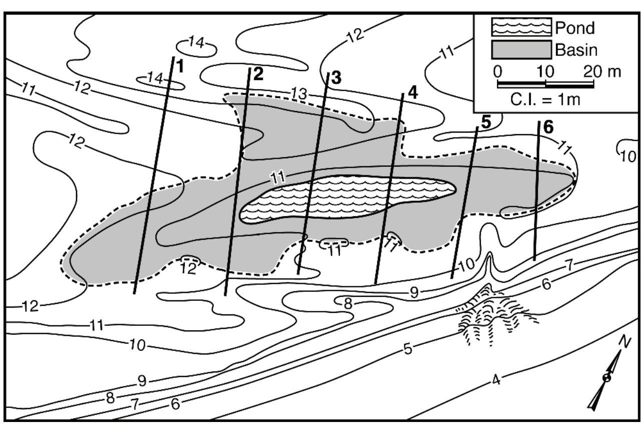

Figure 7. Map showing characteristics of Lake Putu. Lines 1 – 6 are basin transects.

Although perched ponds are less common in stabilized dunes than in active dunes, a few can be found in the delta (Fig. 9). It is not known what initiated the pond illustrated in Figure 9; however, some such ponds begin as blowouts, possibly when ground squirrel dens have been enlarged by bears. Once initiated, thermal degradation increases the pond's depth due to subsidence.

Ice Wedges and Lake Expansion

Many of the lakes in the Colville Delta are bordered by ice-wedge polygons which are subject to erosion by wind-generated waves, ice scour, and temperature-induced thaw. These processes are much less active than those accompanying a flooding river so that lake-bank retreat, even in the larger lakes, is relatively small. Another difference is that the eroded or thawed materials from a lake's shoreline remain in the lake. In Figure 10, the importance of wind-wave erosion is demonstrated by the repetitive saw-like form of the irregular shoreline. The predominating northeast wind causes wave action, which thermally erodes the ice-wedge polygons along the shoreline. The resulting form contrasts with that of the relatively smooth channel shoreline (Fig. 10).

Many of the low-center polygons that surround lake basins have water levels that are lower than lake levels. When the ice wedges facing the lakes melt and the ridges around the polygons collapse, lake water invades creating an inverted relief with a highly irregular bench around the lake margin (Fig. 11).

Expansion of lakes by physical and thermal erosion frequently results in the elimination of barriers between adjacent lakes so that they join. The resulting combination often produces a lake that has an irregular shape.

Lake Tapping

One of the most distinctive changes in delta morphology occurs because of the tapping or breaching of lakes by migrating river channels. An examination of the delta's shorelines in 1971 (Ritchie & Walker 1974) showed that 59% are erosional, 35% are depositional, and 6% are neutral. Rates of retreat vary from an average of a fraction of a meter to two or more meters per year (Walker et al. 1987). In the process not only are the materials of which the banks are composed removed, but any ponds or lakes that the banks previously protected are breached. If the river banks are high and the lakes (usually ice-wedge polygons) are perched at the top above floodwater level, bank erosion, especially via ice wedges, causes the ponds to drain (Fig. 12). Often within peat banks, ice-wedge melting progresses inward from the bank, draining additional ponds (see McGraw, this Proceedings).

Once tapping occurs, lake drainage follows and the former lake level, if the lake bottom is below the level of the river, subsequently fluctuates with river stage. It then serves as a settling basin and begins to fill with the sediment transported into it by the river. The coarsest material is deposited near the lake entrance, and the fines are spread throughout the lake basin. The nature of the deposition is such that the lake basin becomes segmented as it fills. As the river continues to erode lakeward, the entrance channel is enlarged and the near-river deposits begin to be eroded.

Another morphologic/hydrologic change that occurs with lake tapping is the creation of a scour hole at the entrance to the lake. These scour holes as well as lake morphology changes are illustrated in the discussion below of Lake Nanuk (Polar Bear), Lake Tuttut (Caribou), and Lake 35.

Within the delta there are examples of virtually every stage in the life history of tapped lakes from those recently tapped to those nearing complete destruction.

Lake Nanuk and Lake Tuttut

Lake Nanuk (Polar Bear Lake) and Lake Tuttut (Caribou Lake) were two of the delta's largest lakes until they were tapped by migrating river channels (Roselle 1988). Lake Nanuk faced the Nechelik Channel whereas Lake Tuttut, which is just east of Lake Nanuk, faced Sakoonang Channel. It is not known just when Lake Nanuk was tapped, but it was probably in the late 1930s or 1940s based on the width of the entrance channel and the smallness of the lake delta displayed on 1948 photographs. In contrast, however, Lake Tuttut was tapped in 1971 at the time a field crew was working in the delta (Fig. 13).

Subsequent to tapping, two major events occurred: the lakes began to fill with sediment and the entrances began to enlarge. Because Lake Nanuk faces a channel that carries (at least during flood) some 25% of the delta's discharge it is filling at a much more rapid rate than Lake Tuttut whose facing channel only carries about 2% (Arnborg et al. 1966). Although the low-water stage of Lake Tuttut displays extensive bottom material, most of it is the result of the fact that it was sufficiently shallow to begin with so that once drainage occurred bottom materials became exposed.

In 1962, depth measurements were made by boat in Lake Nanuk between its southern- and northern-most points, a condition that today, because of this shallow depth, would be

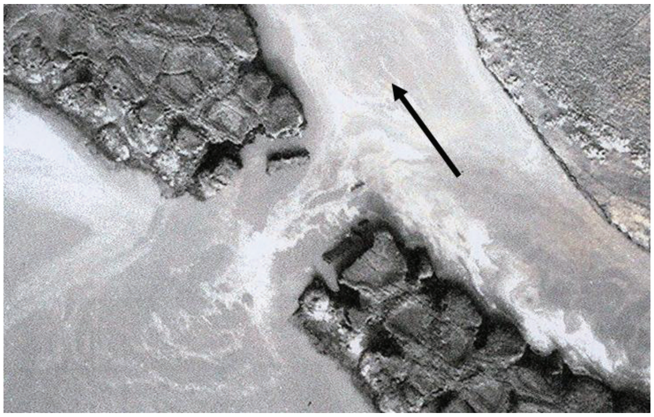

Figure 13. Photograph of Lake Tuttut entrance.

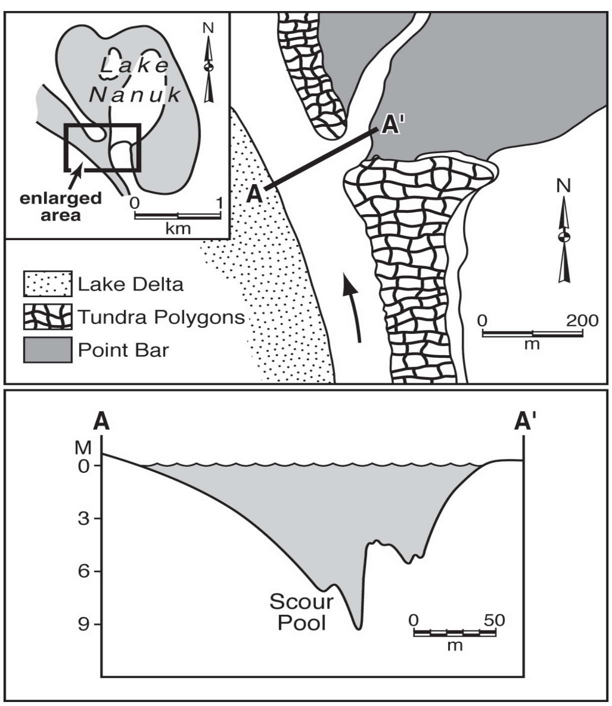

Figure 15. Scour hole at Lake Nanuk's entrance.

impossible (Fig. 14). In addition to showing the amount of fill that has occurred during the past 70 or so years, Figure 14 also shows the evolution of the entrance (also exit) channel with time. Such a long, winding channel is a typical feature of tapped lakes after they begin to fill. The channel in Lake Tuttut shows the same feature.

Upon tapping, lakes, most of which have levels some 2 m above normal river level, drain rapidly enlarging the opening and developing a scour hole at their mouths (Fig. 15).

Lake 35

Lake 35 (the number given the lake in a catalog of lakes made in the 1970s) is located in the northcentral part of the delta (Walker 1978). The changes that have occurred through the tapping of Lake 35 are among the most distinctive changes to have happened in the delta in the last century. The changes include not only the development of a scour hole, the exposure of shallow bottom areas, the creation of a lake delta, and widening of the inlet (outlet), but also the addition of other lakes to the system and the rearrangement of river channel flow. These changes are diagramed in Figure 16. The locations of the changes that are discussed below are indicated by the letters A, B, and C in Figure 16:1.

When the first air photos of the delta were made, Lake 35 and its adjacent lakes were essentially distinct and not impacted by the river, even during flood stage (Fig. 17). The exact dates of the initiation of various events are unknown because their recognition depends on the dates of photo coverage or field observation. Although, in 1949 there was some overflow and percolation along ice wedges between some of the lakes, the first major change was the tapping of Lake 35 a few years before 1970. By 1971 a small delta had formed, and at low water a bench was visible along both the south and north sides of the lake.

By 1981 (Fig 16:2) the adjacent lakes were all connected by irregular water courses through ice-wedge polygons as

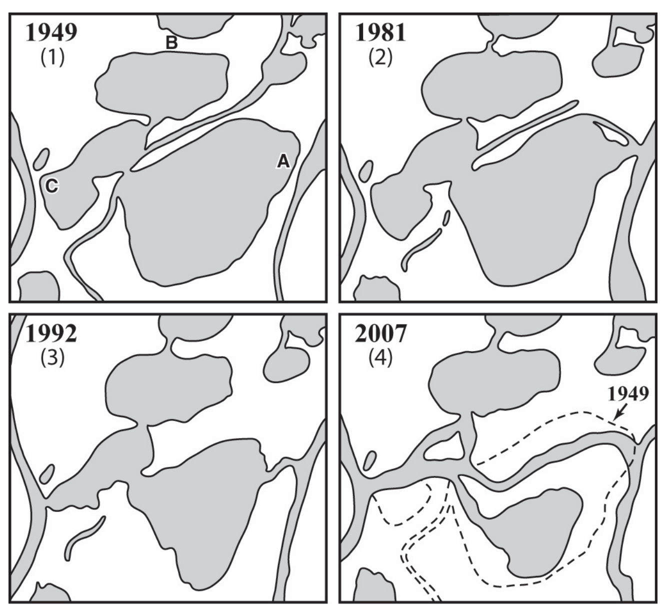

Figure 16. The modification of Lake 35 between 1949 and 2007, explanation in the text.

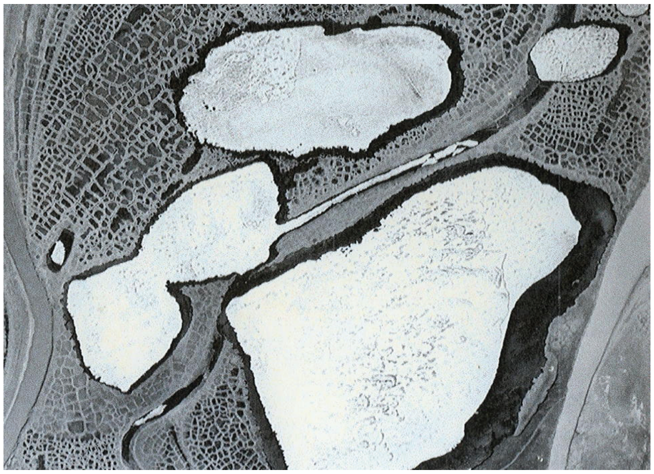

Figure 17. Lake 35 prior to tapping (See Fig. 16:1 A).

exampled at Figure 16:1 B, the lakes were still distinctive, the exposed shore areas around Lake 35 had expanded, and Lake 35's delta had shifted northward.

Eleven years later (Fig. 16:3) tapping had occurred at location C. It appears that, in this case, much of the erosion that caused the rupture was the result of floodwaters flowing through Lake 35 from east to west. Further, by this time, deposition in Lake 35 had reduced the actual water surface to less than half its original size.

The impact of this flow from east to west continued to increase so that by 2007 (Fig. 16:4), Lake 35 had become channelized. Because so much water and sediment was now being carried toward the west, the original distributary that caused the initial tapping some 40 years earlier ceased flowing north at low stage.

Conclusions

Although there are other types of lakes and ponds in the delta, such as those formed as toeheads at channel bifurcation points, the most distinctive relationships between permafrost and ice wedges with lakes are those associated with perching and ice-wedge polygons and with the processes of riverbank and lake bank erosion.

Lake tapping not only alters a lake's morphology, but also, through deposition, creates ideal conditions for former taliks to become frozen and for new sets of ice-wedge polygons to develop.

Acknowledgments

The research for this paper, which is based in part on field work conducted in the Colville River Delta since 1961, was supported by a number of organizations both financially and logistically. Included are: ONR, AINA, the North Slope Borough, the town of Nuiqsut, ARCO, Conoco Phillips, ABR, and Louisiana State University. To all of them, I extend my thanks. The assistance of Molly McGraw, Clifford Duplechin, and Mary Lee Eggart, and the suggestions made by two anonymous reviewers are much appreciated.

Submarginal Glaciotectonic Deformation of Pleistocene Permafrost

Abstract

Recent advances in our understanding of glacier-permafrost interactions provide an alternative hypothesis to interpret Pleistocene glaciotectonic sequences in regions where permafrost no longer exists. Instead of necessarily forming under unfrozen subglacial conditions, some glaciotectonic sequences may have formed by submarginal deformation of warm, partially-frozen permafrost. An example from North Norfolk, U.K., suggests that an ice sheet during Marine Isotope Stage 12 advanced across permafrost terrain, deforming it beneath the margin. Such a scenario can help explain some features whose formation under unfrozen conditions is problematic, including (1) the substantial thickness of the deforming layer and (2) the preservation of stratified intraclasts. Accordingly, glacial geologists should remain open to the possibility of glacier-permafrost interactions when interpreting glacigenic sequences. Such a re-interpretation could have major implications for reconstructing basal thermal regimes and modeling palaeo-ice sheets.

Keywords: basal thermal regime; eastern England; glacier-permafrost interaction; glaciotectonic deformation; Pleistocene permafrost.

Introduction

Whilst the ability of glaciers to deform their substrates has long been recognized (Lamplugh 1911), the glaciological significance of glaciotectonic deformation was not fully appreciated until the late 1970s (e.g., Boulton & Jones 1979). Since then, numerous papers have inferred the process at many Pleistocene localities and demonstrated its widespread occurrence beneath former continental ice masses (e.g., Hart et al. 1990, Clark 1994, Benn & Clapperton 2000). In addition, it is has been invoked to explain states of fast ice flow (e.g., Hart & Smith 1997, Truffer et al. 2000), ice streaming (Alley et al. 1986), high sediment fluxes (Dowdeswell & Siegert 1999), and the creation of distinctive glacial landforms and sediments (Boulton 1987, Benn & Evans 1996).

The majority of this research has assumed that sediment deformation only occurs beneath warm-based ice, when subglacial sediments are unfrozen and water-saturated. This stems from the widespread assumption that basal processes are inactive at subfreezing temperatures (e.g., Paterson 1994) and by inference that cold-based glaciers are slow moving and geomorphologically ineffective (Kleman 1994). Recent research has demonstrated, however, that cold-based glaciers can slide over and deform their beds (Echelmeyer & Zhongziang 1987, Cuffey et al. 1999) and therefore actively erode and deposit (Atkins et al. 2002). This conclusion is supported by work in high-latitude Pleistocene glacial environments where thick sequences of deformed permafrost provide evidence of extensive glacier-permafrost interaction beneath former ice sheets (Mackay et al. 1972, Astakhov et al. 1996, Murton et al. 2004).

Whilst the implications of glacier-permafrost interactions are being explored within glaciology (e.g., Cutler et al. 2000), little attempt has been made to consider their potential implications for interpreting Pleistocene glacigenic sequences. But if we consider deformation under partly-frozen conditions as an alternative hypothesis, it may help to explain features difficult to reconcile with deformation under entirely unfrozen conditions.

We suggest here that submarginal deformation of permafrost can help to explain key aspects of the well-known glaciotectonic sequences of North Norfolk, U.K.

Processes and Products of Subglacial Sediment Deformation

Whilst the importance of subglacial sediment deformation is widely acknowledged by glaciologists and glacial geologists, the identification of an appropriate flow law for subglacial tills remains elusive and controversial. To date, four flow laws have been applied to subglacial sediment rheology: (1) linear viscous, (2) non-linear viscous, (3) non-linear Bingham, and (4) Coulomb-plastic (Kavanaugh and Clarke 2006). Models one to three consider tills as viscous fluids. In model one, the strain rate is linearly related to the shear stress, and the till viscosity is independent of porewater pressure. Models two and three are both non-linear, with porewater pressure determining the till's shear resistance, and the latter incorporating a yield strength determined by the Mohr-Coulomb failure criterion (Boulton & Hindmarsh 1987). Model 4 differs from the first three models in that it treats tills as plastic materials, with no permanent deformation occurring until a yield strength (again based on the Mohr-Coulomb failure criterion) is surpassed, after which they experience infinite strains. The choice of flow law is highly significant, as it represents a key control on the dynamic behavior of glaciers and ice sheets. However, there is currently conflict between the strong evidence for the Coulomb-plastic model derived from studies at modern-day glaciers and the geological evidence for the viscous fluid models, illustrated by contrasting deformation profiles.

Initial research at modern-day glaciers suggested that subglacial tills behaved like viscous fluids, with both field measurements (Boulton & Hindmarsh 1987) and geophysical data (Alley et al. 1986) suggesting that subglacial sediments deformed pervasively in layers several metres thick. Subsequent work, however, has favoured a Coulomb-plastic rheology, with new observations and borehole measurements suggesting that subglacial sediment deformation is restricted to thin shear zones only a few tens of centimetres thick (e.g., Iverson et al. 1995; Engelhardt & Kamb 1998; Fuller & Murray 2002). For example, recent work by Kavanaugh & Clarke (2006) at the Trapridge Glacier, British Columbia, concluded that the Coloumb-plastic model provided the closest match to the field instrument records. The model, in turn, predicted a deformation depth of 0.35 m, in close accordance with the measured depth of ~0.3 m.

Geological evidence has also been widely employed, both to infer the existence of subglacial sediment deformation beneath former ice sheets and to reconstruct the sediment deformation profile. Cited evidence includes a range of structures that belie varying amounts and styles of deformation involving both ductile and brittle failure (see Hart 1995, Boulton et al. 2001, & Evans et al. 2006 for lengthier reviews). At low strains, folds are commonly developed where compression occurs on the up-glacier flank of an obstacle. As shear strains increase, the folds are progressively attenuated and boudinaged, which can generate a tectonically-laminated deposit, which in turn can later be re-folded. The shearing can affect pre-glacial materials to generate glacitectonites (Banham 1977). Ultimately, high strain deformation can homogenize sediments and form so-called deformation tills (Benn & Evans 1996); in this case, clast fabrics (van der Meer 1993, Hart 1994) and micro-scale structures provide the only evidence of the sediment's strain history, although the ability of the former to infer strain history remains controversial (Benn 2007).

Geological evidence has frequently been used to infer pervasive deformation within a deforming layer several metres thick (e.g., Hart et al. 1990, Alley 1991), supporting a viscous fluid model of till rheology. But such a conclusion is increasingly difficult to reconcile with the results of field-based investigations at modern-day glaciers. Whilst this paradox has been used to argue that subglacial deformation is less extensive or deep-seated than originally thought (e.g., Piotrowski et al. 2001), this paper considers an alternative hypothesis, that the geological evidence may instead indicate subglacial deformation under contrasting thermal conditions.

Glaciotectonic Deformation of Permafrost

The deforming-bed model was originally limited to the situation where warm-based glaciers overlie thawed beds (see Alley 1991). Consequently, ice-sheet models commonly include the boundary condition that basal velocities are zero where the temperature of the basal ice falls below the pressure melting point (e.g., Payne 1995). There is growing evidence, however, that this assumption is not universally applicable. Echelmeyer & Zhongxiang (1987), for example, found that over 60% of the surface motion of the cold-based Urumqi No. 1 Glacier in China was accommodated via the deformation of ice-rich subglacial sediment with an effective viscosity two-orders of magnitude lower than the overlying ice. This demonstrates the ability of glaciers to couple with subglacial permafrost.

Permafrost that has never thawed since it was overridden and deformed by Pleistocene ice sheets provides an important touchstone for interpreting glaciotectonic sequences in regions where permafrost no longer exists. Previous work has highlighted evidence for glacier-ice thrusting near the northwest limit of the Laurentide ice sheet in western Arctic Canada (Mathews & Mackay 1960, Mackay et al. 1972), and for a deformable bed of permafrost beneath the southern Kara ice sheet in western Siberia (Astakhov et al. 1996). More recently, we have detailed the stratigraphy and glaciotectonic structures of permafrost in the Tuktoyaktuk Coastlands of western Arctic Canada (Murton et al. 2004). Several important observations arise from these studies.

First, the thickness of glaciotectonically-deformed permafrost is substantial. Astakhov et al. (1996) reported thicknesses of tens of metres from the western Yamal Peninsula and the lower Yenissei region, and Murton et al. (2004) reported thickness of at least 5–20 m from the Tuktoyaktuk Coastlands (Fig. 1a, 1b). Second, ductile deformation of warm, ice-rich materials is inferred from recumbent and S-shaped folds, sand lenses and layers (Fig. 1c), whereas there is less evidence for brittle failure in the form of pinch-and-swell structures and ice-filled tension gashes. Third, submarginal erosion of permafrost is indicated by (1) incorporation of rafts of massive ice (Fig. 1d) and smaller ice clasts into frozen glacitectonite (Fig. 1b), and (2) angular unconformities (décollement surfaces) beneath the glacitectonite (Fig. 1a). Adjacent layers of frozen silt, clay, and sand have deformed around some ice clasts, giving the latter the misleading appearance of 'dropstone-like' structures. Overall, the permafrost was probably warm, ice-rich, and contained limited amounts of liquid water – a type of easily deformable permafrost termed 'plastic frozen ground' (Tsytovich 1975).

A Reconsideration of the Glaciotectonic Sequences of North Norfolk

The coastal cliffs of northeast Norfolk exhibit a complex sequence of glacial sediments (e.g., Lee et al. 2004). Banham (1968, 1977, 1988) recognized evidence for glaciotectonic processes, a conclusion supported by Hart & Boulton (1991), Hart & Roberts (1994), and, in part, by Lunkka (1994); the latter author also recognized evidence for subaqueous processes. Lunkka's conclusions, and those of Roberts and Hart (2005), probably reflect the influence of Eyles et al. (1989), who interpreted the whole sediment pile in glaciomarine terms. Eyles et al.'s interpretation, however, has received little support, and Roberts and Hart (2005) have re-affirmed their view that the 'Laminated Diamict' at West Runton is

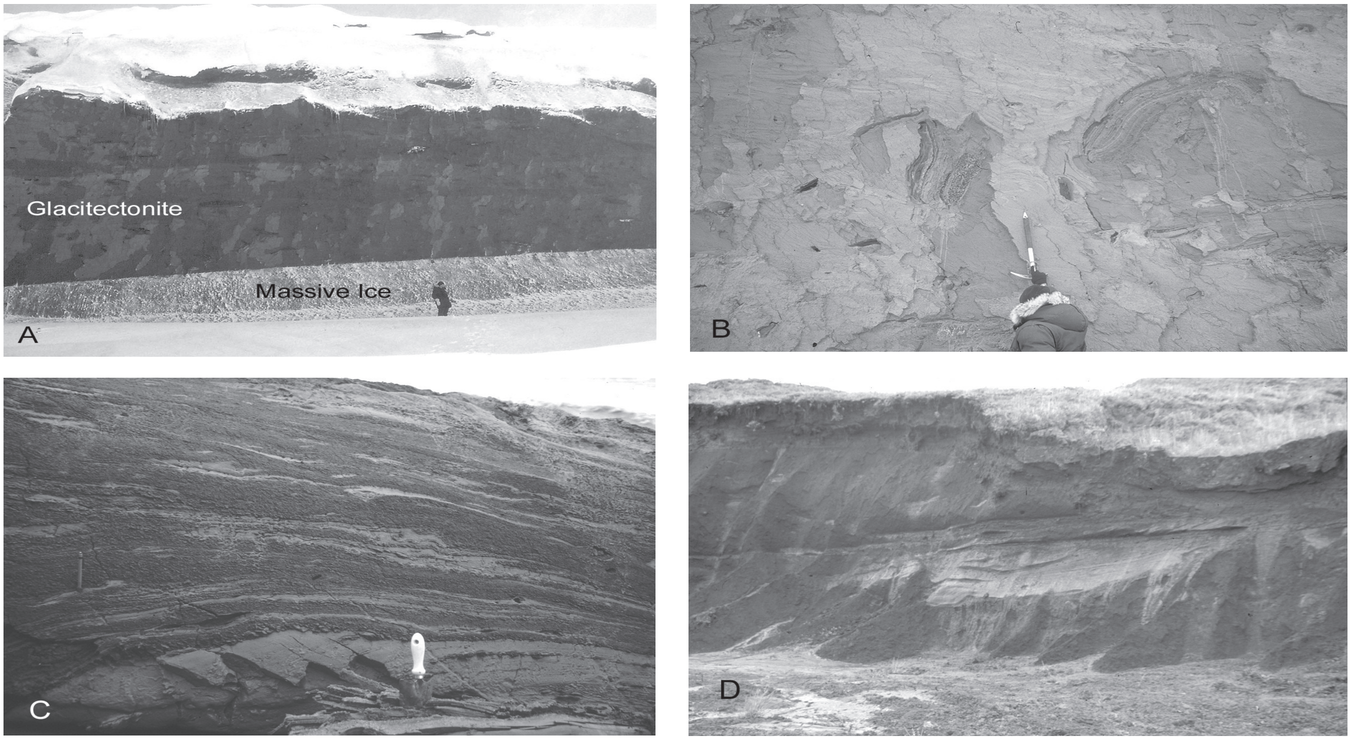

Figure 1. Glaciotectonically-deformed permafrost in the Canadian Arctic: (A) frozen glacitectonite above massive ice at Pullen Island - note intervening angular unconformity (69º46′25″N, 134º24′18″W, figure for scale), (B) close-up of chaotically-orientated and deformed sand lenses and ice clasts at Pullen Island (figure for scale), (C) sand lenses and fold noses between silty clay at North Head (69º43′22″N, 134º26′08″W), (D) raft of massive ice (~14 m long) within frozen glacitectonite at Liverpool Bay (69º50′10″N, 129º20′12″W).

essentially a subglacially-deformed sediment package, although the primary depositional process of some of the sediment may have been subaqueous. They recognize two types of stratified diamict, Type 1 and Type 2. While both types of laminae are said to be the product of "primary extensional glaciotectonism, with ductile, intergranular pervasive shear and brittle shear, … the lateral continuity of Type 2 laminae and the presence of dropstone-like structures supports a primary subaqueous origin with secondary subglacial deformation" (p. 123). Preservation of Type 2 laminae is attributed to "low strain at the lower interface of the deforming bed" (p. 138). In an earlier iteration of this material (Roberts and Hart in Lewis et al. 2000), these authors noted that the presence of ice wedge pseudomorphs implied subaerial permafrost conditions during the onset of glaciation.

Remarkably, none of the work mentioned above has paid significant attention to the existence of pre-glacial permafrost. Wedge-shaped structures do occur at several horizons in the pre-glacial sediments (West 1980), but many are small and isolated, and both Worsley (1996) and Preece (2000) have questioned their permafrost origin. They could be hydrofractures, water-escape structures or soft-sediment deformations. Nevertheless, the largest wedge-shaped structures in these sediments possess convincing ice wedge-pseudomorph characteristics associated with permafrost (Whiteman 2002). They extend downwards from the upper surface of the pre-glacial sediments and have been correlated to the widespread, Anglian periglacial soil-stratigraphic-unit known as the Barham Soil (Rose et al. 1985). There can be no doubt that cold permafrost subject to thermal contraction cracking was an integral component of the Norfolk landscape prior to glaciation. Less certain are the thickness, ice content, and temperature of the permafrost.

We suggest that submarginal deformation occurring under partially-frozen conditions at temperatures close to, but slightly below, the pressure melting point ("warm permafrost") represents an alternative hypothesis for interpreting the glaciotectonic sequences of North Norfolk. This hypothesis may elucidate some features that are hard to explain if the substrate was entirely unfrozen:

First, the prevailing model of an unfrozen deforming layer ≤15 m thick (Hart et al. 1990) appears increasingly at odds with observations from modern glaciers that suggest that even under thick ice, deformation is restricted to layers a few tens of cm thick or at most, 1–2 m thick (Engelhardt & Kamb 1998). Whilst the incremental stacking of thin, deforming layers at the ice margin might create a thick sequence of deformed sediments (e.g., Evans & Hiemstra 2005, Benediktsson et al. in press), this cannot account for the size and coherence of the structural features observed at West Runton, for example. In contrast, the presence of a thick and pervasively-deformed sequence (Fig. 2a) is entirely consistent with deformation at subfreezing conditions, as documented by the authors in the western Canadian Arctic (Murton et al. 2004) and by Astakhov et al. (1996) in Western Siberia.

Second, the streamlined sand lenses at West Runton (Fig. 2b, c, e, g, Hart et al. 1990, Lunkka 1994) are difficult to reconcile with high-strain deformation under unfrozen

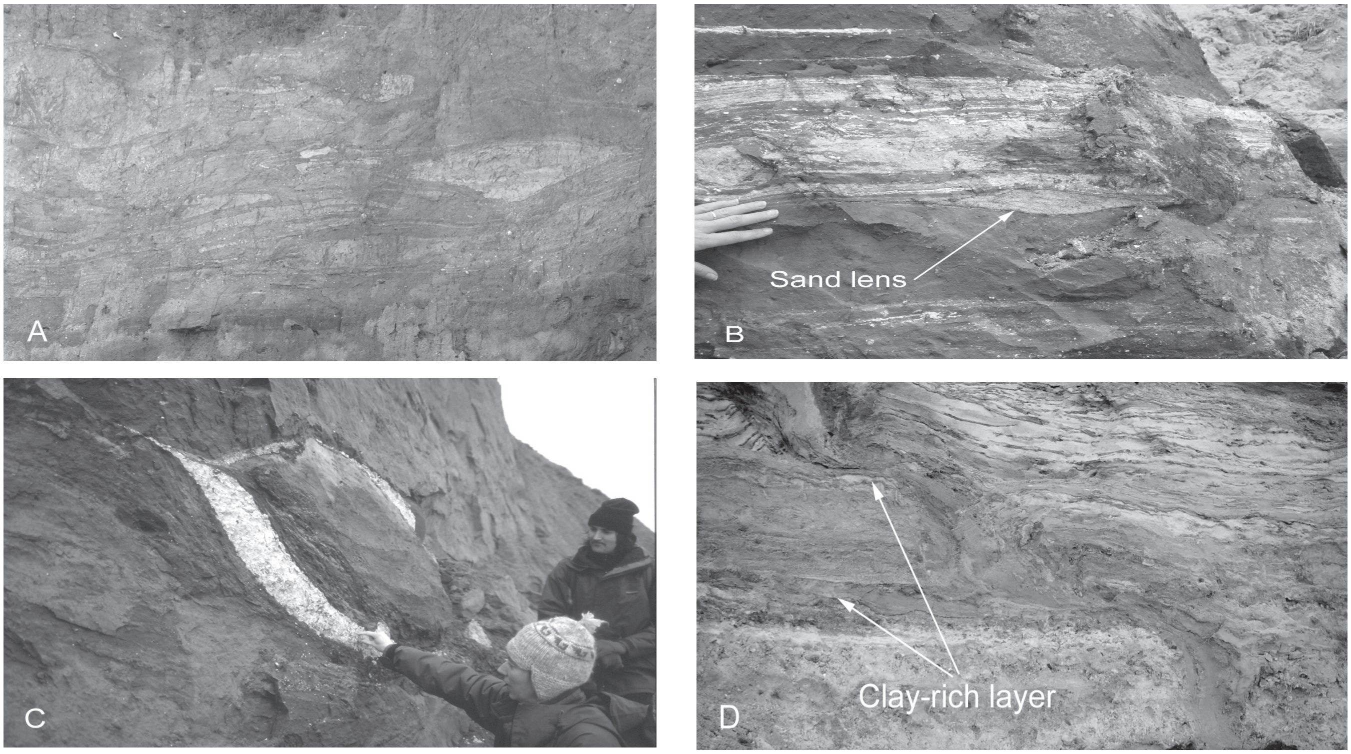

Figure 2. Glaciotectonic features in Northern Norfolk: (A) streamlined lenses, pods and folds at Weybourne (52º56′25″N, 1º08′42″E, area depicted ~10 m across), (B) stratified and streamlined sand lens at West Runton (52º56′25″N, 1º15′21″E, hand for scale), (C) streamlined sand lens surrounded by chalk, West Runton (figures for scale), (D) sheared ice wedge pseudomorph, West Runton (area depicted ~0.8 m across).

conditions. If the fine-grained till surrounding the sand lenses experienced high porewater pressures, then the lenses could not have been well drained and therefore able to act as more resistant masses. Also, it is difficult to envisage how they could have remained intact as they lacked any cohesion (see also Piotrowski et al. 2001). In contrast, the survival of recognizable intraclasts within an actively deforming till, and the associated rheological heterogeneity, are easy to explain if deformation takes place at temperatures below, but close to, the pressure melting point. The presence and quantity of liquid water, and therefore the mechanical properties of frozen ground at these relatively warm temperatures, are strongly grain-size dependent (Williams & Smith 1989). Consequently, if such a sequence was overridden by ice, deformation would occur preferentially within the fine-grained till matrix (which contains liquid water), whilst the sand intraclasts should remain frozen and largely intact. This prediction is consistent with field observations of subglacially-deformed permafrost in the western Canadian Arctic, showing streamlined and occasionally boudinaged sand lenses within a pervasively deformed till matrix (Murton et al. 2004, Fig. 2c). Menzies (1990) has similarly argued that undeformed, sand intraclasts within a deformation till in Ontario, Canada must have been frozen when deformation took place, producing a "block-in-matrix" mélange.

Observation of a sheared ice wedge pseudomorph at West Runton provides additional evidence for a grain-size-related variation in rheology. The pseudomorph has been displaced by several centimeters where it transects clay-rich layers, whilst those parts situated within sand-rich layers have not been substantially deformed (Fig. 2d). This is consistent with the findings of Astakhov et al. (1996), who found deformation within permafrost sequences to be restricted to ice-rich or clay-rich layers.

Finally, the deformed permafrost hypothesis is consistent with the pre-glacial history of the region. There is extensive evidence that the area was characterized by permafrost conditions immediately prior to glaciation. Therefore, the ice would have initially advanced over frozen ground, probably warming it from cold to warm permafrost. Cutler et al. (2000) have modeled interactions between the Green Bay lobe of the southern Laurentide Ice Sheet and pre-existing permafrost and concluded that glacier-permafrost interactions would have persisted for 80–200 km up-glacier of the margin, and could have remained intact for up to a few thousand years beneath the advancing ice.

Discussion

With recent research suggesting that subglacial permafrost has been more widespread than previously thought (Cutler et al. 2000) and that glaciers can couple with ice-rich materials (Astakhov et al. 1996, Bennett et al. 2004, Murton et al. 2004), it seems highly likely that there should be evidence of this process within the geological record.

At present, the alternative hypothesis advocated in this paper remains speculative. Whilst there is clear evidence for deformation under subfreezing conditions in high-latitude regions where permafrost has remained intact, we currently lack any sedimentological criteria with which to recognize glacier-permafrost interactions in areas where the permafrost has subsequently thawed. More detailed investigation of the origin and significance of undeformed intraclasts within pervasively deformed sequences might provide a useful starting point as a research avenue amenable both to field and laboratory testing.

If such criteria, capable of distinguishing between deformation under unfrozen and partly-frozen conditions can be developed, then the potential applications are highly significant. They could enable the basal boundary conditions of past ice sheets to be reconstructed on the basis of geological evidence, thereby providing an opportunity to independently test the predictions both of numerical ice-sheet models and geomorphological inverse models.

Conclusions

Recent research indicates that subglacial sediment deformation and erosion can remain active at subfreezing temperatures, allowing some glaciers to couple with and deform permafrost beneath their margins. Submarginal deformation of past permafrost may explain some problematic features of the glaciotectonic sequences in North Norfolk, previously attributed to deformation of an unfrozen substrate. Deformation under subfreezing conditions should be considered as an alternative hypothesis elsewhere, particularly in ice-marginal settings where pre-glacial permafrost is known to have occurred. It is hoped that further research on the products of glacier-permafrost interactions will help to identify geological criteria for distinguishing between deformation of permafrost and that of unfrozen materials.

Simulations of Present Arctic Climate and Future Regional Projections

John E. Walsh
International Arctic Research Center, University of Alaska Fairbanks

Abstract

Projections of changes in permafrost require credible projections of the atmosphere that overlies terrestrial regions containing permafrost. The critical atmospheric variables for permafrost are surface air temperature and precipitation, especially snowfall. In this study, global climate models used in the Intergovernmental Panel on Climate Change (IPCC) Fourth Assessment Report are ranked on the basis of their simulations of regional Arctic temperature, precipitation and sea level pressure. When evaluated by the root-mean-square error relative to an atmospheric reanalysis, the models that perform best over the pan-Arctic and broader Northern Hemisphere domains are generally found to have the smallest errors over permafrost areas (e.g., Alaska). However, even the highest ranking model has some areas in which its simulations are problematic. The changes of temperature and precipitation projected by the highest ranking models are generally larger than the changes projected by the other models used by the IPCC.

Keywords: Arctic; climate; climate models; permafrost; temperature.

Introduction

Global climate models are the most widely used tools for projections of climate change over the timescale of a century. The periodic assessments by the Intergovernmental Panel on Climate Change (IPCC) have relied heavily on global model simulations of future climate driven by scenarios of increasing greenhouse gas concentrations. The global model simulations show a polar amplification of the greenhouse-driven warming and of other variations in climate (Serreze & Francis 2006, Wang et al. 2007), although the ratio of the models' projected changes to the natural variability is not necessarily greater in the Arctic than in lower latitudes (Kattsov & Sporyshev 2006).

Given the likelihood that the Arctic will experience greater climate changes than most other regions over the next century, the credibility of the model simulations of Arctic climate becomes a key issue when, for example, atmospheric simulations are used to drive projections of changes in permafrost. The absence of databases for validation of future climate simulations increases the importance of evaluations of models' ability to simulate recent climate, for which syntheses of observational data are available.

Greenhouse-driven climate change largely represents a sensitivity to forcing, i.e., the radiative forcing associated with carbon dioxide, methane, water vapor and other radiatively active gases, as well as associated changes in cloudiness. Hence the models' sensitivity to forcing is an essential consideration in assessing the credibility of climate projections. While changes in the radiative forcing associated with increasing greenhouse gases have thus far been relatively small (only a few Watts per square meter, IPCC 2007), a far more potent change in forcing occurs each year through the seasonal cycle of solar radiation. In the present paper, we place the models' ability to capture the *seasonal cycle* of present-day climate at the core of a strategy for evaluating the models' simulation of Arctic climate. Our evaluation is motivated by regional applications of the climate model output in the Arctic, specifically in the regions such as Alaska and Greenland where permafrost may be vulnerable to a warming climate. These regions have surface states that can be fundamentally altered by relatively small climate changes of temperature and precipitation, especially during the cold season when precipitation determines the depth and density of the snowpack that insulates the soil.

Models and Methodology

Our evaluation is based on the 20th-century simulations by the fifteen of the models used in the Fourth Assessment Report (AR4) of the Intergovernmental Panel on Climate Change (IPCC. 2007). For those models with ensembles of 20th-century simulations, only one (the first archived) simulation is used. Also, output from about seven additional models that were added to the IPCC archive after this study began is not included here. The output used here consists of the monthly grids of surface air temperature and precipitation for 1958–2000, which is a subperiod of the 20th-century simulations by these models and is also the period spanned by the validation fields (see below). The models are listed in Chapman & Walsh (2007, their Table 1). Most of the model simulations were begun in the 1800s and continued through 2000 with prescribed greenhouse gas concentrations and, in some cases, estimated sulfate aerosols and variable solar forcing (see discussion in Wang et al. (2007)). The simulations were continued through the 21st century with forcing prescribed from the IPCC's greenhouse scenarios (A2, A1B, B1, etc.). For the evaluation performed in this study, we use the output from the 20th-century simulations.

The IPCC model output is compared here against the European Centre for Medium-Range Weather Forecasts (ECMWF) Re-Analysis, ERA-40, which directly assimilates sea level pressure (SLP) observations and some air temperature observations into a reanalysis product spanning 1958–2000. Precipitation is computed by the model used in the data assimilation. The ERA-40 is one of the most consistent and

Table 1: Summary of performance rank derived from the models' RMSE for three variables: temperature, precipitation and sea level pressure over three domains: Alaska, pan-Arctic (60-90ºN) and the Northern Hemisphere extratropics (20-90ºN). An integrated rank, defined as the sum of ranks over the three domains and the three variables, is included in the right-most column.

Overall Rank	Model

15	IAP_FGOALS1_0_G	15	15	15	15	15	14	12	13	10	124

accurate gridded representations of these variables available, and it compares favorably with other reanalyses of the Arctic (Bromwich et al. 2007). It is therefore, a logical choice for observational analyses from which we determine the model biases of late-twentieth-century surface air temperatures, precipitation and SLP. (Data and documentation for the ERA-40 can be found online at http://www.ecmwf.int/research/era/Products.). While the ERA-40 reanalysis was performed at T106 (~125 km) resolution with 60 levels, we use the version of the output archived on a 2.5° latitude x 2.5° longitude grid for compatibility with the climate model output. This grid resolution, to which the varios model grid configurations were interpolated, is typical of the resolution of the global climate models.

To facilitate GCM intercomparison and validation against the reanalysis data, all monthly fields of GCM temperature, precipitation and SLP are interpolated to the common 2.5° × 2.5° latitude–longitude ERA-40 grid. Our evaluation of the models' simulated fields uses monthly, seasonal, and annual climatological means for the late-twentieth-century period 1958-2000.

The core statistic of our validation is the root-mean-square error (RMSE) evaluated from the differences between ERA-40 and each model for each grid point and calendar month. In all cases, the differences are between climatological means for the 1958–2000 period. The RMSE calculations are performed for each of the fifteen models, for each calendar month, and area-weighted for each of three domains: Alaska, the "pan-Arctic" polar cap (60–90°N) and a middle-high latitude "Northern Hemisphere" domain (20-90°N). The Alaska domain is contained within the Arctic and Northern Hemisphere domains (except for a small portion of southeastern Alaska), so the results for the various domains are not independent. The reason for our choice of the three overlapping domains is that, although our primary interest is in the models' performance for a region that contains permafrost (Alaska), the simulation of present-day and future climate in Alaska will depend on the simulation of regions from which weather systems move toward Alaska. In particular, the larger-scale circulation over much of the Northern Hemisphere influences Alaska via advection and teleconnections, so credible simulations of future changes will depend on the models' ability to capture the large-scale circulation of the pan-Arctic and Northern Hemisphere domains.

As a seasonally inclusive measure of the models' success in simulating the regional and larger-scale climates, we sum the RMSE values over the 12 calendar months. In this respect, we are evaluating the models' ability to simulate the seasonal cycle and hence the models' sensitivities to the cycle of solar forcing. While success in capturing this sensitivity does not guarantee a realistic sensitivity to greenhouse gas forcing (infrared radiation), one may view a climate model's ability to respond to seasonally varying solar radiation as a prerequisite for a realistic response to perturbations of infrared radiation.

After summation of the regional mean RMSEs over the 12 calendar months, the sums are used to rank the models. The model with the smallest 12-month sum of the RMSE is ranked #1 for that variable and region, while the model with the largest 12-month sum of the RMSE is ranked #15. The ranks can then be summed over different variables and/or different domains, depending upon a user's priorities for variables and regional emphasis. The raw RMSE values for individual months also enable users to assess the utility of a particular model for a particular month or season.

Results

Present climate

This paper's main objective is an identification of the models that are most successful at simulating the seasonal cycle of the climates of Alaska and the Arctic. Information on the variables most relevant to permafrost is contained in Figures 1 and 2, which show the 12-month mean RMSEs of the different models, arranged in order of increasing RMSE, for the surface air temperature (Fig. 1) and precipitation (Fig. 2). Each figure contains a separate display for the three domains discussed earlier: (a) Alaska, (b) the pan-Arctic, 60–90°N, and (c) the extratropical Northern Hemisphere 20–90°N. It is apparent from these figures, especially Figure 1 for temperature, that the models vary widely in their ability to capture the seasonal climates of Alaska. For example, the yearly averaged RMSE of temperature over Alaska varies from 2.9°C in MPI-ECHAM5 to 11.0°C in IAP-FGOALS. The range for the pan-Arctic domain (60–90°N) is even greater, from 2.9°C to 13.6°C. While the ranges are smaller for the other variables, the RMSEs still vary across the models by nearly a factor of two for precipitation and by more than a factor of two for sea level pressure. Similar ranges are found for the larger domains, i.e., the pan-Arctic and hemispheric polar caps.

A noteworthy feature of Figures 1 and 2 is the tendency for some models to rank highly for both Alaska and the larger domains, although there are exceptions. Table 1 provides a synthesis of the model performance based on the RMSE metric. This table ranks the models from 1 (smallest RMSE) to 15 (largest RMSE) for each variable and domain. As in Figures 1 and 2, these ranks are based on RMSEs summed over all twelve calendar months, so they incorporate the models' successes or failures in capturing the seasonal cycle.

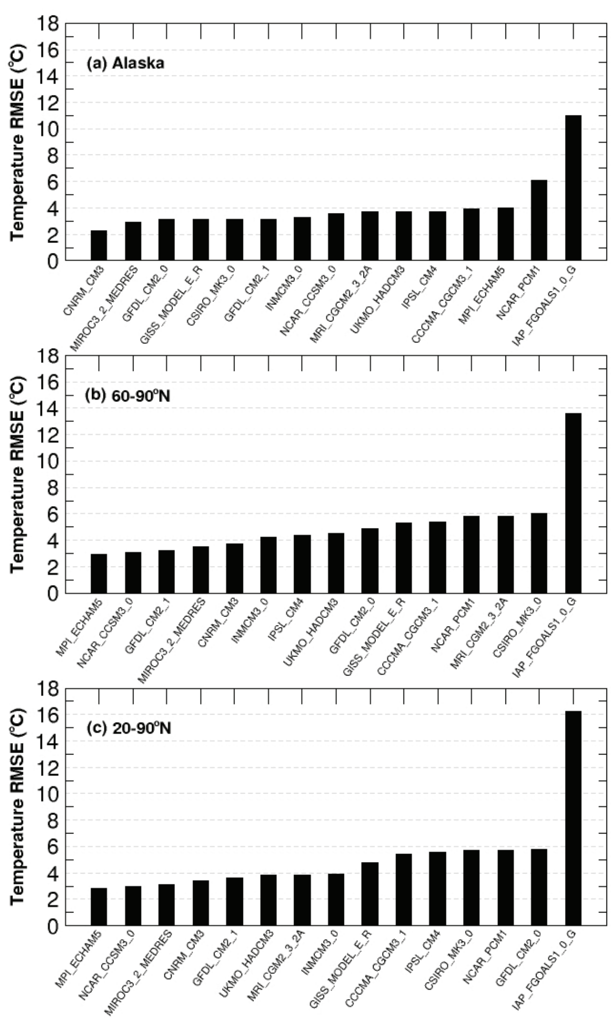

Figure 1. Area-averaged and annually-average Root Mean Square Error (RMSE) of simulated monthly mean (1981–2000) temperatures from 15 models for (a) Alaska, (b) 60–90°N, and (c) 20–90°N.

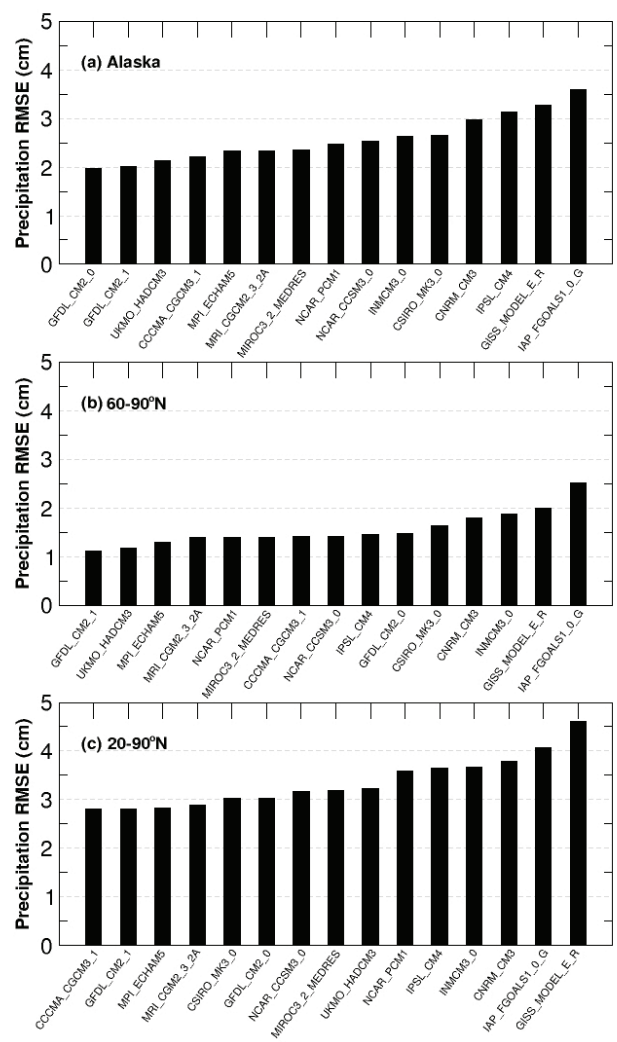

Figure 2. Area-averaged and annually-average Root Mean Square Error (RMSE) of simulated monthly mean (1981–2000) precipitation from 15 models for (a) Alaska, (b) 60–90°N, and (c) 20–90°N.

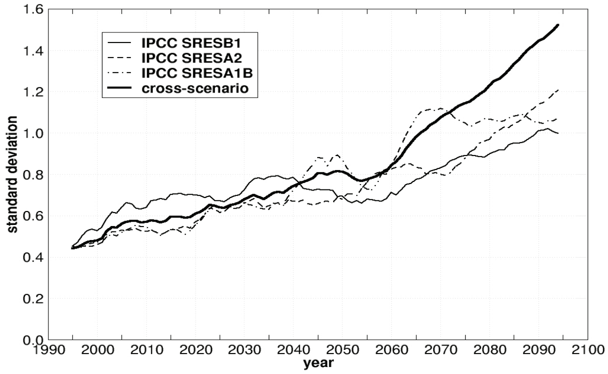

Figure 3. Across-model variability, expressed as 11-year running standard deviations of annual surface air temperature for three greenhouse gas forcing scenarios: IPCC SRES B1, A1B and A2. Also plotted is the across-scenario variability, expressed as the 11-year running standard deviation of surface air temperature across the three IPCC scenarios.

The right-most column of Table 1 is the sum of all 9 ranks (3 domains x 3 variables) of the models. We refer to this column as our "integrated rank". Because the domains are nested, this "integrated rank" effectively double-weights the model performance over the Arctic polar cap (60–90°N) and triple-weights the model performance over the Alaskan (i.e., Alaska is included in both larger domains).

It is apparent from Table 1 that, according to our metric and the integrated rank derived from it, two models outperform the others by a considerable margin. These two top-ranking models are MPI-ECHAM5 and GFDL-CM2.1. Both models consistently rank in the top five for all regions and variables, with the exception of temperatures over Alaska. As a cautionary note, MPI-ECHAM5 shows a large negative bias (and hence RMSE) of temperature during January-March over Alaska, illustrating that potentially important regional errors can be present in even the best-performing models. The MIROC3.2-MEDRES and UKMO-HADCM3 models are the third and fourth models in integrated rank, followed by the CCCMA-CGCM3.1 and GFDL-CM2.0 models.

The top-ranking models for Alaska are GFDL-CM2.0, GFDL-CM2.1, UKMO-HADCM3, MPI-ECHAM5, MIROC3.2-MEDRES (in a tie with CCCMA-CGCM3.1 and MRI-CGM2.3.2A). There is substantial overlap among the top performers for the larger domains (pan-Arctic and Northern Hemisphere) and the other subregional domains not discussed here (e.g., Siberia and Greenland).

Projected changes

A key issue underlying model evaluation is the possibility of a relationship between the models' projected greenhouse changes and the relative accuracy of the simulations of present-day climate. Before addressing this question directly, we highlight uncertainties in future projections by distinguishing the effects of uncertainties in the future greenhouse forcing scenarios (A2, A1B, B1) and uncertainties inherent in the across-model variance. In order to assess the relative contributions of these two sources of uncertainty, we evaluated (1) the intermodel variability for each scenario, expressed as centered 11-year running means of across-model standard deviations of annual temperature change; and (2) the across-scenario variability, expressed as standard deviations of projected temperature change across the three scenarios. The temporal evolution of these two measures of variability is plotted in Figure 3. The across-model and across-scenario variances in the projected temperatures are comparable through the first half of the 21st century, but the increases in variability associated with the choice of greenhouse gas scenario begin to outpace those of across-model variability by about year 2070. By the end of the 21st century, the across-scenario variability is about 50% greater than the across-model variability.

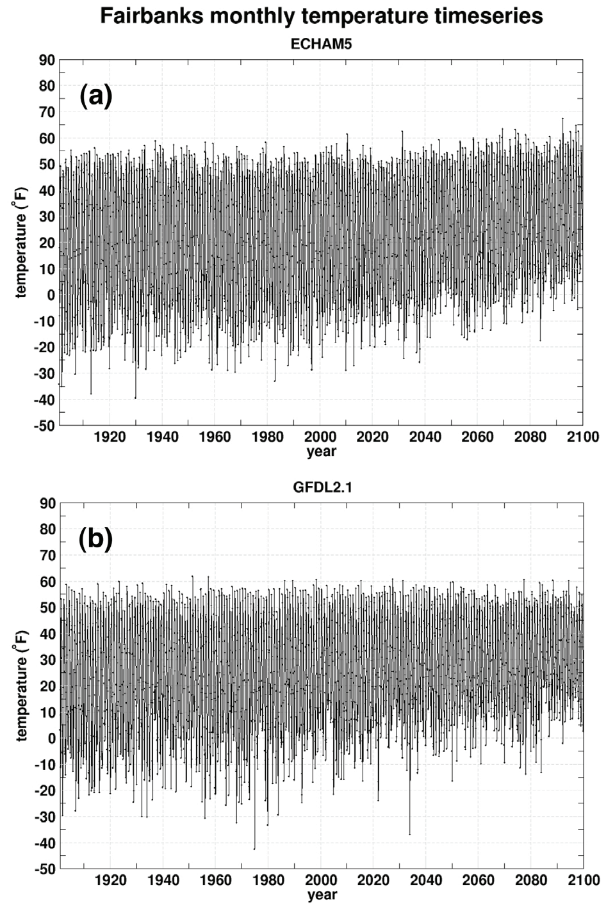

Figure 4. Monthly temperatures (ºF) at the grid cell containing Fairbanks, AK in the A1B simulations by the (a) MPI ECHAM5 and (b) GFDL CM2.1 models.

In order to illustrate the projected temperature changes, we show in Figure 4 the two time series of projected temperatures for a grid cell (near Fairbanks, Alaska) in which discontinuous permafrost is now present. The two models chosen for Figure 4 are MPI ECHAM5 and GFDL CM2.1, which have the highest integrated ranks in Table 1. It is apparent from Figure 4 that warming occurs in both models (as in all the other models). However, the warming

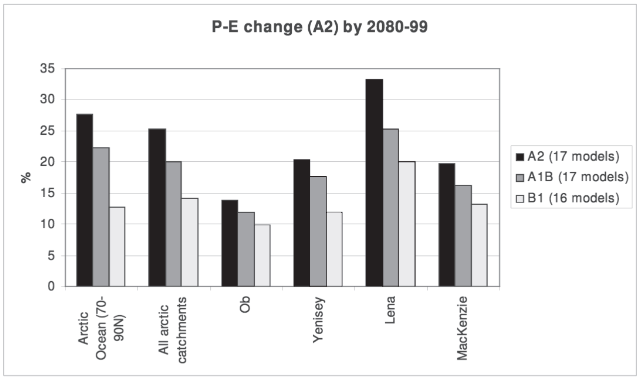

Figure 5. Percentage changes of annual mean P-E (river discharge) in A2, A1B and B1 scenarios for 2080-2099 over different regions (watersheds): the Arctic Ocean (70–90ºN), all Arctic Ocean terrestrial watersheds, the Ob, the Yenisey, the Lena, and the Mackenzie.

that is readily apparent in both the minimum (winter) and maximum (summer) temperatures in the MPI ECHAM5 model is apparent primarily only in the coldest (winter) months in the GFDL model. Most of the models show this seasonal asymmertry of the warming at Arctic locations For example, in the GFDL CM2.1 simulation, the temperature of the coldest winter month increases from about -25˚C (-12˚F) in the early 1900s to about -12˚C (+10˚F) by the 2090s. There is, however, considerable interannual variability. This interannual variability is obscured by temporal (e.g., decadal) or multi-model averaging.

Figure 5 shows the percentage increase in precipitation less evapotranspiration (P-E), averaged over various Arctic terrestrial drainage basins and over the Arctic Ocean (70-90ºN), for the 2080–2099 time slice relative to the 1980-1999 time slice for the A2, A1B and B1 scenarios. The strongest relative increase of P-E (a 33% increase in the A2 scenario) is projected for the Lena Basin, which is largely underlain by permafrost. The weakest relative change is shown for the Ob Basin, which is largely devoid of permafrost. P-E is also projected to increase over the Arctic Ocean, although the increased input of freshwater by P-E over the Arctic Ocean represents only about half the increase of P-E from projected river discharge (P-E over the surrounding Arctic terrestrial drainage basins). While the increase of P-E over the Arctic Ocean is largest in summer and autumn, the increases of P-E over the terrestrial drainage basins are largest in the winter, implying an increase of snowfall. Because snow insulates permafrost during winter, the effect of increased snowfall on permafrost may act to enhance the direct effects on permafrost of warming of the air temperature (Zhang 2005).

Figure 6a shows the models' projected warming for 60–90°N plotted as a function of the integrated rank of the models. The warming is defined here as the area-weighted linear change in surface air temperature from 2000 to 2099. While there is considerable scatter in the warming, there is a tendency for the highest-ranking models to simulate the greatest warming over the 60–90°N zone. The projected

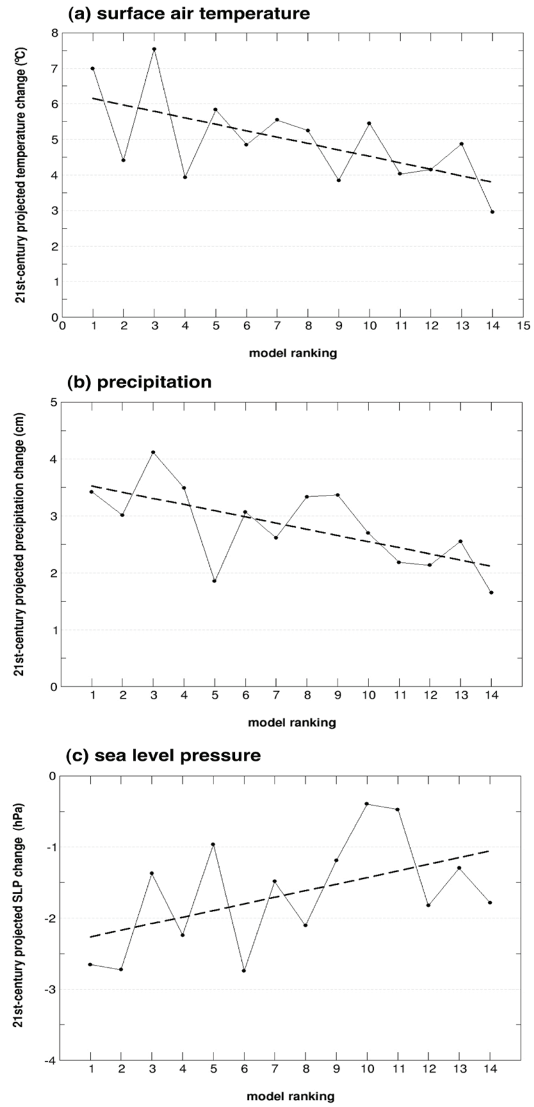

Figure 6. Projected change of (a) surface air temperature (ºC), (b) precipitation (cm) and (c) sea level pressure (hPa) averaged over 60–90ºN for 2081–2100 relative to 1981–2000. Changes are plotted vs. model performance rank (x-axis). Linear best fit is shown as a dashed line in each plot.

changes of precipitation (Fig. 6b) show a similar dependence on the models' integrated ranks, with better performing models projecting larger increases of Arctic precipitation than the lower-ranking models. While there is more scatter in the corresponding SLP results (Fig. 6c), there is a tendency for larger 21st century decreases in Arctic sea level pressure to be projected by higher-ranking models than by lower-ranking models.

Conclusion

This study has emphasized model simulations of climate over Alaska, which we have chosen because it contains large areas of permafrost. Model performance over Alaska is generally neither better nor worse than the performance over the pan-Arctic and Northern Hemisphere domains. During winter and autumn, the temperature errors over Alaska are somewhat smaller, but the precipitation errors are generally larger, than over the larger domains. The specific models that perform best over the larger domains tend to be the ones that perform best over Alaska. Although not shown here, model performance over other permafrost areas (e.g., Greenland) appears to be comparable to the same models' performance over Alaska.

In the context of permafrost, the most important results of the model simulations are the trends toward a warmer and wetter climate. A wetter climate implies more snowfall during winter. To the extent that snow cover insulates the soil during winter, the changes in the two main controls of permafrost temperatures will favor a warming of permafrost in areas such as Alaska. (Osterkamp 2007) However, the warming also implies a shorter snow season. A high priority for research is the determination of net effect of two competing changes of snow: larger snowfall rates during the cold season, but a shorter snow season.

There is a tendency for the models with the smaller errors to simulate a larger greenhouse warming over the Arctic. Since several models have substantially smaller systematic errors than the other models, the differences in warming imply that the choice of a subset of models may offer a viable approach to narrowing the uncertainty and obtaining more robust estimates of future climate change in regions such as Alaska and the broader Arctic. The results obtained here suggest that the uncertainty might be narrowed by eliminating models with the weaker projected warming in the Arctic, as those models tend to have the largest errors in simulations of the present-day climate. Such an approach has already been suggested by Overland & Wang (2007) and Kattsov & Sporyshev (2006), and will be pursued in future assessments of Arctic change.

A key limitation of this study is the coarse resolution of the global climate models, which are not able to resolve many of the topographic features that are crucial to permafrost distribution. The differences between north-facing and south-facing slopes within a grid cell represent one such example. In order to include finer-scale features, it will be necessary to employ either (a) statistical downscaling approaches using algorithms trained on observational data, perhaps including permafrost measurements, or (b) regional climate models, which effectively provide a "dynamical downscaling". Since regional climate models are driven at their lateral boundaries by the output from global models, and since statistically downscaling of projections requires global or regional model output, the global model assessment described here has relevance to downscaling approaches. Moreover, the permafrost community is generally ahead of the global climate modeling community in the sophistication of modules used to simulate permafrost. Given that this situation is likely to persist as permafrost models improve, the optimum strategy for projecting future changes of permafrost may be to utilize off-line permafrost simulations driven by downscaled output (including snowfall) from large-scale models.

The Freezing Process Deformation of Soil Under Higher Confining Pressure

Dayan Wang, Wei Ma, Zhi Wen
State Key Laboratory of Frozen Soil Engineering, Cold and Arid Regions Environmental and Engineering Research Institute, CAS, Lanzhou, China

Abstract

This paper describes results from a series of laboratory tests carried out after the samples subjected to the K_0 consolidation process, which could simulate the deep soil stratum-forming history. The observed results from these tests have shown that the high of the soil sample under higher confining pressure decreases with the soil temperature decreasing, and the downtrend will stop and keep a constant when the temperature reaches a desired level. The variation of the specimen size depends on the confining pressure, soil temperature, and soil type. For soil under the same temperature level, the higher the initial confining pressure, the smaller the variation of the specimen size. For a soil under the same confining pressure level, however, the high of the higher negative temperature soil specimen will reduce unceasingly. When the soil temperature is lower than -5°C, the fluctuation of the soil temperature hardly influences the final high of the soil specimen. In addition, the high variation of the loess sample is much less than the sand sample under the same other factors.

Keywords: artificial frozen soil; higher confining pressure; K_0 consolidation.

Introduction

Ground freezing has been recognized by mining and civil engineers as undoubtedly the most effective and consistently reliable method of providing temporary support and of preventing groundwater from flowing into deep excavations. Its uses does not deplete aquifer reserves by continuous pumping, nor does it pollute or alter the groundwater regime in any way, thus eliminating any adverse affect on adjacent structures, installations, and populations. Frozen wall design and construct, based on how to reasonably choose the physical-mechanical parameter of artificially frozen soils, is a key factor affecting the application of this technology. Therefore, in the last 20 years, a lot of research has been carried out in relation to the test techniques, physical parameters, mechanical characteristics, and freezing temperature of deep soils (Cui et al. 1998, Ma et al. 1993, 1995, 1999, 2000, Ma & Chang 2002, Zhou et al. 1999, Wang et al. 2002), and drawn a series of significant results. Although the obtained results could resolve some practical difficulties arising from the application of artificially frozen soil construction, we could not obtain the reasonable strength theory and the constitutive model of frozen soil forming in the deep alluvium. Generally, the mechanical properties of the frozen soils are influenced by its physical characteristics. The study of soil deformation properties in the process of freezing under higher confining pressure is involved in the stability of the surface construction and is particularly important for establishing the constitutive model of artificially frozen soil forming under the deeper stratum. However, very few experimental data on this problem exist because of the technical difficulties; for example, how to restore the tested soil to the original state of deep alluvium and then freeze it in the laboratory, and the time-consuming nature of the above-mentioned process. Guided by the earlier studies, this paper was designed to study the features of deep soil deformation during freezing under different negative temperature, initial confining pressure, and soil type. Among these, the initial confining pressure represents the degree of the stratum depth.

Preparation of Specimens and Test Procedure

The soils used in the current study were typical Lanzhou loess and Lanzhou sand, and their engineering properties are shown in Table 1a and Table 1b. The testing scheme is found in Table 2.

Table 1a. The basic physical properties of sand specimens.

Soil type	Composition of grains (%)				Dry density	Water content
Lanzhou	＞0.5	0.5～0.05	0.05～0.005	＜0.005	g/cm^3	%
sands	25.6	54.23	8.04	12.13	2.0	10.5

Table 1b. The basic physical properties of loess specimens.

Soil type	Composition of grains (%)				Liquid limit (%)	Plastic limit (%)	Dry density (g/cm^3)	Water content (%)
Lanzhou	＞0.1	0.1～0.05	0.05～0.005	＜0.005				
loess	1.7	5.4	58.6	34.3	24.6	17.7	1.78	16.5

The procedure for preparing the sample is generally performed according to the Specification of Soil Test (GB/T50123–1999) issued by the Ministry of Water Resources, PRC. All the specimens, typically 61.8 mm in diameter and 125 mm in height, were compacted in 6 layers, with a relevant density and water content according to the different soil types, shown in Table 1. The specimen was then covered with rubber sleeves to prevent evaporation of water, and put into the K_0 consolidating instrument, which was developed by our laboratory and used the working principle of oil side-limiting control with the greatest confining pressure of 15 MPa and the lowest temperature of -60°C. In this chamber, the specimen could experience drained triaxial compression before freezing. This process can simulate an increase of overburden, and restores the loading history and initial stress states of soils in the field.

To assure that the soil sample does not laterally deform, the static lateral pressure coefficient of the tested soils was obtained from preliminary experimental study (Ma & Cui 2000). The consolidating pressures were controlled at a certain rate, shown in Table 2. When the confining pressure reached the desired pressure, the loading process stopped and began to lower the temperature. The axial deformation was automatically measured by the axial pressure system monitoring the changes of axial displacement, and the data were collected continually by computer.

Table 2. The controlling parameters of this experiment.

Soil type	K_0	Speed of the axial loading（MP/s）	Speed of the radial Loading (MP/s)
sands	0.32	10×10^{-5}	3.2×10^{-5}
loess	0.34	10×10^{-5}	3.4×10^{-5}

Results and Discussion

Influence of soil temperature on the deformation

Temperature is a key factor in the study of frozen soil formation, for frozen ground is defined as soil or rock having a temperature below 0°C. The data presented in Figure1 show the ΔH with the time, where ΔH is defined as the variation of sample height obtained in the freezing process. From Figure 1, we can conclude that the high of the loess sample became sharply reduced with the ambient temperature decrease. When the sample temperature is consistent with the ambient temperature, the variation of the sample height is related to the frozen soil temperature status. The lower the surrounding temperature, the more steady the deformation of the sample, and the shorter the time needed to reach stabilization. With

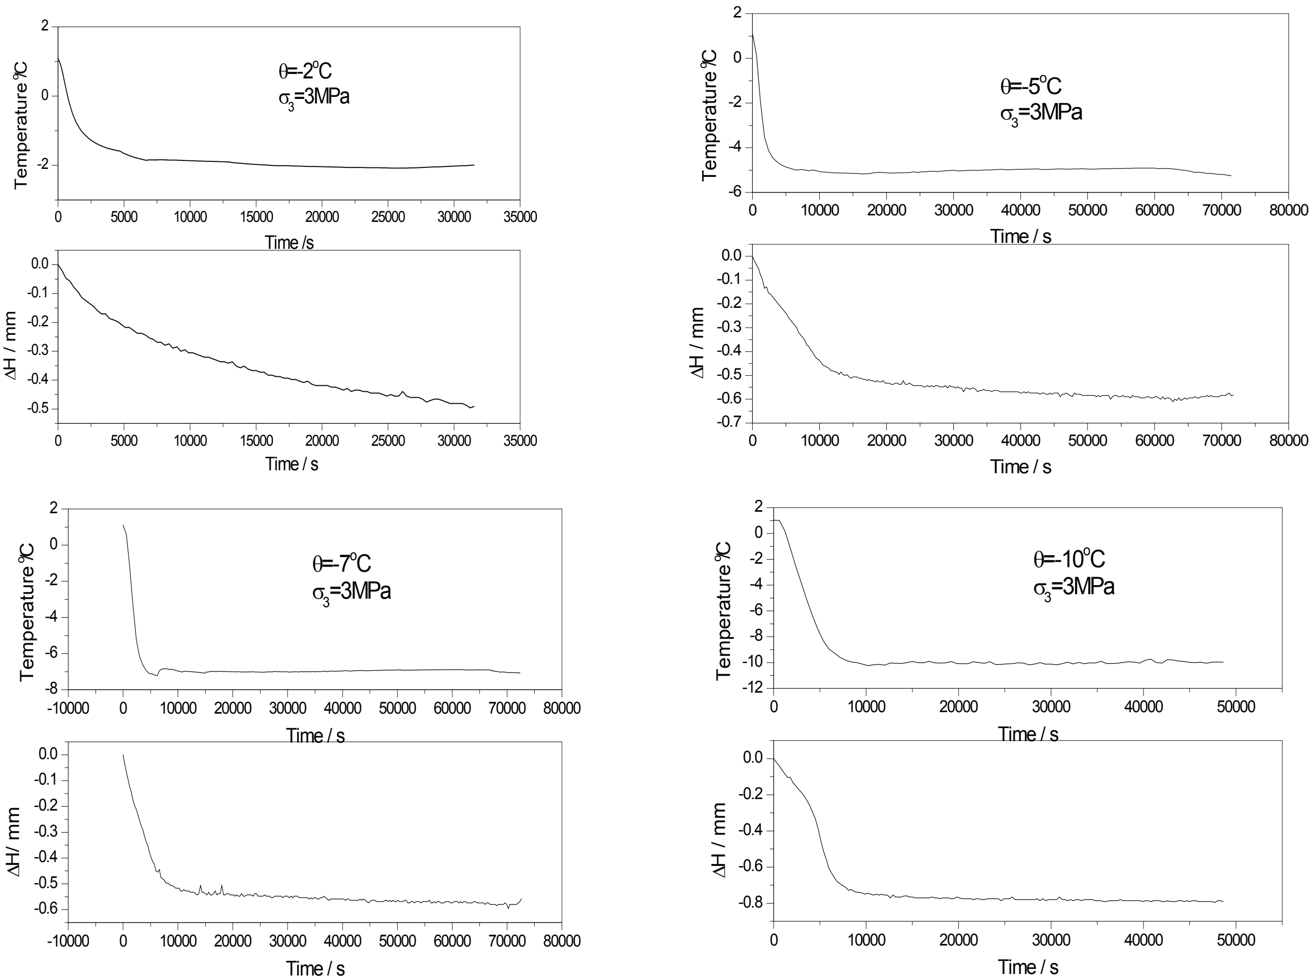

Figure1. Effect of the frozen soil temperature on the variation of loess specimen high in the process of freezing.

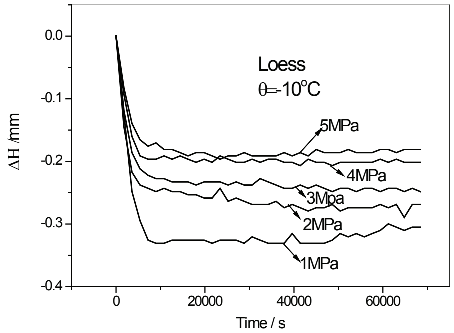

Figure 2. Effect of the initial confining pressure on the variation of loess specimen high in the process of freezing.

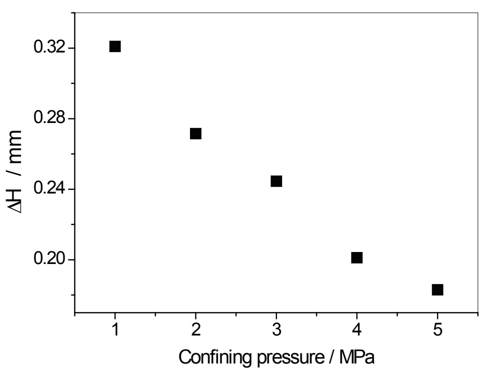

Figure 3. The variation of loess specimen high versus the initial confining pressure.

respect to soil frozen to a temperature lower than -5°C under the same initial confining pressure, the time that the sample deformation reaches stabilization almost equals the time of the surrounding temperature reaching the desired temperature. The sample high variation is about 0.6 to 0.8 mm and independent of the soil temperature. However, for frozen soil with a temperature higher than -5°C, the axial deformation progresses ceaselessly, even though the soil temperature is equal to the surrounding temperature.

Influence of the initial confining pressure on the deformation

Figure 2 shows the variation of the sample high with time from the lowering temperature to -10°C process on the loess subjected to K_0 consolidated to confining pressure σ_3 of 1~5MPa, respectively. From Figure 2, we can conclude that the sample high reduces sharply with the surrounding temperature dropping, and then stops and holds a constant when the sample temperature equals the surrounding temperature. The variation of frozen sample high was heavily influenced by the condition of the initial confining pressure. If the variation of the sample high was taken as the deformation resulted from freezing the soil, we can find from Figure 3 that the deformation of the sample after having been frozen was linearly decreased with the initial confining pressure increase.

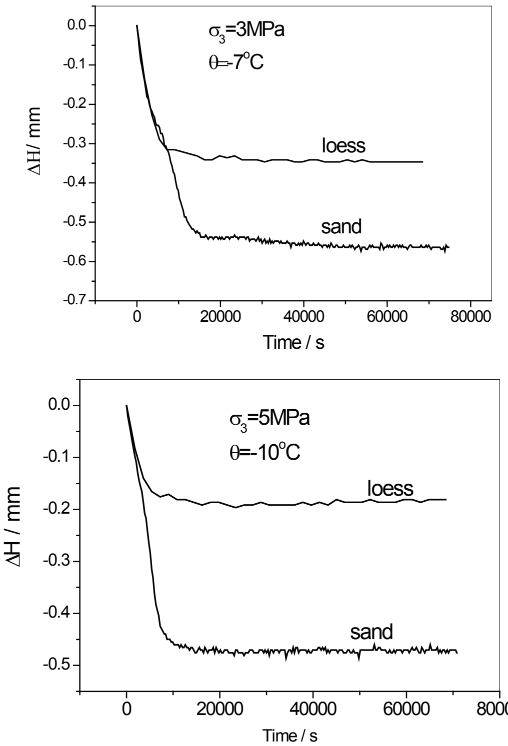

Figure 4. Comparison of the specimen high variation of the two types of soils used in this study.

Table 3. Comparison of the specimen high variation of the two types of soils used in this study.

confining stress	1MPa	2MPa	3MPa	4MPa	5MPa
sand	0.7214	0.5858	0.5364	0.6541	0.471
loess	0.3209	0.2715	0.2445	0.2012	0.183
differential value	0.4	0.314	0.2919	0.453	0.288

Influence of the soil type on deformation

The variation of deformation in the freezing process is affected by characteristics of the soil type. It can be concluded from Figure 4 that the deformation of the sample is larger than that of the loess sample under the same initial confining stress and negative temperature, despite the sample's high decrease when the temperature drops to -7°C or -10°C. After the loess sample and the sand sample experienced the K_0 consolidation process under initial confining stress varying from 1 to 5MPa and completely frozen, a comparison of the variation sample high obtained that the deformation of sand sample is larger than that of loess under the same other condition, and the difference is about 0.3 to 0.4 mm (see Table 3). This suggests that, even for the samples consolidated to the same confining pressure and frozen at the same negative temperature by the same method in the process of using artificial ground freezing to reinforce ground, the soil group would heavily influence the deformation of the freezing soil, causing differential settlement of the ground surface. The builder must consider this point in the design.

Conclusions

It is important to recognize that the deep artificial ground freezing process could cause stratum settlement. This study simulated the deep artificial ground freezing process in the laboratory by K_0 consolidation and presented the findings of a comprehensive study of the effects of the stratum depth, frozen soil temperature, and soil group on settlement expressed by the sample deformation. The following conclusions can be drawn:

1. When the surrounding temperature drops to lower than 0°C, the high of the soil sample subjected to K_0 consolidation will decrease with the temperature decreasing. Until the temperature reaches the desired temperature, the variation of soil sample high stops and keeps a constant level. Therefore, freezing the deep soil could lead to settlement of surface ground. The magnitude of settlement is decided by the soil depth, frozen soil temperature, and soil group.
2. In the process of freezing, deformation of the soil sample was linearly decreased with the initial confining stress increase; namely, with the stratum becoming deep, the sample deformation produced by freezing the soil will decrease.

Sample deformation caused by the freezing process was affected by the soil group. In the range of the studied confining pressure, the deformation of sand was always larger than that of loess. The differential value is about 0.3 to 0.4 mm.

Abstract

The 110 kV power transmission line from Amdo to Damxung, Tibet, is in the patchy permafrost zone in southcentral Tibet. Frost heave/thaw settlement of the tower foundation soil was one of the major challenges for geotechnical design and construction. Surveys on frozen ground conditions were conducted for assessing frost hazards. The thermal and strain/stress interactions of tower foundation and soils were monitored, tested in situ and in the laboratory, and analyzed. Shallow oblique and straight concrete-column foundations and thermosyphon-cooled pile foundations were proposed and adopted with proven mitigative results. Tower site selection and ground improvement were proven most cost-effective. Data-bank and engineering measures, as well as experiences from the 110 kV power line were very helpful for the design and construction of the proposed 400 and 750 kV power transmission lines and other linear foundation engineering in warm, elevational permafrost regions on the Qinghai-Tibet Plateau.

Keywords: frost-hazard mitigation; ground-improvement; 110-kV power-line; permafrost; site-selection; tower foundation.

Introduction

Towers for transmission lines are commonly either self-supporting or guyed. A tower supported on the top of frost zone will experience frost heave with the presence of frost-susceptible soil and available moisture. The seasonal vertical movement may be detrimental. If the heave is differential between footings supporting the tower, the tower will tip and/or the structure will be unevenly stressed. The guyed tower might experience an overstressing of the guys or of their anchors. Differential footing settlements may occur during thaw-weakening in spring. If the tower is on a slope, progressive downslope movement may occur with successive freeze-thaw cycles.

Granular material may be used to control or eliminate detrimental vertical movement. Due to the intense winter cold, it is usually impractical to make the mat thick enough to completely prevent frost penetration or heave in the underlying frost-susceptible mat, particularly when the mat is naturally well-drained. However, the magnitude of frost heave may be substantially reduced by a relatively modest surcharge, consisting of the weight of the gravel plus the load from the structure (U.S. Department of Defense 2004). Pile foundation with flanged sleeves to isolate the pile from frost heave forces also can be used.

However, studies closely related to the tower foundations of power transmission lines are limited. Myska & How (1978) presented a case study for installation of pile foundations for a microwave tower system, Gillam-Churchill, Manitoba, Canada. This is a route of about 250 km in the continuous and widespread permafrost zones. In this case study, grouted rod anchors for the tower guys were installed without pre-design subsurface investigations, and the subsurface investigations for the foundations were conducted concurrently, using anchor installation drilling equipment. Precast concrete piles were installed in augered holes. To avoid on-site concreting, the pile caps were constructed of pre-fabricated structural steel.

The 110 kV transmission line from Damxung to Amdo in southcentral Tibet originally was to supply the power needed for engineering construction and operation of the Qinghai-Tibet Railway system at an average elevation of 4500 m. It was the first 110-kV transmission line in the permafrost region on the Qinghai-Tibet Plateau. The 281-km line starts from Damxung in the south and via Nagqü, ends at Amdo in the north, of which 173 km is from Damxung to Nagqü and 108 km from Nagqü to Amdo (Fig. 1). The line traverses regions of patchy permafrost, extensive taliks, and seasonally frozen ground in the vicinity of the southern lower limit of permafrost on the Qinghai-Tibet Plateau.

Large amounts of then-existing data, research papers and reports, previous engineering experiences, and lessons learned were collected and analyzed for the route selection and for the subsequent preliminary and detailed designs for construction for this unprecedented power line on the Qinghai-Tibet Plateau. These data and studies generally included, but were not limited to, published research and review papers on permafrost and cold regions engineering, frozen ground engineering geology reports for the design, construction, and operation of the Qinghai-Tibet Highway, the Golmud to Lhasa fiber-optic cables and an oil products

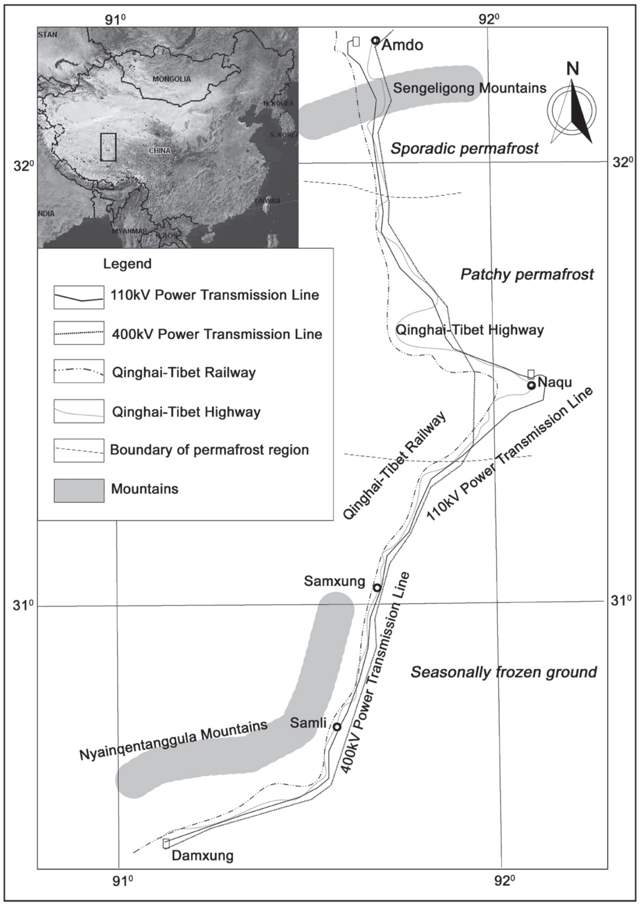

Figure 1. Sketch map of the study region from Amdo to Damxung on the Qinghai-Tibet Plateau.

Figure 2. Landscape of patchy permafrost zone north of Amdo on the Qinghai-Tibet Plateau, with the 110 kV power transmission line crossing the Amdo River in southern front of the Shengeligongshan Mountains.

pipeline. Experts on frozen ground engineering from the Cold and Arid Regions Environmental and Engineering Research Institute, Chinese Academy of Sciences were consulted and their advice sought for in situ engineering surveys, design, and construction. Data on meteorology related to the Qinghai-Tibet Railway, then under construction, also were gathered and analyzed. The planning of the power line began in September 2002. All preliminary and construction designs were completed, reported, reviewed, and delivered by December 2003.

The majority of the power line route is located in areas impacted by seasonal frost, but some sections also are affected by warm, patchy, and ice-rich permafrost. Therefore, it was highly desirable to clearly delineate the interfaces and depths of frozen ground in order to cost-effectively design and build the transmission line tower foundations. Frost heave and thaw settlement are the two most frequently occurring hazards, which can induce abnormal differential deformation strains and stresses in frozen soil foundations and subsurface infrastructures. However, studies on the impacts of frozen ground on the safety and long-term stability of tower foundations for transmission lines were very limited in China before the early 2000s.

Power transmission lines are very important for construction of key engineering projects and for the sustainable societal and economic development in a region. However, the constraints for their engineering reliability and long-term stability are very exacting. Although the power transmission lines share some common features with other linear engineering projects, their survey, design, and construction for the frozen ground engineering geology are unique and site-specific because of the large distance between towers and the elevation/suspension nature of power lines compared to other linear engineering infrastructures such as roads and pipelines. The related surveys, selection of foundation types, design, and construction of tower foundations directly or indirectly affect the safety, integrity, long-term stability, profitability, and societal benefits. Therefore, differential frost heaving and thaw settlement are paid great attention during all phases (surveys, design, and construction) of power-line foundation engineering.

Because of its proximity to the southern lower limit of the plateau-elevation permafrost, potentials of frost heaving, sensitivity to thaw settlement of foundation soils, and depths of seasonal frost and thaw penetration in tower foundation soils vary markedly, even over short distances. Adverse cryogenic hazards resulting from freeze-thaw processes occur extensively and frequently. Their impacts on tower foundations are complicated and highly uncertain in various spatio-temporal scales due to their migratory nature. Therefore, the boundaries and depths of the permafrost table or seasonal frost penetration and frozen or unfrozen soils, as well as adverse cryogenic features, should be well understood in order to provide reliable criteria for designing cost-effective tower foundations and/or mitigative measures of hazardous foundation soils.

Frozen Ground Along the Power Line Route

The elevation along the power line route ranges from 4200 m to 4980 m. The topography is gentle and open, with relative relief generally less than 500 m. The annual mean air temperatures generally are colder than 0°C. Frozen ground, predominantly seasonally frozen ground, is found

Table 1. susceptibility classification of permafrost (revised from State Forestry Administration 2001).

coefficients	δ <1	1< δ <3	3< δ <10	10< δ <25	δ >25
Thaw-sensitivity	Insensitive	Weakly sensitive	Sensitive	Very sensitive	Collapsing

extensively at all terrains from Nagqü to Damxung, and permafrost is generally found in the Amdo area.

Patchy permafrost

Patchy permafrost is generally connected with the active layer in areas north of Amdo, but it is separated from the active layer by a talik layer in the south (Wang & Wang 1982). Permafrost at elevations above 4700 m between Amdo and Damxung occurs in the Shengeligongshan Mountains, in intermontane basins in the vicinity of Highway Maintenance Squad Stations (HMSSs) 119, and 121 to 124 along the Qinghai-Tibet Highway, in the wetlands in the Liangdaohe River Basin (Figure 1). Patchy permafrost generally occurs in locations with better moisture conditions, fine-grained soils, and good vegetative cover favoring the development and protection of permafrost (Jin et al. 2007a, 2007b) (Fig. 2). Hazardous periglacial phenomena such as frost mounds and icings also are well developed.

Seasonally frozen ground

Seasonally frozen ground generally is found in intermontane basins between the Shengeligongshan Mountains and HMSSs 119, between HMSSs 121 and 122, 122 and 124, where permafrost occurs. The depths of seasonal frost penetration are 3.7–3.9 m in the Amdo area, 2.8–3.0 m in the Nagqü area, and 1.2–1.5 m in the Damxung area, as revealed by meteorological data. Ground surveys also confirm that seasonal frost penetration depths vary greatly from 1.2–4.0 m from Amdo to Damxung.

Hazardous periglacial phenomena

Pingos, seasonal frost mounds, and icing generally occur in concentrated small areas from HMSS 119 to the Liangdaohe River. Most of their occurrence is controlled by active faults (Wu et al. 2004, 2005, Jin et al. in press). Retrogressive thermal slumps also are found in very limited areas and are avoided.

Frozen Ground Engineering Geology

Classification of frozen soils for engineering purposes

On the basis of ice content, frozen soils were divided into 5 types: ice-poor, ice-medium, ice-rich, ice-saturated permafrost, and ice layers with soil inclusions. On the basis of frost heaving coefficients, the frost-heave susceptibility of soils was similarly divided into five grades: non-frost heave, weak frost heave, frost heave, strong frost heave, and very strong frost heave (State Forestry Administration 2001).

Frost heaving of seasonally frozen ground

The magnitude of vertical frost heave differs significantly with depth, even in a uniform soil layer, due to moisture migration and subsequent ice segregation. Generally, the major frost heaving occurs at depths less than two-thirds of the maximum depth of the seasonal frost penetration (State Forestry Administration 2001).

Moisture and the content of fine-grained soil are the major factors leading to frost heave in foundation soils. Drainage conditions of excess water from the foundation soil also influence frost-heave forces. To mitigate the impact of frost heave, one needs to eliminate the effect of soil moisture by using lubricants (generally hydrophobic material such as bitumen mixed with 5% used machine oil, industrial vaseline, or heavy oil) on the walls of the tower foundation, separating foundation and soil. When foundation soils are rich in soil moisture or water supply, mixing and heating of coarse sands with used oil (1:6 in weight), placing a 20-cm-layer of this mixture around the foundation, and compacting well offered one solution. Drainage controls such as ditches and a water-retaining berm on the shaded side of the tower, especially on the slope in the permafrost regions, can be applied to prevent re-entry of ground water to tower foundation soils. The effect of fine-grained soil can be reduced by replacing it with well-compacted, clean gravel (the <0.074 mm clay less than 12%) within 0.5 m around the foundations outer surface. Refills for bedrock tower locations should be well-compacted gravels, and the outer surface of the tower foundation should be lubricated.

On the basis of coefficients (δ), which are a percentage of volumetric settlement of vertical column of tested soil, the thaw-sensitivity of permafrost, can be divided into five grades as in Table 1.

Research on Frozen Subsoil

Analysis of frost-heave forces

The normal frost-heave forces toward the bottom of foundation were mitigated by deeper (greater than maximum frost or thaw penetration depth) burial of the tower foundation. The mitigative effect was enhanced using with well-compacted gravel to a depth of 0.3–0.5 m beneath the tower foundation.

For tower foundation in areas impacted by seasonally frozen ground, a lubricant separating foundation wall from subsoil was used for tower location with weak frost- heaving subsoils. For subsoils with frost heave to very strong frost heave susceptibility, a mixture of used oil and coarse sand was placed within 0.2 m around the foundation and compacted well after lubricating the foundation walls. The impact of fine-grained soil also was mitigated by clean gravel refill within 0.5 m around the foundation outer surface. Drainage control ditches on the shady side of the tower also were used on the slopes to cut off the surface water supply to foundation soils. Deeper burial of the tower foundation, compacted

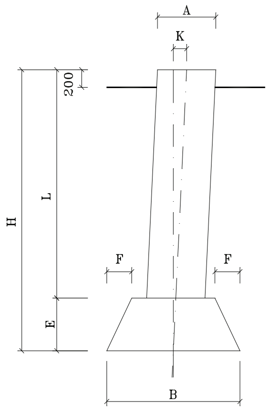

Figure 3. Sketch map of the oblique reinforced concrete column foundations for the power line tower.

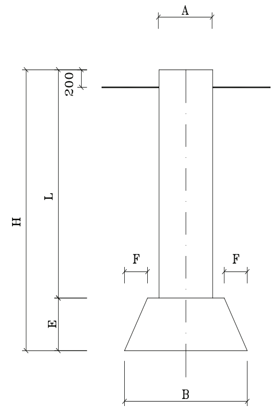

Figure 4. Straight reinforced concrete column foundation with constant cross-section.

gravel, reinforced structural integrity, and spatial stiffness were used to reduce deformation of foundation soils.

Soils above the permafrost table subjected to tangential seasonal frost-heave forces were mitigated using similar approaches. After the in-situ concrete-pouring during construction, permafrost temperatures beneath the bottom of the foundation rose, leading to thawing or thinning of permafrost. Therefore, the bearing capacity of unfrozen soils was used in design for safety. Deeper burial of tower foundation also was used to alleviate deformation of foundation soils.

In addition, the foundations were poured shortly after excavation, keeping the permafrost temperature as close to the original as possible. Thick ground-ice layers beneath tower foundations were removed. Local environmental and geological conditions were protected as cost-effectively as possible. Abandoned construction materials or soils were removed from around the tower foundations, and the ground surface was re-vegetated.

Design of Tower Foundations

Shallow foundation

Oblique column foundations of reinforced concrete (Fig. 3) to distribute the stresses were used extensively for the transmission line in montane areas. Frost-heave force was generally small, because the freezing of the subsoil generally lasted less than two months and resulted in very shallow (<1 m) seasonally frozen ground. Wind speed is generally less during the cold season, and frost-heave force is less than the anchorage force of the bottom of the foundation, satisfying the safety criteria for tower foundations.

Straight, reinforced concrete column foundation with constant cross-section (Fig. 4) also was used. Because the freezing time of subsoil was still short in shallow (<2 m) seasonally frozen soil regions, frost-heave forces were mainly affected by the subsoil features and moisture contents, satisfying the safety requirement of the transmission lines.

Straight reinforced concrete column foundation with variable cross-section areas (Fig. 5) was used where the subsoil freezing is long in deep (>2 m) seasonally frozen soil regions. This form of foundation more reasonably balanced the loads, made full use of material and effectively minimized the side surface area, such as to use the cylinder column, to reduce the tangential frost-heave forces.

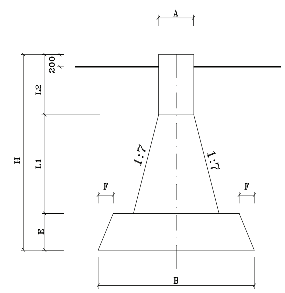

Figure 5. Straight reinforced concrete column foundation with variable cross-section.

Pile foundation

Pile foundations were suitable for frozen subsoil under all geological conditions. When the upper structure of foundation burdens was heavy and constraints for differential settlement deformation were critical, pile foundations were usually embedded in the permafrost layer to obtain higher bearing capacity with minor changes in the ground temperature field (Heilongjiang Province Academy of Cold Area Building Research 1989). Pile foundations were divided into drilled-hole driven-in pile, inserted-in pile, and cast-in-situ pile. Pile foundations were used in deep (>4 m) seasonally frozen soil regions and in permafrost wetlands. The advantages of pile foundation include minor damage to the environs and significantly-reduced disturbance to frozen subsoil. However, the disadvantages include more precise engineering requirements and higher investment.

In critically important situations, thermal or thermosyphon-cooled pile foundations (Figs. 6, 7, 8) were adopted to supplement other techniques for maintaining the stability of the subsoil. Thermal pile foundation included pile foundations where the pile itself was the thermosyphon, and pile foundations where the thermosyphon(s) were inserted

Figure 6. Thermosyphon-cooled tower of power transmission line in alpine meadow in the vicinity of Damxung along the Qinghai-Tibet Highway. The thermosyphons were installed in each of the four feet of the tower supported by mat/pile foundation.

Figure 7. Enlarged picture for details of the thermosyphon-cooled tower foundation.

into or around the pile foundation. Both kinds of foundation were used in warm permafrost to maintain the ground temperatures at the predesigned conditions and subsequent long-term stability of the frozen subsoil.

Tower foundation types and improvement of subsoils

Selection of tower foundation types:

Tower foundations were placed in non-frost or weakly frost-susceptible soil zones, such as the top of mountains with bedrock, slopes and lowlands with coarse-grained soils with the least possible soil moisture content.

Subsoil improvement:

a) Replace with non-frost or weakly frost-susceptible soils, such as clean gravels and sands, with less than 12% to 15% clayey particles. Refill depth 80% of the maximum depth of frost penetration, extended about 0.3–0.5 m on side wall of the foundation.

b) Physical and chemical smearing of 2–5 mm thick hydrophobic material such as heavy oil, bitumen mixed with 5% used machine oil, or industrial vaseline on wall of the foundation to reduce cohesion between the foundation and subsoil. Wrap the outside of the foundation with bituminous felt or impervious geotextiles and thickness of about 0.2–0.3 m of sand or gravel placed around the foundation.

c) Insulating material such as EPS, furnace slag, sod, or humic soil (peat) spread on the surface.

d) Drainage control to avoid water collection established at the sides of foundation. Excessive water drained by ground gutter or basal pipe/culverts.

e) Structure methods included deep anchored foundations. Burial depth of iron tower foundation should be 0.3–0.5 m more than the maximum depth of frost penetration to increase the anchorage forces of the foundations.

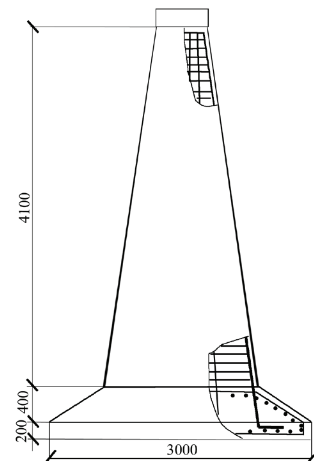

Figure 8. Sketch of reinforced concrete piling of tower foundation beneath the tower of Figures 3 and 4.

Operation Status

The 440-km long Amdo-Damxung power line was the largest electric network construction project. Construction started in April 2003, and was completed and put into operation in December. As a result of the project, the Central Tibet and Nagqü Power Networks were combined, greatly benefiting the local inhabitants and providing the critical needs for building the Qinghai-Tibet Railway.

During the early operation period, frequent power outrages were experienced due to bird and wind hazards. Some appreciable deformations and settlement were observed after the pouring of the concrete during construction. The deformations were later adjusted during the tower foundation installation processes. In addition, during construction in July and August 2003, the tower foundation subsoils at several sections were soaked by rain storms, resulting in differential settlement and horizontal displacement of tower foundations. It was soon rehabilitated and monitored afterwards, with satisfactory performance. Monitoring results during 2004–2007 indicated that the foundations in frozen ground were in designed condition.

Summary, Conclusions, and Prospects

a) The 110 kV power transmission line from Amdo to Damxung, Tibet Autonomous Region, China, is located in the patchy permafrost zone where frost heaving and thaw settlement were two challenging problems for design and construction of the line.

b) Surveys and assessment of frozen ground conditions for engineering geology were conducted for the evaluation of the potential of differential frost heaving and thaw settlement of tower foundation soils along the route.

c) The thermal and strain/stress of tower foundation and subsoils were analyzed for proper design and construction of the 110 kV power line.

d) Oblique and straight reinforced concrete column foundations and ordinary and thermosyphon-cooled pile foundations were proposed and adopted where appropriate. Tower site selection and ground improvement also were proven cost-effective.

e) Basic site selection principles included using bedrock foundations on mountain slopes and tops and coarse soils with least possible soil moisture on gentle slopes and lowlands.

f) Ground improvement measures generally included refilling with non- or weakly frost-susceptible soils, surface treatment to enhance water-proofing of foundation surfaces, insulation materials to decrease thaw penetration depths, drainage control to reduce frost heaving potential, and deep or bolted tower foundations exceeding the maximum depth of frost penetration.

g) The data bank and engineering measures, as well as experiences from the 110 kV power line would be very helpful for the proposed construction of 400 and 750 kV power transmission lines and other linear foundation engineering in warm, elevational permafrost.

Hydraulic Conductivity in Frozen Unsaturated Soil

Abstract

Freezing experiments of silt and sand columns were carried out, and water and heat flows were observed. To estimate unsaturated hydraulic conductivity of soils, $K(h)$, at above-freezing and subzero temperatures, Darcy's law was solved under a non-isothermal condition with ice formation. $K(h)$ steeply decreased with decreasing soil water pressure, h, and more gradually decreased with soil freezing. The results show that the hydraulic model, in which water content became constant under $h< -10^5$ cm, underestimated the $K(h)$ of frozen soil, and suggest that the impedance factor, which reduced $K(h)$ for frozen soil, is not necessary when accurate soil water and soil freezing characteristics are available. The hydraulic model, which can express two types of soil water flow, such as capillary and film flows, appears to be useful for expressing the hydraulic properties of soils under the freezing process.

Keywords: soil freezing characteristic; soil water characteristic; TDR; unsaturated hydraulic conductivity; water and heat flows.

Introduction

Knowledge of water flow in frozen and thawing ground is important to investigating water and solute redistributions in soil during winter (Baker & Spaans 1997) and in studying the mechanism of frost heaving (Wettlaufer & Worster 2006). Changes in soil properties, such as hydraulic conductivity, have also received research attention. For example, changes caused by ground freezing have been examined by applying an artificial soil-freezing technique to stabilize soil and form a barrier against hazardous waste (McCauley et al. 2002). Moreover, a major concern of hydrological and climate modeling is how to express change in soil hydraulic properties.

Burt & Williams (1976) and Horiguchi & Miller (1983) measured the steep decrease in hydraulic conductivity with soil freezing, although within a small temperature range. Using oil as a fluid, McCauley et al. (2002) measured saturated hydraulic conductivity of frozen soil at various temperatures. However, few experimental studies have examined the unsaturated hydraulic conductivity of frozen soil, $K_f(h)$. The unsaturated hydraulic conductivity of unfrozen soil, $K(h)$, is usually expressed by the formula proposed by Brooks & Corey (1964), Clapp & Hornberger (1979), or van Genuchten (1980). For frozen soil, Harlan (1973) used $K(h)$ instead of $K_f(h)$, assuming the same film-water geometry between frozen and unfrozen soils. However, numerical simulations have suggested that this assumption overestimates water flow near the freezing front (Harlan 1973, Taylor & Luthin 1978, Jame & Norum 1980). Guymon & Luthin (1974) and Tao & Gray (1994) expressed $K_f(h)$ from $K(h)$ by subtracting ice content from saturated water content. When the soil is frozen, the presence of ice in some pores may block water flow. To account for this blocking, several impedance factors have been introduced (James & Norum 1980, Lundin 1990, Smirnova et al. 2000). However, Black & Hardenberg (1991) criticized the use of an impedance factor, stating that it is a potent and wholly arbitrary correction function for determining $K_f(h)$. Newman & Wilson (1997) also concluded that an impedance factor is unnecessary when an accurate soil water characteristic curve and relationship between $K(h)$ and soil water pressure are defined.

Measuring unsaturated hydraulic conductivity for frozen soil remains difficult, and a complete expression for $K_f(h)$ is still not available. In addition, the model for $K_f(h)$ should be correlated with the soil water characteristics and soil freezing characteristics for ease of use in numerical simulations (Watanabe et al. 2007). In this experiment, we estimated $K_f(h)$ from water and heat flow measurements in a frozen soil column and discuss a model for $K_f(h)$.

Theory

Assuming that vapor and ice flows are negligible, variably saturated water flow in above-freezing and subzero soil is described using a modified Richards equation as follows (Noborio et al. 1996, Hansson et al. 2004).

$$\frac{\partial\theta(h)}{\partial t}+\frac{\rho_i}{\rho_l}\frac{\partial\theta_i(T)}{\partial t}=\frac{\partial}{\partial z}\left(K(h)\frac{\partial h}{\partial z}+K(h)+K(h)\gamma h\frac{\partial T}{\partial z}\right) \quad (1)$$

where θ is volumetric liquid water content, θ_i is volumetric ice content, t is time, z is a spatial coordinate, ρ_i is density of ice, ρ_w is density of water, h is the water pressure head, T is temperature, and γ is the surface tension of soil water. The terms in parentheses on the right-hand side of equation (1) represent the water flux, J_w, obtained from the change in the amount of liquid water and ice. Thus, if we measure the pressure and temperature gradient, $K(h)$ [or $K_f(h)$ at subzero temperature] would be derived as

*The value for thermal conductivity is average of 2 to 20°C for unfrozen soil and -5 to -20°C for frozen soil.

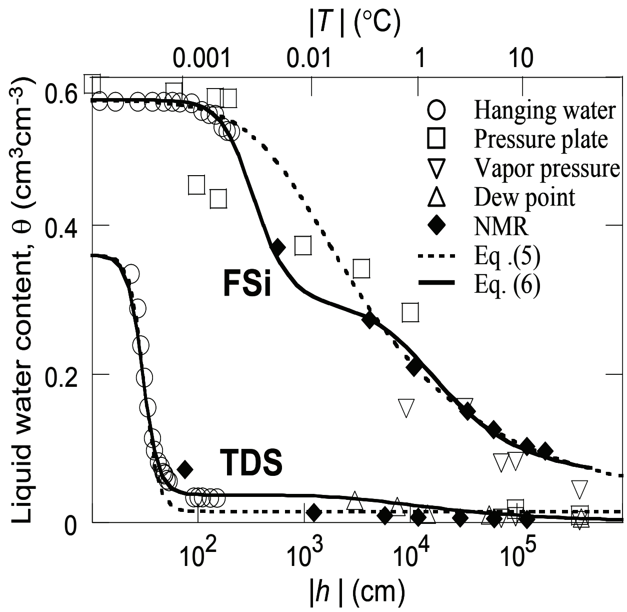

Figure 1. Soil water characteristics measured by hanging water, pressure plate, vapor pressure, and chilled mirror dew point measurement methods, and soil freezing characteristics measured by pulsed NMR measurement for FSi and TDS (in thawing process).

$$K(h) = -\frac{J_w}{\left(\frac{\Delta T}{\Delta z}\gamma h + \frac{\Delta h}{\Delta z} + 1\right)} \tag{2}$$

The value of h in unfrozen soil can be obtained from the soil water characteristics (relationship between θ and h) when measuring the profile of θ, while h in frozen soil can be calculated from the temperature profile derived from the generalized form of the Clausius–Clapeyron equation by assuming a differences between ice and water. Specifically, the ice pressure is sometimes assumed to equal zero gauge pressure (Williams & Smith 1989, Hansson et al. 2004):

$$\frac{dP}{dT} = \frac{L_f}{v_l T} \tag{3}$$

where P is the pressure (= $\rho_w gh$), g is the acceleration due to gravity, L_f is the latent heat of freezing, and v_l is the specific volume of water. Thus, equation (3) gives the soil freezing characteristics (relationship between θ and T) from the soil water characteristics and vice versa.

Material and Methods

The samples used in this study were Fujinomori silt (FSi) and Tottori dune sand (TDS). Figure 1 shows the soil water characteristics measured by several physical methods (Jury & Horton 2004) for both soils as well as soil freezing characteristics measured by pulsed nuclear magnetic resonance (NMR) measurement and depicted by equation (3). FSi is highly susceptible to frost and retains much liquid water even when $|h| > 10^4$ cm ($T < -1$°C), while for TDS, θ = 0.03 when $|h| > 10^2$ cm ($T < -0.01$°C).

The TDS were preliminarily washed in deionized water, and the FSi was passed through a 2 mm screen. Each sample was mixed with distilled and deionized water and packed into an acrylic column with an internal diameter of 7.8 cm and a height of 35 cm. Table 1 lists the experimental conditions and physical properties of the samples. Fifteen copper-constantan thermocouples and seven time domain reflectometry (TDR) probes were inserted into each column, and the side wall of the column was insulated. The TDR was preliminarily calibrated for measuring unfrozen water content by comparison to the pulsed NMR measurement. The column was settled at an ambient temperature of 2°C for 24 h to establish initial water and temperature profiles and then frozen from the upper end by controlling temperature at both ends of the column (T_L = -8°C and T_H = 2°C). During the experiment, no water flux was allowed from either end, and profiles of temperature, water content, and solute concentration (EC_a) were monitored using thermocouples and TDRs. A series of experiments with different durations of freezing were then performed for each freezing condition (i.e., same freezing rate and temperature gradient). At the end of the experimental series, the sample was cut into 2.5 cm intervals to measure the total water content by the dry-oven method. From thermocouples and TDR readings, it was confirmed that each column had the same temperature and water profiles during the series of experiments.

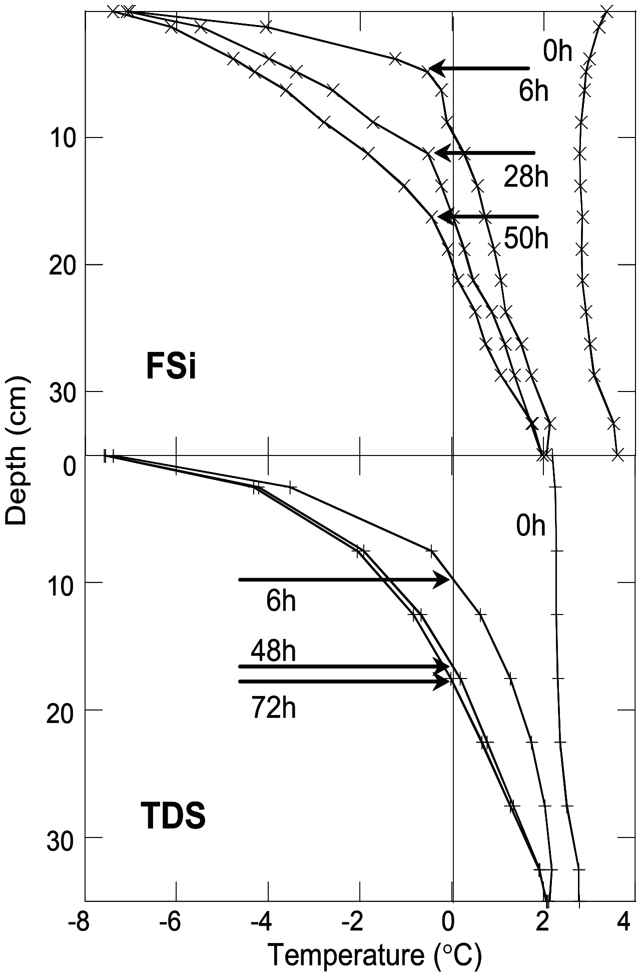

Figure 2. Temperature profiles for FSi (0, 6, 28, 50 h after freezing started) and TDS (0, 6, 48, 72 h after freezing started). Arrows represent the freezing front.

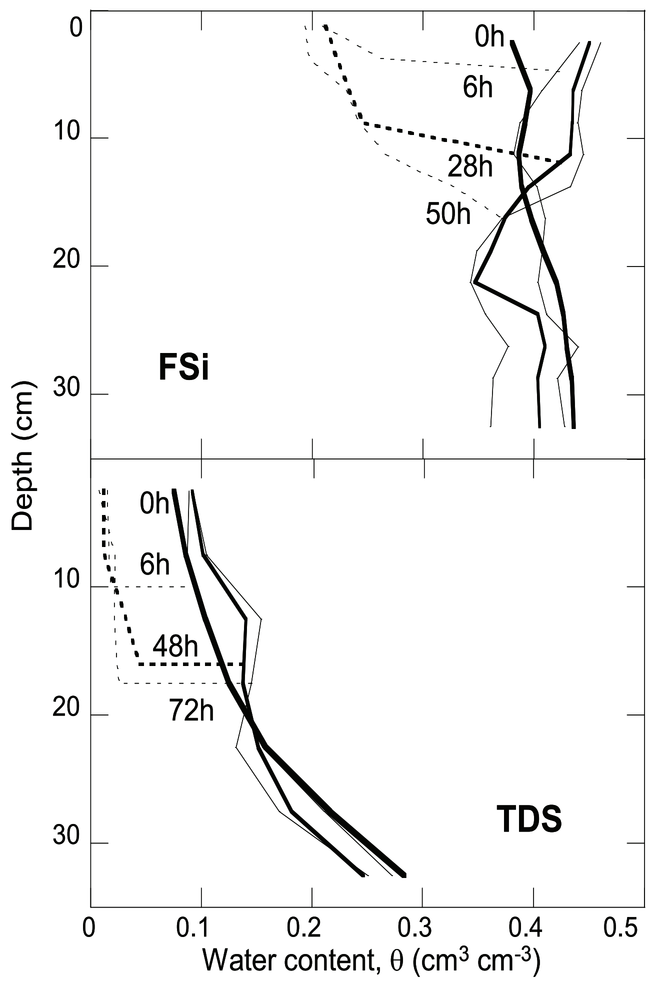

Figure 3. Moisture profiles for FSi and TDS at the same freezing time as shown in Figure 2. The solid line and dashed line represent total water and unfrozen water contents, respectively.

Results

Heat and water flow

Figure 2 shows temperature profiles of the freezing soils. When both ends of the column were set at different temperatures, the soil near the column ends quickly reached the required temperatures. In FSi, the advancing rate of the 0°C isotherm was 1.57, 0.34, and 0.16 cm h^{-1} for 0–6, 6–24, and 24–48 h, respectively, and approximately 0.25°C lowering of the freezing point was observed. The freezing rate of TDS was similar to that of FSi, although TDS had larger thermal conductivity (Table 1). Even after 72 h, the temperature profile of the subzero area in TDS did not reach a linear shape as in FSi and in the unfrozen area in TDS.

Figure 3 presents water profiles in FSi and TDS at the same freezing time as shown in Figure 2. The solid line indicates total water content, θ_t, measured by the dry-oven method, and the dashed line indicates unfrozen water content measured by TDR. The ice content, θ_i, was obtained by subtracting the unfrozen water from the total water content. FSi had a relatively vertical initial θ profile, having similar θ values for h <100 cm (Fig. 1). An increase of θ_t, decrease of θ in the frozen area, and decrease of θ in the unfrozen area with the advancing freezing front were observed, implying that the soil water flowed not only through the unfrozen area, but also the frozen area. The gradient of the initial θ profile of TDS corresponded to its soil water characteristics (Fig. 1). In TDS, the soil water in the unfrozen area flowed to and accumulated near the freezing front because of suction at the freezing front caused by ice formation. Water flow in the unfrozen area continued 48 h or later after freezing began, although there was no apparent advance of the freezing front. Meanwhile, much less water flow was observed in the frozen area.

The profile of water flux, J_w, was then calculated by developing θ profiles (Fig. 3) with the boundary condition of no water flux. In early stage of freezing (0–6 h), soil water in almost the entire column moved upward at about J_w = 0.04 cm h^{-1} for FSi and J_w = 0.01 cm h^{-1} for TDS. The progression of the peak observed in the J_w profile coincided with the freezing front. In the frozen area, J_w in SFi was ≥10 times larger than that in TDS and exponentially decreased as the temperature decreased ($J_w = 0.007|T|^{-0.69}$ for FSi and $0.0012|T|^{-1.45}$ for TDS).

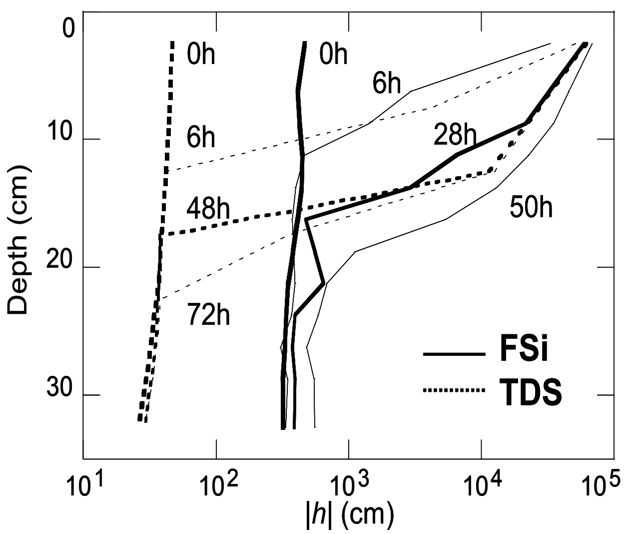

Figure 4. Profile of soil water pressure estimated from Figures 2 and 3.

Change in hydraulic conductivity

Figure 4 shows the profile of soil water pressure h estimated by the soil water characteristics (Fig. 1) with the θ profile (Fig. 3) and equation (3) with the temperature profile (Fig. 2). Solute effect was negligible during the experiments, since very low solute concentration was confirmed by TDR (EC_a) readings. Note that for equation (3) there was discontinuity in the h profiles near 0°C, especially for unsaturated soil; therefore, we used linear interpolation to connect the closest calculated h values between the unfrozen and frozen areas. With freezing, $|h|$ steeply increased ($h < -10^3$ cm). A larger difference in h between unfrozen and frozen areas was observed in TDS than in FSi.

The non-isothermal version of Darcy's law (Eq. 2) could consequently by solved with the J_w, T, and h profiles, obtaining the relationship between the unsaturated hydraulic conductivity, $K(h)$, at above-zero and subzero temperatures with the soil water pressure, as shown in Figure 5. In the range $h > -10^3$ cm (unfrozen), $K(h)$ decreased steeply with increasing $|h|$, while it decreased gradually in the range $h < -10^3$ cm (frozen). Similar $K(h)$ was observed when different freezing conditions were applied (T_L = -5°C and T_H = 5°C in Fig. 5 for TDS). These changes were clearer for $K(h)$ of TDS, which agreed well with the value obtained using the evaporation method (Sakai & Toride 2007). In the frozen area, $K(h)$ in FSi was about 10 times larger than that in TDS, which is why more water flow was observed in frozen FSi. Figure 6 shows the relationship between $K(h)$ and liquid (unfrozen) water content measured by TDR. In frozen TDS, $K(h)$ decreased steeply from 10^{-5}–10^{-8} cm h^{-1} with decreasing θ from 0.04–0.01 cm^3 cm^{-3}, while $K(h)$ of frozen FSi decreased more gradually.

The $K(h)$ of frozen soil also correlated with temperature T and with ice content θ_i. The decrease of $K(h)$ with lowering T and θ_i was well fitted by power law as $K(h) = 3 \times 10^{-6}\,|T|^{-1.49}$ and $K(h) = 2.3 \times 10^{-8}\,\theta_i^{-2.42}$ for FSi, and $K(h) = 0.7 \times 10^{-6}\,|T|^{-1.75}$ and $K(h) = 8.2 \times 10^{-14}\,\theta^{-6.96}$ for TDS. This power law relationship was consistent with the relationship between J_w and $|T|$ mentioned above. The θ_I–T relationship is sometimes expressed by power law (Anderson & Tice 1972) and can be converted through equation (3) to a θ -h relationship, which may also be expressed by power law (Brooks & Corey 1964). The shape of the formula indicating $K(h)$ may arise from the soil water characteristics (θ-h) and soil freezing characteristics (θ_i-T).

Discussion

Soil freezing characteristics

Soil freezing characteristics are sometimes interpreted from the surface force, pore curvature, when solute effect is negligible (Dash et al. 1995, Watanabe & Mizoguchi, 2002). The surface force accounts for the power law shape of soil freezing characteristics and the effect of the curvature known as the Gibbs–Thomson effect, which creates a shoulder to the soil freezing characteristics by means of the freezing temperature depression, $T_m - T$ depending on the soil pore radius r:

$$T_m - T = \frac{T_m \sigma}{\rho_i L_f r} \tag{4}$$

where T_m is the freezing temperature of bulk water and σ is the ice-water interface free energy. In the soil pore size distribution, two peaks are presumed: one from pores among the soil particles (r = 5–50 μm) and the other from pores on the particle surface (r = 3–10 nm). These peaks would yield two shoulders to the soil freezing characteristics around -0.001 to -0.1°C and -2.5 to -10°C, respectively. By converting the soil freezing characteristics to soil water characteristics through equation (3), the warmer shoulder would correspond to air entry. In the range from water saturation to the other (colder) shoulder, soil water will flow predominantly as capillary flow, but will change to film flow at h lower than the colder shoulder. Soil water characteristic models proposed by Brooks & Corey (1964) and van Genuchten (1980) (Eq. 5) are intended to express unsaturated soil with moderate h and give the constant θ (defined as resident water content, θ_r) at extremely low h. These models, therefore, cannot express the area around the colder shoulder, which is an important portion for soil freezing characteristics (Fig. 1). Durner (1994) combined two van Genuchten models, which express different soil water characteristics, to describe water retention in a soil having a dual porosity distribution (Eq. 6):

$$S_e = \left(1 + |\alpha h|^n\right)^{-m} \tag{5}$$

$$S_e = w_1\left[1 + (\alpha_1 h)^{n_1}\right]^{-m_1} + w_2\left[1 + (\alpha_2 h)^{n_2}\right]^{-m_2} \tag{6}$$

where $S_e = (\theta - \theta_r)(\theta_s - \theta_r)^{-1}$, $m = 1 - n^{-1}$, $w_1 = 1 - w_2$, θ_s is saturated water content, α and n are empirical parameters,

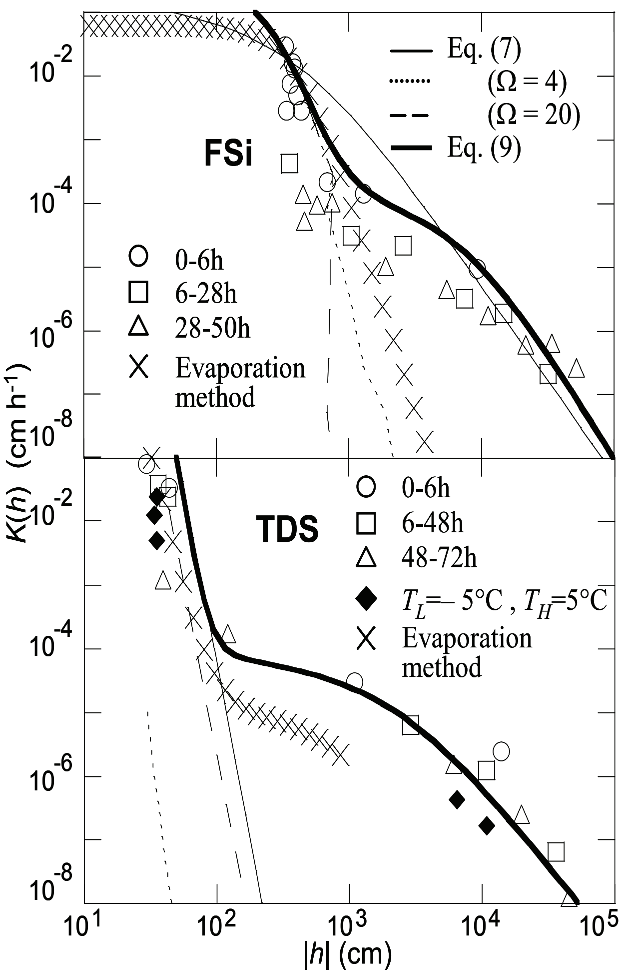

Figure 5. Relationship between unsaturated hydraulic conductivity [$K(h)$] and soil water pressure at above-zero and subzero temperature. Table 1 lists the parameters for equations (7) and (9).

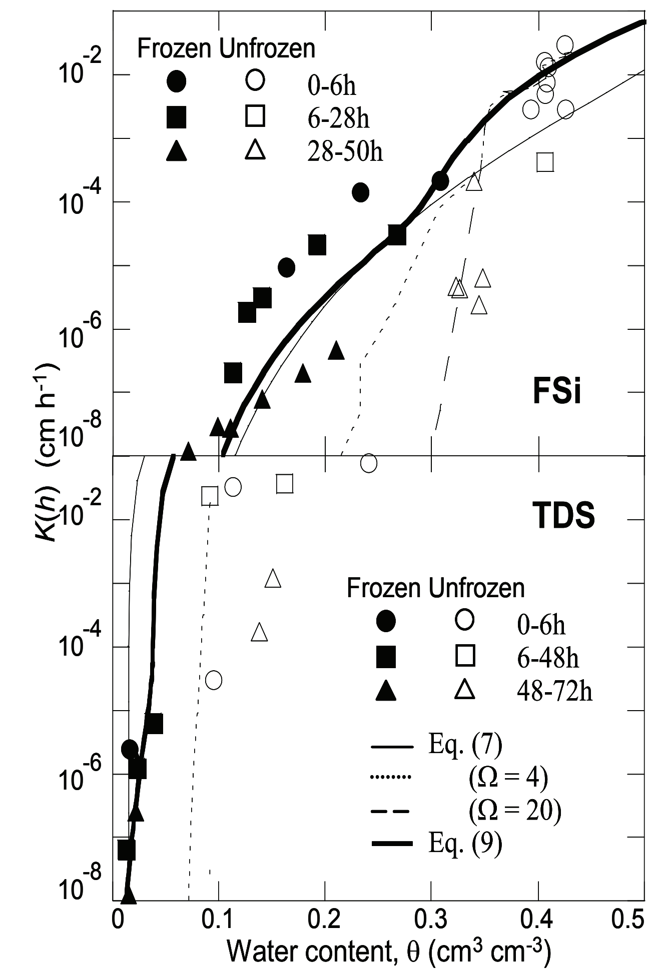

Figure 6. Relationship between unsaturated hydraulic conductivity, $K(h)$, and soil water content at above-zero and subzero temperature. Table 1 lists the parameters for equations (7) and (9).

and w_2 is the weighting factor. Using the parameters listed in Table 1, equation (6) was well fitted to a wide range of soil water characteristics, including soil freezing characteristics, for FSi and TDS (Fig. 1).

Unsaturated hydraulic conductivity for frozen soils

The unsaturated hydraulic conductivity for unfrozen soil, $K(h)$, is often derived from equation (5) (van Genuchten 1980) as follows:

$$K(h) = K_s S_e^l \left[1-\left(1-S_e^{1/m}\right)^m\right]^2 \tag{7}$$

where l is the pore-connectivity coefficient. For frozen soil, $K(h)$ is sometimes reduced by an impedance factor Ω (Lundin 1990, Hansson et al. 2004):

$$K(h)_{frozen} = 10^{-\Omega\theta_i/(\theta_t-\theta_r)} K(h) \tag{8}$$

Applying equations (7) and (8) to our measured $K(h)$ verified that equation (7) could not fit the gradient change of $K(h)$ around $h = 10^{-3}$ cm for FSi and underestimated $K(h)$ at $h < -10^2$ cm for TDS (Fig. 5). The impedance factor might be useful for expressing the steep decrease of $K(h)$ near 0°C, if equation (5) were fitted to the whole range of soil water characteristics (FSi in Figs. 5, 6). However, use of an impedance factor requires caution since it will underestimate $K(h)$ as freezing progresses.

The design of equation (7) was based on the bundle of capillary tube model in which water flow decreases with square decrease in the pore (tube) radius, as Poiseuille flow, and produces a linear reduction in $K(h)$ on a log–log scale when θ is constant. On the other hand, film water can be regarded as the flow proportional to the first or less root of film thickness. The $K(h)$ of frozen soil consequently has a lower grade than that of unfrozen soil. Thus, the Durner model was again applied to $K(h)$, taking care that θ did not become constant at $10^{-3} < h < 10^{-6}$ cm ($-0.1 < T < -100$°C).

$$K\left(S_e\right) = K_s\left(w_1 S_{e1} + w_2 S_{e2}\right)^l \times \frac{\left(w_1\alpha_1\left[1-\left(1-S_{e1}^{1/m_1}\right)^{m_1}\right] + w_2\alpha_2\left[1-\left(1-S_{e2}^{1/m_2}\right)^{m_2}\right]\right)^2}{\left(w_1\alpha_1 + w_2\alpha_2\right)^2} \tag{9}$$

Equation (9) showed good agreement with the $K(h)$ obtained from the column freezing experiment (Figs. 5, 6). This model was originally used for explaining water flow containing two different flow rates, such as among and within soil aggregates. Our results suggest that this model is also suitable for soils under freezing-thawing processes, in which soil water flow changes from capillary flow to film flow.

Conclusion

The sand and silt columns were frozen directionally, and the water and heat flows during soil freezing were measured. The flows depended on the soil types. Unsaturated hydraulic conductivity for frozen and unfrozen soils was estimated by solving Darcy's law under non-isothermal conditions with ice formation, although further consideration of the precision of flux measurements and limits of the Clausius-Clapeyron equation may be required. Hydraulic conductivity steeply decreased with decreasing soil water pressure and water content in unfrozen soil but more gradually decreased in frozen soil. In both unfrozen and frozen states, the silt had higher hydraulic conductivity than the sand, resulting in more water flow during silt freezing.

The shapes of soil water characteristics and soil freezing characteristics were discussed from the viewpoint of the pore size distribution. Use of an impedance factor for calibrating the hydraulic conductivity of frozen soil, which has sometimes created unstable numerical simulations, appears to be unnecessary when the hydraulic model can appropriately express both the soil water and freezing characteristics. Rather, the results suggest that the Durner model is useful for expressing the hydraulic properties affected by the change in the type of water flow during soil freezing.

Abstract

Ground-penetrating radar (GPR) was used to sound subsurface structures below troughs delimiting non-sorted polygons in Svalbard. On marine terraces, a single hyperbolic reflection spreads downward from the ground surface, which represents an active layer soil wedge. Some large troughs are underlain by double hyperbolic reflections extending downward from the ground surface and the frost table, which correspond to a soil wedge and an underlying ice wedge, respectively. On fluvial terraces, a hyperbolic reflection extends downward from the frost table, which represents an ice wedge; the width of the hyperbola corresponds to the width of an ice wedge. The hyperbolic reflections originate from the contrast in water content between the wedge filling and the host material. These results indicate that GPR is useful for distinguishing ice and active layer soil wedges in terms of depth of the hyperbola and for estimating the width of ice wedges without excavation.

Keywords: ground-penetrating radar; ice wedge; non-sorted polygon; soil wedge; Svalbard.

Introduction

Non-sorted polygons are one of the most widespread periglacial landforms in Svalbard. Most of them occur on the bottoms and slopes of inland valleys, uplands surrounding the valleys (Sørbel et al. 2001, Tolgensbakk et al. 2001), and on strandflats (Åkerman 1980, 1987). Direct excavation and drilling revealed that ice wedges are predominant in Adventdalen (inland valley), while active layer soil wedges are more common in Kapp Linné (strandflat) despite similar surface patterns (Matsuoka & Hirakawa 1993). Thus, surface patterns cannot indicate the presence of ice wedges. Since direct methods are time consuming, more convenient methods are required to relate surface geometry to subsurface wedge structures.

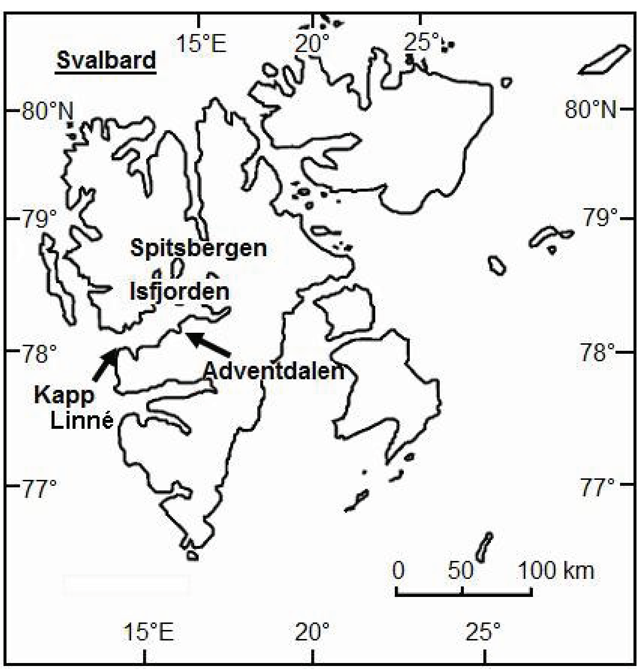

Figure 1. Locations of the study areas.

Ground-penetrating radar (GPR) is a useful tool for imaging near-surface structures. GPR has been applied to permafrost studies since the 1970s to identify areas of massive ground ice (e.g., Dallimore & Davis 1987), internal structure of rock glaciers (e.g., Berthling et al. 2000) and pingos (Ross et al. 2005, Yoshikawa et al. 2006), and to determine the depth of the permafrost table and ice wedges (Hinkel et al. 2001). A recent GPR study attempted to visualize near-surface structures in permafrost with three-dimensional images (Munroe et al. 2007). We also applied GPR to visualize subsurface wedge structures, and particularly to distinguish ice wedges from active layer soil wedges in Svalbard. Furthermore, ice wedge width was estimated from the reflection patterns of radar signal.

Study Sites

Svalbard is an archipelago situated between 74°N to 81°N and 10°E to 35°E. The largest island is Spitsbergen, which covers an area of 38,000 km^2 (Fig. 1).

Kapp Linné is located at the southern edge of the mouth of Isfjorden, central Spitsbergen (Fig. 1). The area is located on a wide strandflat composed of a sequence of raised marine terraces with beach ridges, small lakes, and bogs. The strandflat emerged above sea level after the Lateglacial deglaciation (11–5.5 ka BP) (Landvik et al. 1987). A number of relatively small polygons (5–15 m in diameter) developed on the raised beach ridges consisting of gravely sand and lacking vegetation. The polygons are mostly highcentered and delimited by narrow and shallow troughs. The mounds and troughs are well distinguished by the presence of vegetation only in the latter. The troughs mostly lack well-defined rims at both sides except for some extraordinarily large ones. Åkerman (1980) mapped most of the troughs underlain by active layer soil wedges but extraordinary large ones having ice wedges. Similar mounds and troughs also sporadically occur on the bogs which are composed of peat and covered with vegetation. However, they rarely constitute polygonal patterns and are usually obscured by full vegetation. Åkerman (1980) classified them as ice wedge polygons. The mean annual air temperature (MAAT) is −4.9°C in Kapp Linné (Åkerman 1996). Permafrost is nearly continuous except for a karst area (Salvigsen et al. 1985). The active layer thickness varies from 0.3 m in the bogs to 2 m on the raised beach ridges (Åkerman 1980).

Adventdalen is a broad, U-shaped valley joining Isfjorden at Longyearbyen (Fig. 1). The lowermost 15 km of the valley bottom is covered with fluvial sediments composed of branched river flood plain deposits (Tolgensbakk et al. 2001). Large, low-centered, hexagonal polygons are widespread on the Adventelva river terrace, where the fluvial sediments are covered with fine-grained loess about 3 m thick. The polygons are typically delineated by troughs a few centimeters to 40 cm deep and 20–100 cm wide. The variation in trough size probably represents different generations of thermal contraction cracks constituting a complex polygonal network (Christiansen 2005). MAAT is -6.5°C (1961–1990) at Svalbard Lufthavn (airport) in Longyearbyen (Hanssen-Bauer et al. 1990). Permafrost is continuous, and its thickness is estimated to be 220 m at Janssonhaugen, located in the upper Adventdalen (Isaksen et al. 2001). The thickness decreases to less than 100 m approaching the sea (e.g., Humlum et al. 2003). The active layer thickness in Adventdalen is about 1 m in the fine-grained loess (Christiansen & Humlum 2003).

Methods

Surveys were conducted in late June and late July 2007 in Kapp Linné and in early July 2006, end of July, and middle of August 2007 in Adventdalen. The numbers of survey lines in Kapp Linné and Adventdalen are 44 and 36, respectively. The GPR used in this study was a Noggin Smart Systems, produced by Sensors & Software Inc. The system consists of a cart, an antenna box (Noggin 250), an odometer wheel, a digital video logger, and a battery. The 250 MHz signal was applied to the survey of wedge structures. The resolution is enough to display the target, although the radar signal tends to attenuate in thawed fine-textured sediments.

The GPR antenna transmits electromagnetic pulses into the ground. The transmitted wave is reflected at geological boundaries that have an electromagnetic impedance contrast. The two way travel time (TWT) for the reflected waves is recorded and plotted on a diagram. Radar records were processed with the RADPRO for Windows version 3.0 (Korea Institute of Geoscience and Mineral resources). Processing included conversion of TWT to the depth scale, removal of the direct ground wave during radar acquisition, topographic modification, and gain adjustments. Converting TWT to the depth scale requires the radar transmission velocity in the layer or layers above the reflector. The velocity was determined by direct depth measurements or a point-source reflection analysis. The latter permits estimation of the radar transmission velocity using the shape of hyperbolic patterns produced by point structures (Moorman et al. 2003). The GPR images were compared with the results of direct excavation and/or drilling at six troughs. Soil samples were taken at these troughs to determine the grain size distribution and water content to interpret GPR images, because the contrast of water content, which mainly depends on the difference in grain size distribution at a depth, results in different dielectric constants.

Results and Interpretations

Kapp Linné: Marine terraces

The GPR profiles across polygon troughs developed on beach ridges displayed strong horizontal and hyperbolic reflections (Fig. 2a). The point-source reflection analysis using the hyperbolic reflections estimated that the propagation velocity was around 0.065–0.090 m/ns. This velocity indicates that the horizontal reflections were located at about 1 m depth, which corresponded to the depth of the frost tables revealed by excavation. This coincidence demonstrates that the estimated velocity was reasonable, although the velocity was slightly small for sandy materials. Most of the polygon troughs were accompanied by a hyperbolic reflection extending downward from just below the ground surface. Ice wedges tend to show strong hyperbolic reflections (Hinkel et al. 2001), while the hyperbolas in Kapp Linné are located at depths too shallow for ice wedges. In fact, two excavated troughs on a marine terrace displayed active layer soil wedges restricted within the upper 20–40 cm depth of the active layer (Fig. 2b). The GPR profiles also displayed minor hyperbolic reflections below polygon mounds, which appear to be produced by large stones in the marine sediment.

The GPR profiles of four extraordinarily large troughs were characterized by double hyperbolic reflections extending downward from the ground surface and at about 1 m depth, respectively (Fig. 3a). The upper reflection corresponds to that of active layer soil wedges below smaller polygon troughs. In contrast, the lower reflection may indicate the presence of an ice wedge, because the top of the hyperbola approximates the permafrost table. An excavation conducted in late July exposed a soil wedge just below the trough, surrounded by marine sand partly containing gravels (Fig. 3b). The width of the wedge approximates that of the trough (ca. 80 cm). Despite consisting of similar material to the surrounding marine sediments, the

wedge filling is distinguished by a difference in color. A thin organic layer covers the trough and intrudes into the wedge filling to about 80 cm depth. This intrusion may have originated from the latest cracking activity. The soil wedge extends below the frost table (at ca. 105 cm depth). Further drilling into the permafrost confirmed the presence of an underlying ice wedge which penetrates deeper than 270 cm. The ice wedge corresponds to the lower GPR reflection.

Kapp Linné: Bogs

GPR profiles of widely spaced polygon troughs in bogs showed a narrow hyperbolic reflection underlying a strong horizontal reflection, although the wet surface significantly attenuated the radar signals (Fig. 4a). The propagation velocity was estimated to be around 0.070 m/ns by the point-source reflection analysis using the hyperbolic reflection. This velocity suggests that the top of the hyperbola lay at about 0.3 m depth. Such a hyperbolic reflection may indicate the presence of an ice wedge. The drilling and excavation in late July actually confirmed the presence of a narrow ice wedge reaching 130 cm depth. The excavation displayed a peat layer about 20 cm thick overlying marine sediments. A peat wedge penetrates into the marine sediment below the trough. The active layer thickness was thin and varied from 25 cm in the wedge to 35 cm in the marine sediment. The shallow frost table corresponded to the strong horizontal reflection on the GPR profile. An ice wedge with a top width of 30 cm occurred below the peat intrusion. The top of the ice wedge was located at 40 cm depth. Such a structure agrees with the narrow hyperbolic reflection. The trough lacked a double hyperbola pattern, although the peat intrusion formed an active layer soil wedge above the ice wedge. This is probably due to the difficulty in resolving two features which are so close to each other with a 250 MHz antenna.

Adventdalen: Fluvial terraces

GPR profiles displayed two kinds of reflections: (1) multiple horizontal reflections, which are slightly deformed below troughs; and (2) hyperbolic reflections, which underlie horizontal reflections below troughs (Fig. 5). The point-source reflection analysis using the hyperbolic reflections estimated that the radar velocity was about 0.050 m/ns, which was lower than the values of ice wedges in Kapp Linné. This is probably due to the low propagation rate in the poorly drained loess material. The estimated velocities suggest that the tops of the hyperbolic reflections were located at 1.2 m depth, regardless of the size of the polygon trough. A series of drilling holes across two polygon troughs reproduced the structure of the ice wedges. The drilling revealed that ice wedges were about 1.9 m wide below well-developed troughs (Fig. 5a) and about 0.5 m wide below shallow troughs (Fig. 5b). Below the shallow troughs, the centre of the ice wedge did not agree with the new crack at the ground surface. This relationship was correctly shown in the GPR profile (Fig. 5b), which indicates that the ice wedge has unevenly developed. The top of a hyperbola roughly corresponded to an edge of the ice wedge, which means that the width of hyperbola top represents the width of an ice wedge. The disturbance of the horizontal reflections below the trough may have originated from thermal contraction cracks filled with air and meltwater.

Influences of Grain Size and Water Content on GPR Profiles

Both of the ice and soil wedges showed strong hyperbolic reflections. This means that the dielectric constant is considerably different between ice and frozen soil and between a soil wedge and the host sediment. The dielectric constant varies with material of solids and air and water contents. In particular, the dielectric constant of water significantly affects the composite dielectric constant of soil, because water has an extremely high dielectric constant compared to other substances. These influences were evaluated by measurements of grain size distribution and water content of soils.

Figure 6 summarizes the grain size distribution of soils at 4 sites. The soil samples were taken from both the soil wedge and the host sediment. In Kapp Linné, the composition of the soil-wedge filling is different from that of the marine sediment. Below a marine terrace where a single hyperbola occurs by a soil wedge, the wedge filling is significantly finer than the marine sediment. Below a beach ridge where the double

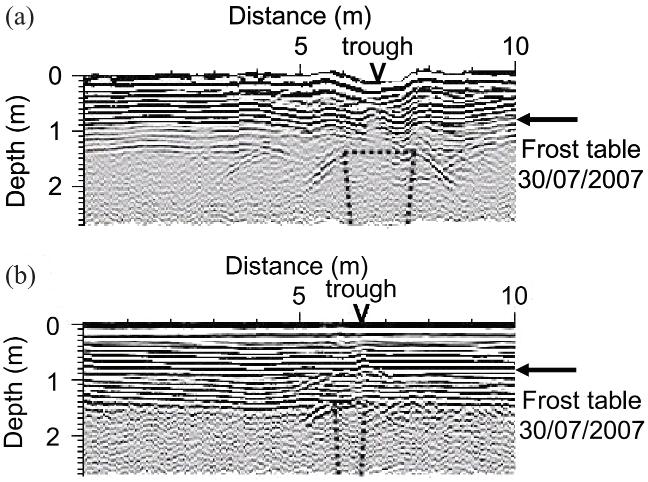

Figure 5. Subsurface structures below low-centered polygons on a fluvial terrace in Adventdalen. (a) A GPR profile across a large polygon trough. (b) A GPR profile across a small polygon trough. The broken lines illustrate ice wedges indicated by drillings.

hyperbolic reflections occur, the wedge and host sediment show similar mean grain sizes, but the wedge filling ranging from gravel to silt, shows a wider size distribution than the host sediment. The difference may result in a different porosity and influence the dielectric constant. A large difference in grain size occurs between samples derived from the bog site, although the soil wedge lacks a hyperbolic reflection. This may result from soil wedge too thin to be detected by 250 MHz signals. In contrast, the samples obtained from the Adventdalen river terrace indicate similar grain size distributions between the soil wedge and the host loess. This probably explains why double hyperbolic reflections did not occur at the Adventdalen study site, where the soil wedges are filled with similar material to the host sediments.

Table 1 shows water contents in and around the soil wedge below the marine terrace at Kapp Linné in summer. The ground surface was dry when the samples were collected. The soil wedge has significantly higher water content than the surrounding materials. This is probably because the organic materials composing the soil wedge have a high water retention capacity, while the marine sediments are highly drained. The contrast probably induces strong reflections.

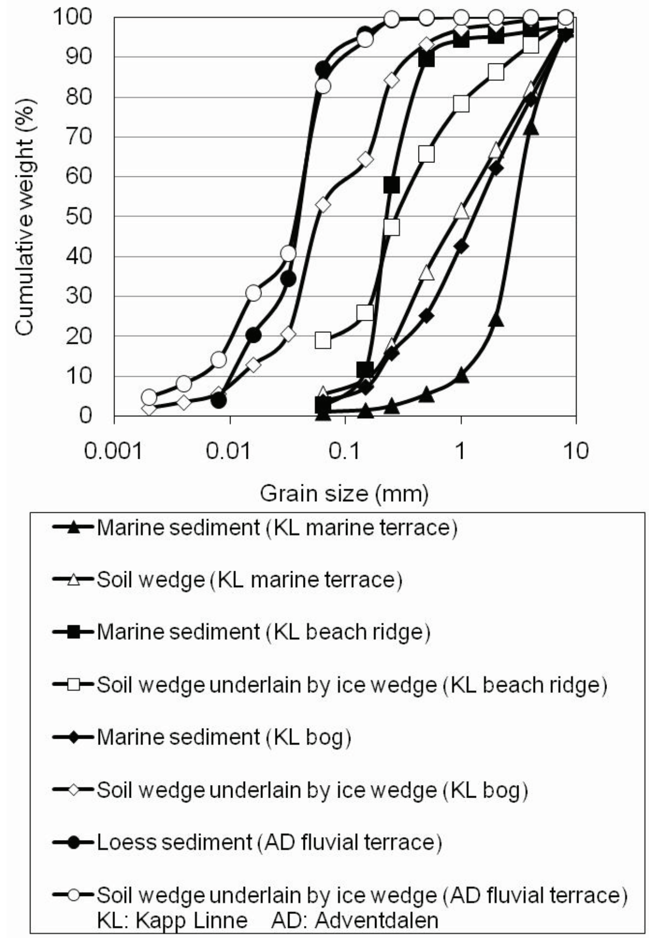

Figure 6. Grain size distribution in soil wedges and the host materials.

Table 1. Volumetric water contents in a soil wedge and the host materials at the Kapp Linné marine terrace site. Samples were taken on July 24, 2007.

Sampling point	*Water content (%)*
Soil wedge (organic)	40.8
Sand layer below soil wedge	15.7
Sand layer aside of soil wedge	8.8
Gravel layer below soil wedge	6.2

Conclusions

The GPR profiles across non-sorted polygons show characteristic reflections representing ice and soil wedges. Hyperbolic reflections extending downward from the ground surface represent active layer soil wedges. Such a sharp reflection is considered to originate from the different water content between the soil wedges and the host sediments. Ice wedges show hyperbolic reflections extending downward from the frost table. The width of the hyperbola roughly coincides with the width of an ice wedge determined by drilling. Where a soil wedge in active layer is underlain by an ice wedge, troughs are underlain by double hyperbolic reflections extending downward from the ground surface and the frost table.

These results indicate that GPR is useful for distinguishing ice and active layer soil wedges, in terms of the depth of hyperbolic reflections, and for estimating the width of ice wedges without excavation or drilling down to permafrost.

Abstract

In northeastern China, mean annual air temperature (MAAT), as a main control factor, increased by 1°C between 1975 and 2000 as compared to 1951–1975 with a warming rate of 0.04°C/yr. In the absence of adequate borehole temperature data, geographic factors such as latitude, longitude, elevation, aspect, and slope were used to describe the present distribution of permafrost and to model scenarios of its potential future changes. The result showed that latitude is the primary factor that determines the distribution of MASST, enabling an equivalent latitude model (ELM) to be constructed and a GIS-based map of present-day MASST distribution to be drawn. Future permafrost changes 50 years from now were then estimated by finite-element modeling. The results indicate that permafrost thickness would not change greatly, apart from some south-oriented slopes, but that permafrost degradation would primarily be caused by increasing mean annual ground temperature.

Keywords: finite element; forecast; mean annual soils surface temperature; modeling, northeastern China.

Introduction

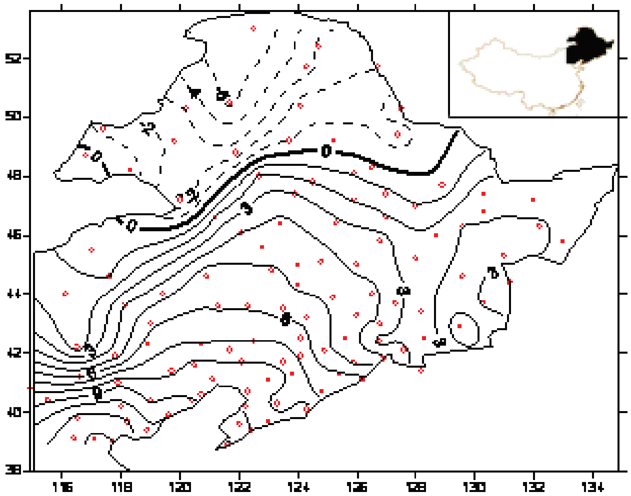
Permafrost in northeastern China (NE China) is warm, thin, and sensitive to atmospheric warming. Research on permafrost in northeastern China was initiated in the early 1950s. During the 1960s and 1970s numerous regional investigations, together with local studies for specific purposes such as water supply, road construction, or coal-mining, were conducted in order to meet the needs of economic development. The boundaries of continuous (>65% occupation), discontinuous (50%–60%), and sporadic permafrost (5%–30%) were empirically determined to correlate with the -5°C, -3°C, and 0°C isotherms of mean annual air temperature, respectively. This pattern has strongly changed during about 30 years of ongoing atmospheric temperature rise and heavy direct impacts from human activities. The most influencing human activities are unceasing deforestation, frequent forest fire, and some large-scale constructions. All these natural and non-natural realities affected the existing and developing conditions of permafrost in NE China. (Zhou & Wu 1965, Guo & Li 1981, Guo et al. 1981, Dai 1982, Northeastern China Permafrost Research Taskforce 1983, Guo & Huang 1989, Peng & Cheng 1990, Lu et al. 1993, Gu & Zhou 1994, Zhou et al. 1996). Degradation of permafrost in northeast China has been of considerable concern during the past decade (Gu & Zhou 1994, Chen & Yin 1996, Wang et al. 1996, Zhou et al. 1996). Many major engineering and environmental projects such as express highways and high-speed railways, the proposed China-Russia Crude Oil Pipeline from Skovorodino, Russia to Daqing, China, or a hydropower project near the Heilongjiang (Amur) River, necessitate an understanding of the status and possible future evolution of permafrost in the NE China over the next 30–50 years. This paper analyzes the effects from increasing MAAT, introduces a concept of MASST zonality, and presents a preliminary forecast concerning the future trends of permafrost conditions in NE China.

Changes of MAAT and MASST

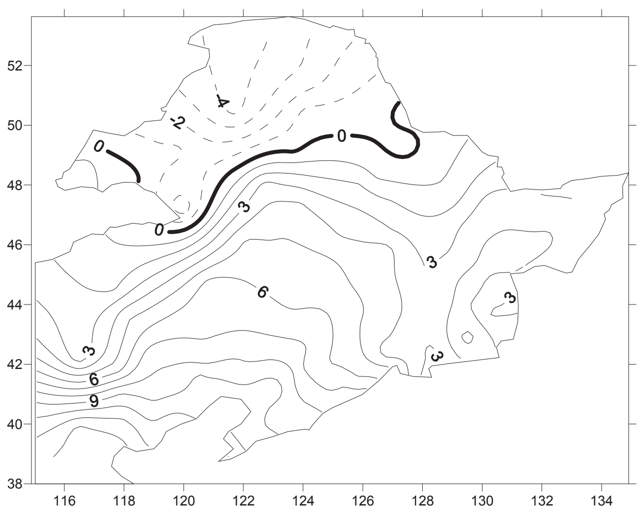
Climate change and permafrost condition

Long-term (1951–2000) monthly air temperature records of 117 meteorological stations (Fig. 1a) in regions with continuous or discontinuous permafrost or seasonally frozen ground within the study area of NE China showed a pronounced warming tendency comparable with warming trends observed in northward zones in Siberia (Yang et al. 2000). In the 1970s, the southern limit of permafrost (SLP) and boundaries between different types of continuous, discontinuous, and sporadic permafrost in NE China were determined by Northeastern China Permafrost Cooperation Group (NCPCG) (Guo et al. 1981). Comparison of the two time intervals 1951–1975 and 1976–2000 illustrates the notable long-term warming trend (Figs. 1a, b).

The pattern of isotherms is quite similar during both time periods but documents a shift in MAAT of about +1°C between the two considered time intervals. This change will definitely affect permafrost: its existence, distribution, thermal condition, and active layer depth. Using the MAAT range of -1°C and +1°C for southern limit of permafrost occurrence (SLP), its climate-induced northward displacement can be estimated at 40–120 km in accordance with previous studies (Jin et al. 2007).The principal cause of the observed permafrost degradation in NE China is atmospheric warming which has occurred since the end of the 19th century. Based on decadal average air temperatures (DAATs) from northeastern China, this change can be divided into three main periods: (1) persistent warming from the end of the 19th century to the 1940s; (2) quasi-stable



(a)



(b)

average temperatures during the 1950s to the 1970s; and (3) a second persistent warming from 1970 to 2000, particularly during 1991–2000a (Qin 2002).

Soils surface temperature and climate change

Mean annual soils surface temperatures (MASST) are primarily influenced by air temperature. In order to better understand their changes in the study area as related to conditions of atmospheric warming, data for the time period 2000–2004 from all 47 systematically observed, national meteorological stations in northeastern China and some of those in the Meng'gu and He'bei provinces in the North China district were employed to analyze the relation between MAAT and MASST. The statistical analysis identified a strong relation between the two (Fig. 2), with MASST being on average about 1.7°C higher than MAAT. Strong correlation between air and ground surface temperatures indicates that higher air temperatures induced a corresponding heat absorption and ground warming over the past decades.

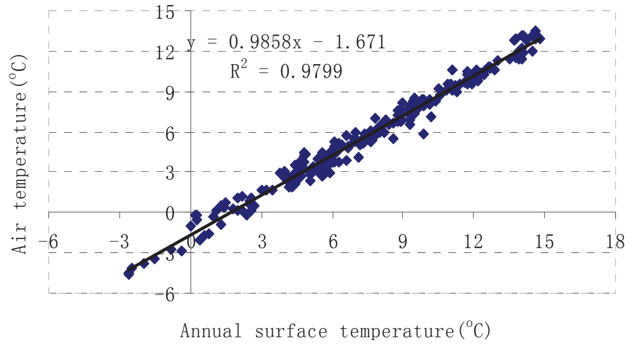

Figure 2. The correlation analysis between mean annual air temperature and soil surface temperatures.

Equivalent Latitude Model for MASST

In its spatial distribution, MASST is basically controlled by latitude (Table 1), but according to the former relative studies, permafrost condition in NE China is very different with topography such as aspect and slope at almost the same location (Brown 1973, Liu et al. 1993). These variations reflected from different mean annual ground temperature (MAGT), permafrost thicknesses, and depths of active layer (Tables 2, 3), so aspect and slope were taken into account to constitute equivalent latitude (Haugen et al 1993):

$$\varphi' = \sin^{-1}(\sin k \cosh \cos \varphi + \cos k \sin \varphi) \tag{1}$$

where k is slope of the surface (°); h is surface aspect (°); φ and φ' are actual latitude and equivalent latitude of the spot (°).

Measured data and previous articles proved that snow has a much greater influence than vegetation on the thermal condition of permafrost, and show a unconspicuous influence if acting together (Fig. 3); but it is a complicated process how snow affects, so MASST is used in the model to remove snow influence.

When replacing the actual latitude with so-calculated "equivalent latitude," the partial correlation between MASST and equivalent latitude increases to 0.957 compared to the previous 0.938. According to trends in altitude changes, a two-section equation was used in the model simulation. This provided more satisfactory results (R^2=0.972>0.957; F=190.86>148.68) (Fig. 4). The two-section equation (Jin et al 2007) is:

$$Ts = \begin{cases} 72.153 - 0.684\varphi' - 0.265\theta - 0.007h & h \le 250m \\ 60.369 - 1.105\varphi' - 0.015\theta - 0.005h & h > 250m \end{cases} \tag{2}$$

where: T_s is mean annual soils surface temperature (°); θ and h is longitude (°) and altitude (m) of the spots; φ' is equivalent latitude of the spots (°).

From Figure 4, the simulant essentially reflected the MASST, F test value is 190.86, indicate that the equivalent latitude model is relatively exact and can be used to predict the MASST distribution. Based on Equation 2, a GIS-based

SMTH/m	2.0~4.0	0.5~1.0	1.0~1.5	1.0~2.0	0.5~1.0	1.0~3.0

MAGT – mean annual ground temperature; PTH – permafrost thickness; SMTH – seasonal melted thickness.

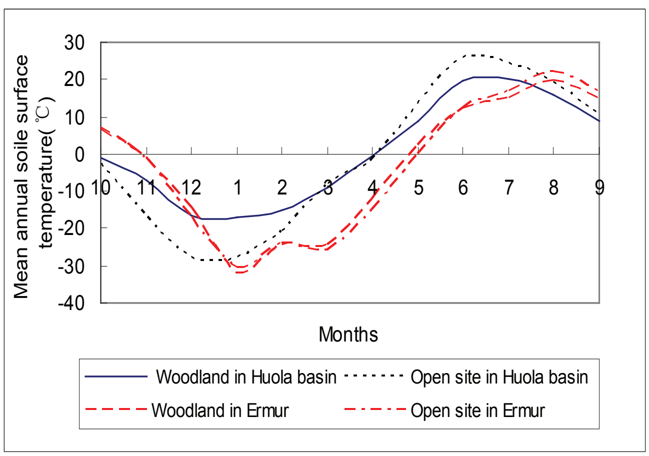

Figure 3. Influence of snow and vegetation on MASST (Huola basin cleaned snow in winter).

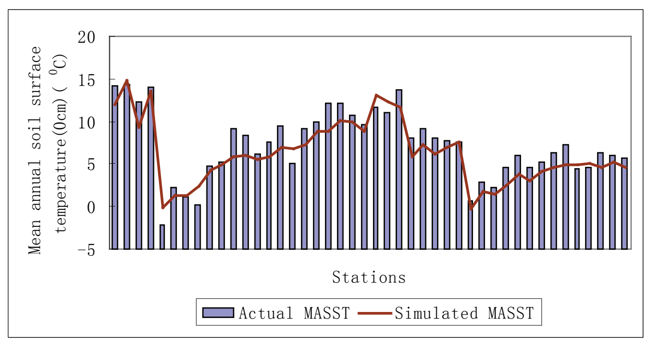

Figure 4. Simulated MASST compared to measured data.

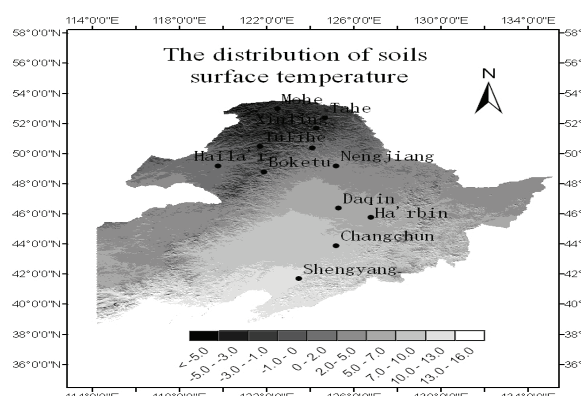

Figure 5. The distribution of MASST in NE China.

MASST distribution map was drawn using C++ programs (Fig. 5). The DEM and other digital data were taken from GTOPO 30 with a horizontal grid spacing of 30 arc seconds (approximately 1 kilometer), Center for Earth Resources Observation and Science (EROS), U.S. Geological Survey (USGS 2007).

The w-shaped pattern of MASST-isotherms is due to elevation effects, as the Da and Xiao Xing'anling Mountains are relatively higher than their surroundings in the western and eastern parts of the study area, ranging from 1000 to 1400–1500 m a.s.l. in the middle section from A'ershan to Yi'ershi and to the source of the Zhuo'er River, but decreasing northward to 500–600 m a.s.l. in the section from Mangui to Gulian. In contrast, the Xiao Xing'anling Mountains are gentler in topography, with meandering river channels, elevations of 500–600 m a.s.l., and few peaks higher than 800 m a.s.l. Large quantities of eroded debris from the steeper eastern slopes have been carried by deeply incised rivers to the Nenjiang River Plain, which lies between the two mountain ranges, with the elevation ranging from several meters to 200–300 m a.s.l.

Permafrost Change with Global Warming

Mathematical model for calculation

On the basis of the MASST distribution, permafrost changes can be calculated using finite element methods of heat diffusion at depth and characteristic surface boundary conditions. The main control equation is:

$$\rho.C\frac{\partial T}{\partial t}=\frac{\partial}{\partial x}(\lambda\frac{\partial T}{\partial x})+\frac{\partial}{\partial y}(\lambda\frac{\partial T}{\partial y}) \qquad (3)$$

In this equation:

$$C=\begin{cases} C_u & (T>T_p) \\ C_f+\dfrac{C_u-C_f}{T_p-T_b}(T-T_b)+\dfrac{L}{(1+W)}\dfrac{\partial W_i}{\partial T} & (T_b\le T\le T_p) \\ C_f & (T<T_b) \end{cases}$$

$$\lambda=\begin{cases} \lambda_u & (T>T_p) \\ \lambda_f+\dfrac{\lambda_u-\lambda_f}{T_p-T_b}(T-T_b) & (T_b\le T\le T_p) \\ \lambda_f & (T<T_b) \end{cases}$$

where ρ is natural density of soils (kg/m3); C is apparent specific heat of soils (J/(kg.K); C_u, C_f are specific heats of thawed and frozen soils; λ is apparent conductivity of soils (J/(m.h.k)); λ_u, λ_f are conductivities of thawed and frozen soils; L is latent heat (K/kg); W, W_i is total water content or ice content (%); T_p and T_b are the upper and lower critical temperature related to phase changing (°C); T is temperature (°C); t is time (h); x and y are spatial variables (m).

Geometrical model for forecasting calculation

An additional geometrical model considered effects from human activities within a distance of 30 m, mainly relating to deforestation in connection with road construction, creation of fire insulation zones, or installing electrical transforming line (Fig. 6); with an additional 30 m added to each side, the total width considered is 90 m. Some borehole data in NE China approved that the gradient at depths greater than 30m is less than 0.004°C/m (Li et al. 1996). The bottom boundary was therefore chosen at this depth.

Boundary conditions

The surface boundary of calculation area presented as:

$$T=T_0+\alpha\cdot t+A\sin\left(\frac{2\pi\cdot t}{8760}+\frac{\pi}{2}\right) \qquad (4)$$

where T is SST (0 cm) (°C); T_0 is MASST (°C); α is increment of MASST, is 0.048 within 50-year period in the future (°C/a); t is time duration; A is amplitude of SST (°C, 18.5°C for the forest surface); $\pi/2$ is the initial phase (corresponding to the warmest part of the year).

In the IPCC WG2 report (Chapter 10–Asia) (IPCC 2007), the minimum future increase in surface air temperature will be 1.4°C (2010a–2039) and 2.5°C (2040–2069), then the surface air temperature would be 2.4°C higher after 50 years in NE China, atmospheric model of A1, A1B, and A2 also examined its increment of 0.026, 0.027, and 0.05, and synthesized α = 0.048 in connection with the actual increment. Therefore the soil surface temperature would be with an approximately same increment based on former 50-year linear relation without any large change in atmospheric circulation.

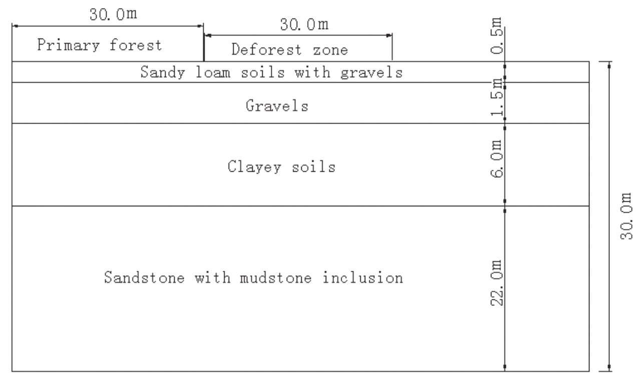

Figure 6. The geometrical model in calculation.

The mean annual ground temperature of present-day stable permafrost temperature regime is inferred from 200 years ahead. Calculated results (Fig. 7) indicated that present MAGT is near to MASST, future MAGT in different MASST zonal areas would increase in various extents: about 0.5°C, 0.4°C, and 0.3°C where the present MASST is -2.0°C, -1.5°C, and -1.0°C, slightly in -0.5°C and 0°C zones, because the nearer to the phase-change area, the more slowly permafrost temperature will change, but much more of that together with anthropic activities: In contrast, the permafrost table deepens most where present MASST is 0°C, the increment ranged from 1.2 m to 0.2 m in 5 different MASST zones (Table 4). Permafrost thickness would not change greatly apart from some south-oriented slopes and areas around 0°C in MAGT. The permafrost degradation would mainly take in place in the form of increasing in mean annual ground temperature.

Conclusion

Mean annual air temperature (MAAT) in NE China increased by about 1°C from 1976–2000 as compared to 1951–1975 with a yearly 0.04°C increase, i.e., higher than mean warming rate of 0.026°C/a estimated by IPCC for the Northern Hemisphere. Mean annual soil surface temperature (MASST) is linearly related to MAAT and may therefore have risen at the similar rate if there aren't any large changes in surroundings. This inevitably caused permafrost warming.

Climatic warming and increased human activity during the last century are both thought to be responsible for the degradation of permafrost in NE China. Extensive and increasing human activity for resource exploitation, agriculture, and economic development have accelerated the processes.

Table 4. Changes of MAGT (at 15 m deep location) and table of permafrost in different zones, present and within next 50 years.

MASST zonal area /°C	Mean annual ground temperature /°C (-15 m)			Permafrost table /m		
	Present	GW	GW+MA	Present	GW	GW+MA
0.0	0.06	0.07	0.10	3.00	4.20	5.85
-0.5	-0.50	-0.45	-0.40	2.80	3.40	5.20
-1.0	-0.99	-0.77	-0.64	2.65	3.10	4.70
-1.5	-1.44	-1.11	-0.86	2.50	2.80	4.00
-2.0	-2.03	-1.56	-1.12	2.40	2.60	3.20

GW – in the scenario of global warming; GW+MA – in the scenario of global warming plus human activities.

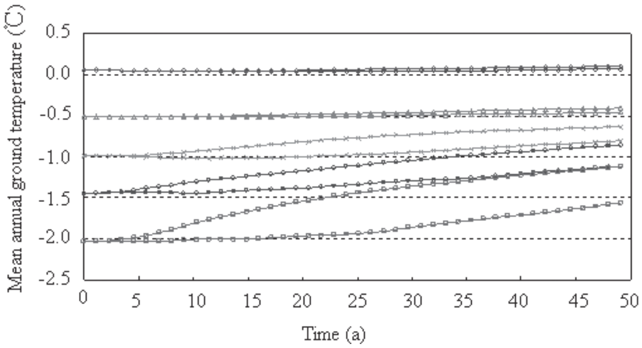

Figure 7. Calculated changing process of permafrost with various MAGT (down to 15 m) in different MASST zonal area within coming 50 years in NE China, under global warming and added anthropic activities (upper and lower line for each case).

A forward projection of atmospheric warming trends revealed that mean annual permafrost temperature would more strongly increase in zones of relatively cold MASST of around -2.0°C than in zones of warm to temperate permafrost. The permafrost table, on the other hand, is expected to deepen most strongly (about 12 m) in zones with MASST near 0°C. These effects are considerably enhanced by effects from direct human impact. Changes in permafrost thickness would be limited, and increasing mean annual ground temperatures are likely to be the predominant manifestation of permafrost degradation.

Abstract

Thermokarst lake deposits are useful archives of climatic and environmental changes in the past, and can contain palaeo-bioindicators such as pollen, plant macro-fossils, diatoms, chironomids, and ostracods. Nevertheless, such studies from permafrost regions including thermokarst lake deposits are still rare. We studied late Holocene ostracods from an excavation of deposits of the Alas Myuryu in Central Yakutia. In order to apply modern data to fossil records, we also studied the present-day relationships between the environmental setting and the geochemical properties of ostracods in six thermokarst lakes of the same region. The fossil ostracod record reflects lake-level fluctuations in the composition and stable isotope data ($\delta^{18}O$, $\delta^{13}C$) of both species. The modern ostracod communities of thermokarst lakes in Central Yakutia are broadly similar to those of Holocene age. Geochemical stable isotopes studies in both modern host water and ostracod calcite are a prerequisite for further interpretation of the fossil records.

Keywords: Central Yakutia; Holocene; ostracods; thermokarst lakes.

Introduction

Thermokarst is a common phenomenon of the cryolithozone generally caused by extensive melting processes of ground ice in the underlying permafrost. Widespread thermokarst processes have been climatically driven and intensified during warm periods in the Quaternary, especially since the Holocene (e.g., Katasonov 1979). They are responsible for the formation of numerous depressions in the landscape surface (alases), which are often occupied by thermokarst lakes. These landscape forms are typical for Central Yakutia (e.g., Soloviev 1973). The deposits of thermokarst lakes frequently contain fossil remains of bio-indicators, e.g., freshwater ostracods, which can be used for palaeoenvironmental reconstructions. Cyclic water level changes in the lakes are related to regional climatic variations (e.g., Nemchinov 1958).

Freshwater ostracods are crustaceans, usually less than 3 mm long, with a bi-valved carapace made of low-magnesium calcite. Changes in climatic and hydrological parameters influence the diversity of freshwater ostracods as well as the geochemical composition of ostracod calcite. In general, several geochemical properties of the calcareous shells of ostracods contain environmental information about the water chemistry and stable isotope composition of the host water at the time of shell formation (e.g., Griffiths & Holmes 2000). In particular, $\delta^{18}O$ and $\delta^{13}C$ records of ostracod calcite provide a highly localized and temporally restricted reflection of the isotopic composition of water, making them useful tools in palaeolimnology (Griffiths & Holmes 2000). The $\delta^{18}O$ of carbonates serves as proxy for temperature of the water, the isotopic composition of which is also influenced by precipitation, drainage basin hydrology, and the precipitation/evaporation ratio (P/E) (Kelts & Talbot 1990). The $\delta^{13}C$ of carbonates reflects changes in the isotopic ratio of the total dissolved inorganic carbon (TDIC) (Griffiths & Holmes 2000). Changes in $\delta^{13}C$ are attributed to changes in aquatic productivity within a lake, CO_2 exchange rates between atmosphere and water TDIC, as well as to the photosynthesis/respiration ratio within the lake (Leng & Marshall 2004).

In this respect, we present here the first combined study of modern and late Holocene ostracod assemblages from Central Yakutia. The first description of ostracods from this area was given by Pietrzeniuk (1977). Further regional studies were carried out on freshwater ostracods of the North Yakutian Lena River Delta, Laptev Sea (Wetterich 2007). In addition, Arctic freshwater ostracod associations were palaeoecologically analyzed in late Quaternary permafrost sequences from Bykovsky Peninsula, Laptev Sea (Wetterich et al. 2005).

Study Area

The studied lakes are situated on the Lena-Amga interfluve and around Yakutsk in Central Yakutia, in East Siberia (Fig. 1). The region belongs to the southern foreland of the Verkhoyansk Mountain Range. The fieldwork on an excavation of the late Holocene deposits of the Alas Myuryu (62°43′N, 131°08′E) was performed in summer

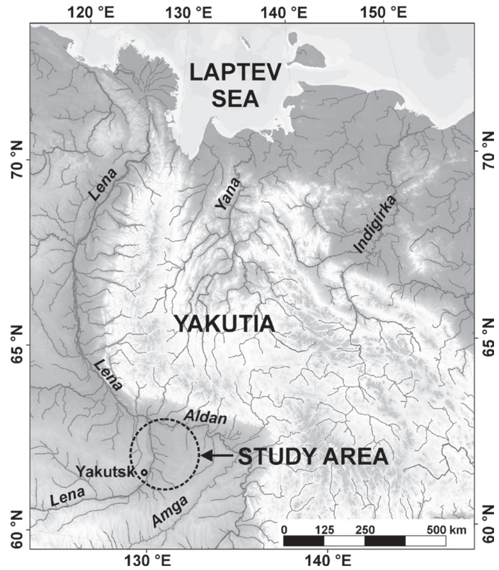

Figure 1. Schematic map of Russia showing the study site on the Lena-Amga interfluve in Central Yakutia (East Siberia). Map compiled by G. Grosse (UAF) using data from GLOBE Task Team (1999).

1997. Six modern thermokarst lakes (between 61°32′N and 62°19′N, 129°32′E and 132°12′E) were sampled in summer 2005 under the auspices of the Russian-German expedition "Central Yakutia 2005" (Wetterich et al. 2007).

Central Yakutia is characterized by a strong continental climate with low annual precipitation (222 mm) and a high temperature gradient over the year (mean temperature in January -37.6°C and in July 19.3°C) and a mean annual air temperature of -8.7°C (Meteorological station Yakutsk; RIHMI-World Data Centre: http://www.meteo.ru).

Materials and Methods

The late Holocene ostracod assemblages of the Alas Myuryu were recovered from a 1.4-m-deep excavation of lake deposits at the desiccated margin of the lake. The sediment samples were freeze-dried, wet sieved through a 0.250 mm mesh size, and then air-dried. About 200 g of each sediment sample was sieved for further ostracod analysis.

Living ostracods were caught at the lake bottoms in the littoral zone of six thermokarst lakes using a plankton net and an exhaustor (Viehberg 2002) in July and August 2005. The ostracods were preserved in 70% alcohol and afterwards counted and identified under a binocular microscope by soft body and valve characteristics.

The stable isotope analyses of oxygen ($\delta^{18}O$) and carbon ($\delta^{13}C$) were performed at the isotope laboratories of the Alfred Wegener Institute (AWI, Potsdam and Bremerhaven, Germany) and the GeoForschungsZentrum (GFZ, Research Centre for Geosciences, Potsdam, Germany).

For $\delta^{18}O$ and $\delta^{13}C$ analyses on fossil and modern valves of adult ostracods we used mass spectrometers (Finnigan MAT 251 at AWI and MAT 253 at GFZ) directly coupled to automated carbonate preparation devices (Kiel II and IV, respectively). Only clean valves of adult specimens were used. Particles adhered to valves were removed with a fine brush under microscope. To ensure enough material for isotope analysis (50–100 mg $CaCO_3$), multi-valve samples of single species have been created. The reproducibility as determined by standard measurements is better than ±0.08% (1σ) for $\delta^{18}O$ and ±0.06% (1σ) for $\delta^{13}C$.

The rain and lake water samples for $\delta^{18}O$ and δD were analyzed by equilibration technique (Meyer et al. 2000) using a mass spectrometer (Finnigan MAT Delta-S at AWI). The water samples for $\delta^{13}C$ analysis on TDIC were preserved by adding HgCl until analysis using a mass spectrometer (Finnigan MAT 252 at AWI). The reproducibility of these data derived from standard measurements is better than ±0.1‰ ($1\ \sigma$).

The values are expressed in delta per mille notation (δ, ‰) relative to the Vienna Standard Mean Ocean Water (VSMOW) for water isotopes ($\delta^{18}O$, δD) and relative to the Vienna Pee Dee Belemnite standard (VPDB) for $\delta^{13}C$ on TDIC and carbonate isotopes.

The dating of organic matter and calcareous valves from seven samples (Table 1) was undertaken at the Leibniz Laboratory for Radiometric Dating and Stable Isotope Research, University of Kiel (Germany) using radiocarbon Accelerator Mass Spectrometry (AMS).

Results and Interpretation

Fossil ostracods

The late Holocene ostracod assemblage consists of 22 species (Fig. 2). The most abundant species during the periods recovered are *Candona candida*, *Fabaeformiscandona rawsoni*, *Ilyocypris lacustris*, and *Limnocythere inopinata*. According to the modern ecological requirements of these species, some facts can be concluded for the living conditions of the fossil assemblage. Most of the species show a great adaptation to changes in both temperature and salinity regime, and are mostly typical for shallow water. The tolerance to temperature ranges from cold stenotherm to warm stenotherm with a great part of thermoeuryplastic (temperature tolerant) species. Furthermore, concerning changes in salinity, most of the species have oligo- to mesohaline ranges; i.e., 0.5 to 18‰ total salt content in the host waters (Meisch 2000). In general, the habitat of the fossil ostracods was a shallow-water environment with significant changes in temperature and salinity, which are linked to lake-level changes. Three periods of different lake conditions are distinguishable (Fig. 2). However, the geochronology of the fossil record from the excavation at the lake margin of the Alas Myuryu does not yield age relations for periods B and C. Whereas period A is well-defined by three dates between about 4300 to 1500 yr BP, period B lacks direct dates, and period A was only dated in its upper part with about 300 yr BP. Furthermore, the lower part of period A is complicated by two rejected ages, which are most likely caused by re-deposition during lake-level changes after sedimentation. Therefore, geochronological interpretation of the fossil data is weak and needs further dates. Nevertheless, late Holocene variations of the lake stages are reflected in taxonomical and geochemical data of the periods A to C (Fig. 2).

Period A (about 4300 to 1500 yr BP) is characterized by moderate water level fluctuations, which are also reflected in the changes in ostracod abundance and diversity. The $\delta^{18}O$ data of *F. rawsoni* with relative ^{18}O-depleted values between about -11 to -8‰ are most likely a sign of a higher P/E due to lower evaporation that caused a generally higher lake level. The shifting $\delta^{13}C$ values of *F. rawsoni* between about -2 to 1.5‰ indicate variable aquatic productivity during period A.

The following period B (after about 1500 yr BP) shows a short-time distinct decrease (at a depth of 58–63 cm) in the abundance of all species which appeared before. That was apparently caused by drying up of the water body. The appearance of *Plesiocypridopsis newtoni* shortly before and during period B (Fig. 2) points to higher salinity, since this species tolerates and even prefers brackish conditions (Meisch 2000). The $\delta^{18}O$ data of *F. rawsoni* reflect drastic changes in the isotopic composition of the lake with shifts between about -12 and -9‰ in a very short time. Afterwards, during a gradual flooding the species composition changed again.

In period C (about 300 yr BP) the species *F. acuminata*, *F. hyaline,* and *F. lepnevae* became common, and moderate lake-level fluctuations took place. In accordance with the $\delta^{18}O$ data of *F. rawsoni*, with relative ^{18}O-enriched values between about -9 to -6‰, the P/E ratio was lower (E>P) and that generally suggests higher evaporation and/or lower precipitation, resulting in a generally lower lake-level compared to period A. The $\delta^{13}C$ values of *F. rawsoni* between about -4 to -1‰ are relatively ^{13}C-depleted and can imply a general lowering in aquatic productivity compared to period A.

Modern ostracods

In six thermokarst lakes of Central Yakutia we observed 15 ostracod species (Fig. 3). In total, up to 250 adult specimens per lake were caught. The highest diversity per lake includes six species. The most abundant species from the fossil assemblages were found, but they are rare in the modern dataset. The dominant modern species are *Candona weltneri* in combination with *C. muelleri jakutica* and/or *F. rawsoni* (Fig. 3).

The studied lakes are shallow, without visible in- or outflows, and mainly fed by precipitation and meltwater from

the underlying permafrost. The high temperature variation in the surface lake waters during the fieldwork ranged from 12°C up to 26°C, and the ionic content expressed as electrical conductivity reached from 0.36 to 0.92 mS/cm.

The results of oxygen and hydrogen isotope analyses of the lake waters are shown in a $\delta^{18}O$ - δD plot (Fig. 4) with respect to the Global Meteoric Water Line (GMWL), which correlates fresh surface waters on a global scale (Craig 1961). Furthermore, in Figure 4 the stable isotope data of seven rainwater samples from August 2005 taken in Yakutsk are presented. Lake water samples are shifted below the GMWL, and this deviation reflects evaporation in the studied water bodies, as indicated by a slope of 4.54 (R^2 = 0.98; shown in Fig. 4).

The geochemical analyses of ostracod calcite ($\delta^{18}O$, $\delta^{13}C$) were performed on valves of the most common species, *C. weltneri* and *C. muelleri jakutica*. The $\delta^{18}O$ of host waters varies between about -15 to -10‰, whereas the $\delta^{18}O$ of ostracod calcite is generally shifted to ^{18}O-enriched values and ranges between about -12 to -5‰ (Fig. 5). The shift between $\delta^{18}O$ in host waters and ostracod calcite includes metabolic (vital) and temperature effects. Vital offsets on the isotopic composition of several species of Candoninae of up to 3‰ were already proposed by other studies, (Xia et al. 1997, von Grafenstein et al. 1999, Keatings et al. 2002, Wetterich et al. 2007). The temperature-dependence of $\delta^{18}O$ fractionation is reflected by the variation of the shift within a species, where increased temperatures correspond to smaller

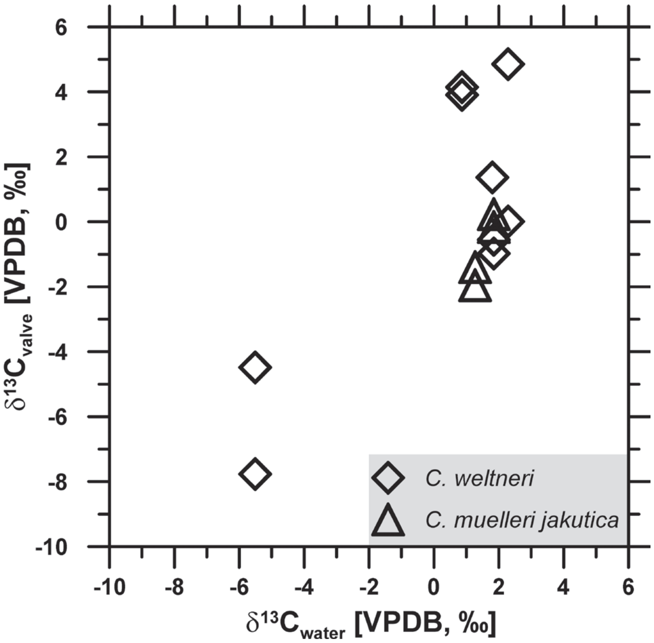

Figure 6. Stable isotope composition of $\delta^{13}C$ in ostracod calcite and ambient waters for female and male specimen of adult *C. weltneri* and *C. muelleri jakutica*.

shifts (e.g., Leng & Marshall 2004). The observed variation in the shift can be explained by different temperatures of the host water at the time of calcification.

The $\delta^{13}C$ of the studied host waters TDIC shows two different ranges at about -5.5‰ and between 1 to 2.5‰. The corresponding $\delta^{13}C$ data on ostracod calcite show considerable scatter from about -8 to -4‰ and -2 to 5‰, respectively. The scatter in $\delta^{13}C$ indicates the influence of complex abiotic and biotic effects at different times of shell secretion on $\delta^{13}C$ fractionation, as is expected in natural waters.

Discussion

For the late Holocene, Wolfe et al. (2000) detected a similar pattern of cellulose-inferred lake water $\delta^{18}O$ in a North Yakutian lake sediment record. They found most ^{18}O-depleted values between 2000 and 500 yr BP due to probably cooler conditions and less influence of evaporation. After 500 yr BP, the data change to relative ^{18}O-enriched values, as it is also recorded in the $\delta^{18}O$ record of ostracod calcite in period C, indicating a warming trend with higher evaporation.

The observed modern ostracod assemblages from Central Yakutian thermokarst lakes are characterized by species with preferences for lower water temperatures and lower salinities (e.g., *C. candida*, *C. muelleri jakutica*, *C. welterni*, *F. hyalina*, *F. rawsoni*). The most common species, *C. weltneri,* is described as cold stenothermal to oligothermophilic and oligohalophilic (Meisch 2000). Other species are tolerant to changes in temperature and salinity. In comparison to Arctic ostracod assemblages (Wetterich et al. 2007) from North Yakutia (Lena River Delta, Laptev Sea), the Central Yakutian fauna generally lacks strictly cold-adapted species such as *F. harmsworthi*, *F. pedata*, and *Tonnacypris glacialis*. Nevertheless, other species, such as *C. candida*, *C. muelleri jakutica,* and *F. hyaline,* are common in both regions. The $\delta^{18}O$ record of ostracods from North and Central Yakutia shows differences. The $\delta^{18}O$ in valves of Arctic ostracods is relatively more ^{18}O-depleted and ranges between about -20 to -13‰ (Wetterich et al. 2007), whereas the $\delta^{18}O$ of the Central Yakutian ostracods ranges between about -12 to -5‰. This general tendency in the $\delta^{18}O$ records reflects the general lower temperatures and lower evaporation in the north with higher P/E rations as compared to Central Yakutia.

Comparing the Central Yakutian $\delta^{13}C$ records of modern and late Holocene ostracods, we observe a reversed pattern, in which the fossil data are relatively more ^{13}C-depleted (mostly lighter than 0‰) than the modern ones (mostly heavier than 0‰). That may imply generally higher aquatic productivity today as compared to the late Holocene, since plants preferentially fix $^{12}CO_2$ during photosynthesis thereby leaving TDIC enriched in ^{13}C (Griffiths & Holmes 2000). The generally lower range in ostracod $\delta^{13}C$ between -2 to -11‰ from modern North Yakutian ponds (Wetterich et al. 2007) as compared to Central Yakutia may point to dominance of organic matter decay in the northern waters, since these microbiological processes release ^{13}C-depleted CO_2 and lower $^{13}C/^{12}C$ ratios in TDIC (Griffiths & Holmes 2000).

Conclusions

Periodic short- and mid-term climate variability leads to significant changes in hydrological conditions; e.g., to drastic water-level changes in thermokarst lakes of Central Yakutia, as it was first described by Nemichov (1958). A drying-up period of the thermokarst lake within Alas Myuryu in the late Holocene was observed in both taxonomical and geochemical properties of fossil freshwater ostracods. The uncertain geochronology of the record presented here renders unclear the relationship between lake changes as reflected by ostracod data and the Holocene environmental history. Nevertheless, freshwater ostracods are useful indicators for reconstruction of aquatic conditions in the past.

The modern ostracod assemblage reflects today's environmental conditions that are characterized by moderate lake-level variations due to evaporative effects during the summer season. The high variability in the modern $\delta^{18}O$ and $\delta^{13}C$ data of ostracod calcite underscores the need for further studies in this context.

Abstract

A wetland complex on Ellesmere Island, Canada, typical of many such complexes in the polar oases, consists of patches that include tundra pond, ice wedge trough, wet meadow, and mesic ground. In the spring, overland flow generated by snowmelt filled the topographic depressions and flooded the wetlands, flushing out the chemicals in the surface ice formed in the previous season. As floodwater receded and the surface flow connections were severed, wetland patches were largely separated. Vertical processes of evaporation and rainfall dominated. The diverse hydrological and chemical environments that emerged were possibly responsible for the different vegetation assemblages on the wetland complex. For High Arctic wetlands, permafrost significantly influences the thermal, hydrological, and chemical regimes. Frozen ground favours surface runoff, but restricts hydrological linkages among wetland patches. Shallow thaw allows prolonged active-layer saturation, and ground ice melt or thermokarst alters the concentration of various ions.

Keywords: High Arctic; hydrochemistry; hydrology; tundra pond; vegetation; wetland.

Introduction

Wetlands occur in small patches or extensively as wetland complexes in the High Arctic (Woo & Young 2003, 2006). The existence of wetlands is predicated upon frequent excess of water with gains greater than losses so as to maintain a high water table to facilitate the development of ponds or hydrophytic vegetation. The presence of permafrost enables prolonged retention of water in the wetlands, as the frozen soil limits percolation and has only a shallow thawed layer that does not require a large amount of water to saturate.

Cowell et al. (1978) noted that the formation of wetland in permafrost areas is favoured by shading and insulation provided by vegetation, peat which insulates the frozen substrate, and the lack of water movement largely due to low gradients. While the factor of vegetation cover is less important in the tundra and polar desert than in the forested areas, the presence of peat is a major consideration in retarding ground thaw (Yi et al. 2007). Poor drainage allows frequent saturation that is requisite for wetland occurrence. While the hydrology and the vegetation of Arctic wetlands have been studied (e.g., Bliss 1977, Bowling et al. 2003, Rovansek et al. 1996) and hydrochemical sampling of wetland and pond waters (e.g., Keatley et al. 2007) has been made across the Arctic, there has not been an integrative investigation on the hydrology, hydrochemistry, and vegetation of a wetland complex. It is proposed that these wetland characteristics are interrelated, and the present study examines these several aspects at a High Arctic wetland in Canada. Results of this study are applicable to other wetlands in the continuous permafrost region.

Study Area and Methods

The study area is located near Eastwind Lake on Fosheim Peninsula, Ellesmere Island, Nunavut, Canada (80°08′N, 85°25′W) (Fig. 1). This High Arctic site has a polar oasis climate that is generally warmer than the polar desert (Edlund & Alt 1989, Woo & Young 1997). The weather station at Eureka, 20 km away, measured 76 mm annual precipitation, though this value may be an underestimation due to poor gauge catch (Woo et al. 1983).

The wetland complex where the study was undertaken in 2005 occupies a shallow depression at the foot of a long slope. This topographic setting favours the collection and storage of surface and subsurface runoff. The wetland complex drains northwestward via a small channel. Within the wetland complex are six tundra ponds and wet grounds criss-crossed by ice-wedge polygons (Fig. 2). Two lines of palsa-like features follow the rims of the polygons to deflect the paths of the surface runoff from the hill slope to the ponds. The entire area is underlain by fine-grained diamict to a depth of at least 2 m. The diamict has a high carbonate content, while the wetland complex lies below the Holocene marine limit (Bell 1996) so that the soils have a high salt content. In the wet meadow and mesic ground, a 0.1 m layer of organic litter and peat lies atop silt and clay. Part of the mesic ground and the pond rims have also a thin peat layer below mineral soil, likely buried during the last glaciation.

Hydrological methods are given in detail in Woo & Guan (2006). A vegetation survey (presence/absence) was conducted in July 2005 for the main terrain types following

Figure 1. Location of the study site on Fosheim Peninsula, Ellesmere Island, Nunavut, Canada.

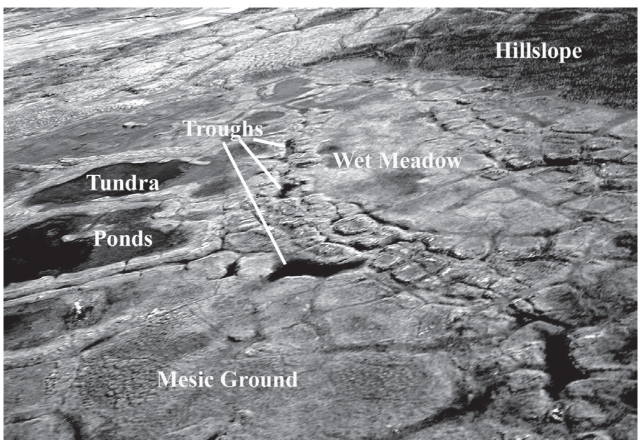

Figure 2. Photograph of the wetland complex showing hill slope, tundra ponds, ice-wedge troughs, mesic, and wet meadow sites.

the approach of Edlund et al. (1990) to determine the floristic diversity of the wetland-complex.

Water samples were collected once every six days from the start of overland flow on June 2 until mid-August. Samples were taken from the water in the northern ice wedge trough and from one of the six tundra ponds. Water was also sampled from a pool in the wet meadow and from a 15-cm diameter pit dug down to the frost table in the mesic area. In the pond, daily electrical conductivity measurements were combined with pond volume estimates to yield total solute load values in units of mS m^{-3} cm^{-1}. All water samples were kept cool (~4ºC) and in the dark prior to field analyses. Immediately after collection, samples were analyzed for total Fe. Hach FerroVer pre-measured reagents were used for total Fe measurements. The FerroVer reagent acidifies and extracts colloidal iron and iron sorped to organic matter otherwise not detected in analyses for "dissolved" iron. Samples were acidified to pH 2.5 using concentrated nitric acid before filtration through a 0.45 µm glass microfibre filter, prior to cation (Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}) analysis at York University in Toronto, Ontario, using a Spectra-10 Atomic Absorption Spectrometer. This technique yields concentrations as a sum of the dissolved, colloidal, and acid-soluble suspended constituents.

Hydrological Processes

Throughout the long and cold winter, the dominant hydrological processes were the accumulation and redistribution of snow. By early June, just prior to the onset of snowmelt, the snow was unevenly distributed, as governed largely by terrain. The uplands and slopes had 163±65 mm, the wet meadows accumulated 95±4 mm, the mesic site had 80±8 mm, while the tundra ponds collected 68±18 mm of snow (all in snow water equivalent unit). From the melt period until the onset of freezeback, the magnitude of various hydrological processes varied, giving rise to strong seasonality in the wetland hydrological behaviour. The melt period occurred when the winter snow cover melted within about 10 days, generating substantial overland flow on most hill slopes and across the wetland. This was the major event that flooded large parts of the study area, infilling depressions and ponds and saturating the thinly thawed soils. Lateral surface flow enhanced hydrological connectivity across the landscape and evaporation was effective at this time around the summer solstice. Evaporation rate from the ponds averaged 2.7 mm d^{-1} and was 2.5 mm d^{-1} for the saturated areas. Ground thaw accelerated soon after the snowmelt season and the thawed active layer was able to accommodate more infiltration. A deepening of the frost table together with high evaporation loss led to a drop in the water table. Surface flow ceased, first on the hill slopes, then the mesic ground, and finally the wet meadows and between the tundra ponds.

Subsurface flow in the active layer was meager due to the shallow thaw, the low gradient (an elevation drop of 10 m over a distance of 1625 m) and the low hydraulic conductivity once the water level fell into the mineral soil layer (pumping tests and falling head tests yielded hydraulic conductivity values of 10^{-2} to 10^{-4} m s^{-1} in the organic layer and 10^{-6} to 10^{-7} m s^{-1} in the mineral substrate). The curtailment of hydrological connectivity is a major consideration in the wetland complex, as individual wetland patches became largely separated from their surroundings. Only vertical processes of rainfall, evaporation, and to a limited extent, ground ice melt controlled the water balance of the wetland patches. In summer, different types of wetland exhibited divergent hydrological behaviour. The wet meadows were no longer flooded, and the pools of water shrank as the water table dropped (Fig. 3). The ponds not only had lower water levels, but drying along their edges allowed wet meadows to emerge. Only the ice-wedge troughs with a steady supply of water from ground ice melt and confined by high rims retained water throughout the summer. The mesic ground often had dry patches between the wet areas that had a water table below the surface, partly maintained by meager subsurface flow from hill slopes. Summer rain was seldom sufficient (total of 27 mm in 2005) to rejuvenate surface flow, though a rainfall event in the following year raised the pond levels to the point of overflow (Woo & Guan 2006).

Table 1. Average pH, electrical conductivity (μS cm^{-1}) and concentration of selected major ions (μmol L^{-1}) for four types of wetland waters in the 2005 summer. Standard deviations are shown in brackets.

	Tundra pond	Wet meadow	Mesic ground	Ice wedge

Hydrochemical Processes

The mean values and seasonal changes in the concentration of selected ions (Ca^{2+}, Na^{+}, K^{+}) and pH for four types of wetlands are shown in Table 1 and Figure 4. In the spring season, extensive inundation by snow meltwater runoff of low ionic concentration (electrical conductivity-

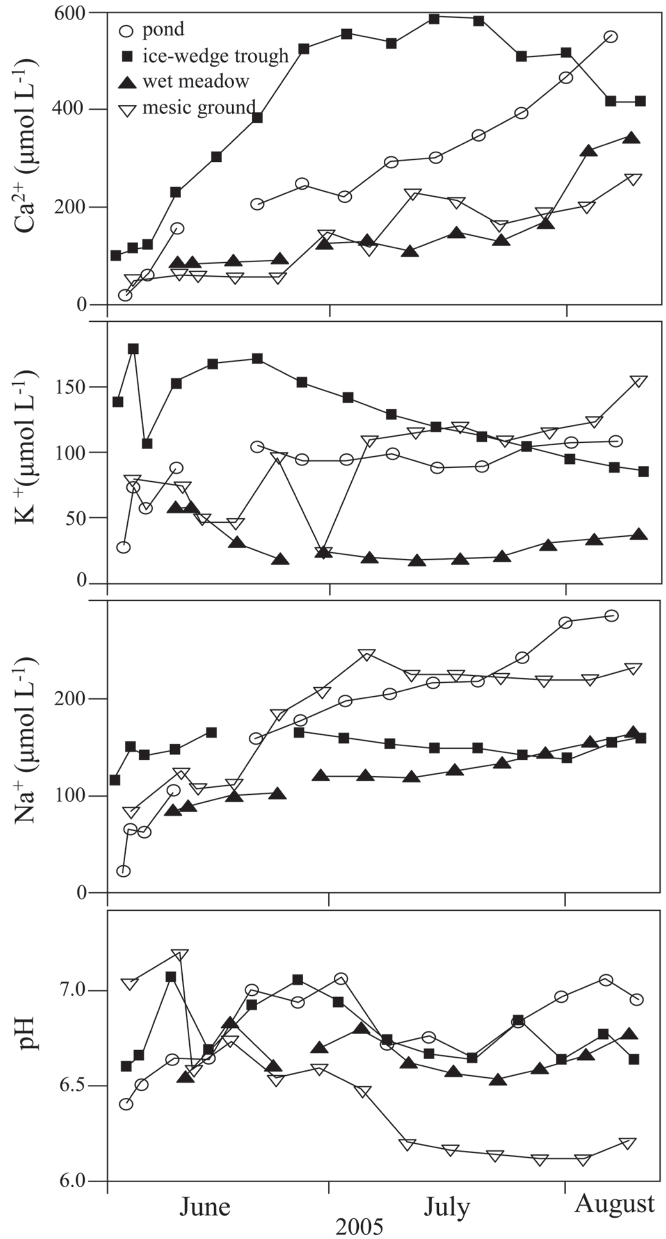

Figure 4. Seasonal change in concentration of selected major ions (Ca^{2+}, Na^{+}, K^{+}) and pH in the water of four types of wetlands (pond, ice wedge trough, wet meadow, and mesic ground).

EC = 13±7 μS cm^{-1}, pH = 6.0±0.6) homogenized the hydrochemical environment of the entire wetland complex. The hydrochemistry of different wetland types was similarly low in ionic concentrations, except for potassium in the ice-wedge troughs. Its initial high value may be attributed to the trough water being in contact with the organic soil exposed on the trough walls. Later in the thaw season, however, the concentration declined as plant growth took up more K^{+} from the trough water. With the cessation of snowmelt runoff, a weakening of hydrological connectivity between the wetland patches and their surroundings became a major consideration in the evolution of wetland hydrochemistry. Rainfall was low (27 mm) and the rainwater has low chemical concentrations (Ca^{2+} = 20±16 μmol L^{-1}, equivalent to 10 μS

cm^{-1}) so that rainfall dilution of the wetland waters was not a major consideration.

Evaporation was effective in reducing the amount of water stored in the wetland. Thus, while the solute load remained relatively unchanged during the summer, a continuous loss of water to evaporation caused a distillation of solute cations, responsible largely for their increasing concentrations after the snowmelt season. This effect is typically evident in the tundra ponds which showed a steady increase in all cations concentrations but not in the total load (Fig. 5). Without surface runoff, both the input of chemicals and the export of soluble ions were limited by the low subsurface flow. By late summer, the in situ suprapermafrost groundwater which is a mixture of meteoric and soil water, and meltwater from seasonal ground ice and from wedge-ice (samples of ground ice showed an electrical conductivity of 233 μS cm^{-1}) had enhanced chemical concentrations compared with the spring conditions. A decrease in pH from late July onwards was possibly related to senescence of the pond vegetation that started around the same time, leading to leaching of organic acids from the plants.

Of particular interest was a thermokarst collapse event along an ice-wedge trough. Prior to the collapse, Ca^{2+} alone increased while K^+ declined steadily, a pattern seen only in the trough (Fig. 4). Afterwards, the concentration of Fe increased from 47 to 276 μmol L^{-1}, and of Na^+ from 149 to 160 μmol L^{-1}, but the concentrations of the other cations measured were reduced. The iron is likely to be colloidal Fe, but our analyses cannot differentiate between its soluble and colloidal forms. The thermokarsting episode showed an abrupt addition of constituents from the soil and ground ice, and an influx of ice meltwater that quickly altered the chemical content of the water in the trough.

In summary, hydrochemical behaviour of the wetlands is strongly influenced by the hydrological processes. Surface and subsurface runoff bring in or remove chemicals; vertical processes of snowmelt and direct rainfall on the wetland add atmospheric fallout (both dry and wet) while ground ice melt (including thermokarst) contributes chemicals from the soil and the ground ice to the water. The addition of water from horizontal and vertical fluxes may dilute or increase the chemical concentration, but evaporation reduces the water volume, thus increasing the concentration but not the chemical load. Vegetation growth further modifies the water chemistry.

Vegetation

Climate, geology, and topography control the hydrological and hydrochemical behaviour which, together with the soil factor, govern the wetland ecology. Different ecological settings give rise to distinct vegetation niches (Table 2). The non-wetland hill slopes have good drainage and are covered by a large diversity of vascular plants ranging from grasses to a variety of saxifrages. The mesic areas experience more frequent saturation than the hill slopes, and the vegetation typically reflects these conditions with the presence of cotton-grass (*Eriophorum scheuchzeri*), mosses and a range of graminoid species. The wet meadows lack the diversity

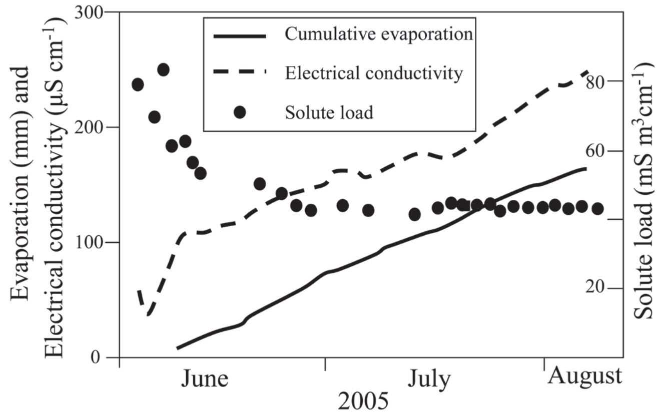

Figure 5. Cumulative evaporation, electrical conductivity, and solute load in tundra pond.

in vascular plants when compared to the mesic sites, but contain various algae species, some graminoids, and cotton-grass (e.g., *Eriophorum scheuchzeri* and *Eriophorum angustifolium*) which reflect their saturated substrate, as was typically noted by other ecologists (Bliss & Matveyeva 1992, Edlund & Garneau 2000). Rims of the ponds experience drying in the summer, and vascular diversity here is comparable to the drier hill slopes. These small strips also appear to represent a transition zone from flooded pond sites with the presence of cotton-grass and algae. As the ponds shrink, the emergent plants include grasses and sedges such as *Alopecurus alpinus, Agrostis mertensi, Calamagrostis neglecta, Carex misandra,* and cotton-grasses such as *Eriophorum scheuchzeri and Eriophorum angustifolim.* Only a few vascular plants exist in these flooded zones (e.g. *Lycopodium alpinum, Pedicularis hirsuta*). The water-filled troughs of the ice-wedge polygons have low vascular diversity (e.g. *Salix arctica, Saxifraga cernua*) and are more typical of flooded sites dominated by mosses and graminoids.

Roles of Permafrost

Permafrost plays an important role in affecting the hydrology and hydrochemical evolution of arctic wetlands, thus also exerting an indirect influence on the development of wetland vegetation.

(1) Ground saturation and water storage: Frozen soil prevents or limits deep percolation, and most hydrological and hydrochemical activities in the High Arctic are restricted to the shallow thawed zone. A thin active layer does not accommodate much water so that where drainage is poor, as in low gradient terrain, the ground is frequently saturated to form wetlands. Annually, rapid release of ample snow meltwater to the thinly thawed soil enables replenishment of surface water storage and homogenization of the chemical conditions of the wetland complex.

(2) Runoff and hydrological connectivity: The extremely poor hydraulic conductivity of permafrost restricts hydrological linkages while low gradient further limits lateral subsurface flow, so that the hydrochemistry of the wetland patches evolves differentially in the thaw season. In the long run, divergent hydrological regimes and

hydrochemical environments lead to the development of different vegetation assemblages. The vegetation itself has feedback on the chemistry as previously discussed.

(3) Ground ice melt: Although the amount of water provided by the melting of ground ice is small relative to other water sources, it nonetheless is important in affecting the water chemistry due to the ionic constituents of the thawing soil and of the ice-water. Ground ice contribution may come steadily through the seasonal thaw of the active layer or arrive rapidly through occasional thermokast events that inject new chemicals and add ice melt water to the wetland environment in relatively short periods.

Conclusion

The wetland complex in the polar oasis of Ellesmere Island shows strong interactions among the hydrology, hydrochemistry, vegetation, and permafrost. A large influx of snow meltwater in the spring leads to general flooding and replenishment of wetland storage. The floodwater also homogenizes the hydrochemistry across the wetland complex. Shallow ground thaw maintains saturated conditions and prevents drainage of the tundra ponds but limits subsurface flow, hence restricting hydrological connectivity among the wetland patches. Vertical processes of rainfall, evaporation, and ground ice melt dominate in the post-snowmelt period. These processes concentrate or dilute the chemical concentration of the wetland waters, leading to divergent chemical evolution paths of the hydrologically isolated wetland patches. Vegetation development represents a long-term response to the divergent physical and chemical environments within the complex. Vegetation growth and the formation of peat significantly reduce the ground thermal conductivity while the abundance of seasonal ground ice in the wetland soils requires much latent heat for ground thaw (Woo et al. 2006a). These conditions give rise to a thinner active layer than in the mineral soils. Such feedback mechanisms among wetland soil saturation, vegetation growth and peat formation, and shallow seasonal thaw, sustain the presence of the arctic wetlands (Woo et al. 2006b).

Abstract

Synoptic meteorological data from Arctic stations established during the first International Polar Year (IPY-1) have recently been collected and digitized. The research program at seven of fourteen stations included ground temperature observations at regular depth intervals. We have analyzed data obtained at the IPY-1 stations at Jan Mayen, Sodankylä, Finland, and at Malyye Karmakuly and Sagastyr, Russia. Descriptive records and more fragmentary data are available for most stations. Initial comparisons indicate that ground temperatures are consistent with surface air temperature (SAT) observations obtained using well-calibrated standard instruments. Using these data, we compare ground-temperature observations with contemporary measurements made at nearby locations.

Keywords: climate change; ground temperature; historical data; permafrost; Polar Year.

Introduction

Ground temperature measurements were recorded at seven of fourteen research stations established in the Polar Regions during the first International Polar Year (IPY-1) (Fig. 1) (Heathcote & Armitage 1959). Time series data were collected in soil at four or more levels down to 1.6 or 2.0 m depth where possible. Measurements were made with calibrated instruments and recorded values tracked variations in surface air temperature (SAT) as expected. The two U.S. stations were not equipped for systematic observation of ground temperature, but at Point Barrow a shaft was sunk to a depth of 37.5 feet for the purpose of obtaining the temperature of the earth, which at the bottom was reported to be a near-constant 12°F (-11.1°C) (Ray 1885). Descriptive observations covering a wide range of cryosphere-related features are commonly found in expedition reports, including notes on ice and ice-processes that were features of the regional landscape. All data obtained during IPY-1 were published *en extenso* by each of the national expeditions. There has been renewed interest in historical data of this type in recent years due to the potential value they hold for improving our understanding of climate change and its impact on the environment.

We present an analysis of the four most complete ground temperature data sets recorded during IPY-1 in the Northern Hemisphere. These were obtained by the Austro-Hungarian expedition at Jan Mayen (von Wohlgemuth 1886); the Finnish expedition at Sodankylä (Lemström & Biese 1886); and by the Russian expeditions at Malyye Karmakuly, on Novaya Zemlya, and Sagastyr, in the Lena River delta (Lenz 1886a, 1886b). Descriptive records obtained at these locations are discussed. Data and an extensive image collection are available at: www.arctic.noaa.gov/aro/ipy-1.

Inspired by Carl Weyprecht (1838–81), the aim of IPY-1 was to investigate those fundamental problems in geophysics which could only be studied effectively through a program of coordinated observation at a widely distributed network of stations anchored in Polar Regions (Weyprecht 1875).

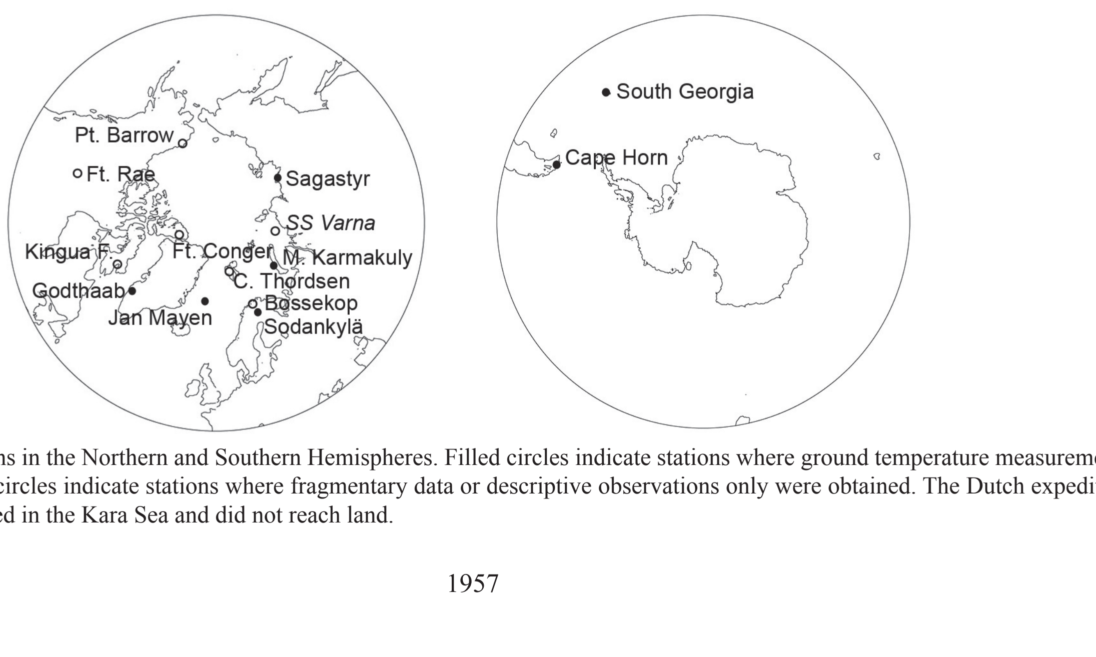

Figure 1. IPY-1 stations in the Northern and Southern Hemispheres. Filled circles indicate stations where ground temperature measurements were obtained. Open circles indicate stations where fragmentary data or descriptive observations only were obtained. The Dutch expedition (SS *Varna*) was trapped in the Kara Sea and did not reach land.

The three main fields of inquiry were meteorology, terrestrial magnetism, and the aurora. The science plan of IPY-1 also encompassed a wide range of additional subjects under the heading of optional observations. In addition to the ground temperature data discussed here, research was undertaken in a variety of subject areas including ethnology, natural history, and oceanography.

It is not surprising that ground temperature and related geocryological studies were undertaken during IPY-1 given the interest in the subject over the previous 40 or more years and the personal involvement of H. Wild, the president of the International Polar Commission (IPC) in this research area (Wild 1878), and G. Wild, president of the Russian Polar Commission and noted permafrost scientist (Baker 1982, Shiklomanov 2005).

Direct comparisons between IPY-1 and modern ground temperature regimes proved to be impossible, primarily due to a lack of modern data at these stations. Landscape transformation was also a factor, especially at Sodankylä, where a reservoir now covers the station site. Since the data were collected simultaneously, we are able to discuss the spatial variability between stations. Given the connection between upper level ground temperatures and synoptic meteorology, we also draw some tentative conclusions about where IPY-1 observations fall within the spectrum of recent monthly mean SAT variability.

Data and Methods

The most complete time series of ground temperature observations in soil obtained during IPY-1 were recorded at Jan Mayen (71.00°N, 008.47°W), Sodankylä (67.41°N, 026.6°E), Malyye Karmakuly (72.38°N, 052.7°E), and Sagastyr (73.38°N, 124.08°E). Two years of observations were recorded at Sodankylä and Sagastyr. A temperature time series in rock was obtained at Godthaab, and fragmentary data of various types were obtained at Cap Thordsen, Fort Rae, and Point Barrow. We have concentrated our analysis on the first four data sets. Data collected at the two Southern Hemisphere stations have not been addressed.

Details on the methods adopted at each station and descriptions of the ground cover and soil type are provided in the expedition reports cited above. An idea of the different environments around each station can also be gleaned from Figure 2 and other graphical information in the reports.

The most detailed metadata available for the four stations relates to the Russian station at Sagastyr. Given that procedures at this station and the stations at Malyye Karmakuly, and Sodankylä were all initiated by H. Wild, IPC president and director of the Central Physical Observatory in St. Petersburg, we can expect that many particulars are common to these three stations. In general, separate holes were excavated to 40, 80, and 160 cm and either glass or wooden tubes inserted. The earth thermometers themselves were enclosed in brass cylinders with their bulbs embedded in a mixture of brass filings and tallow. The cylinders were then attached to wooden sticks that were placed in each tube.

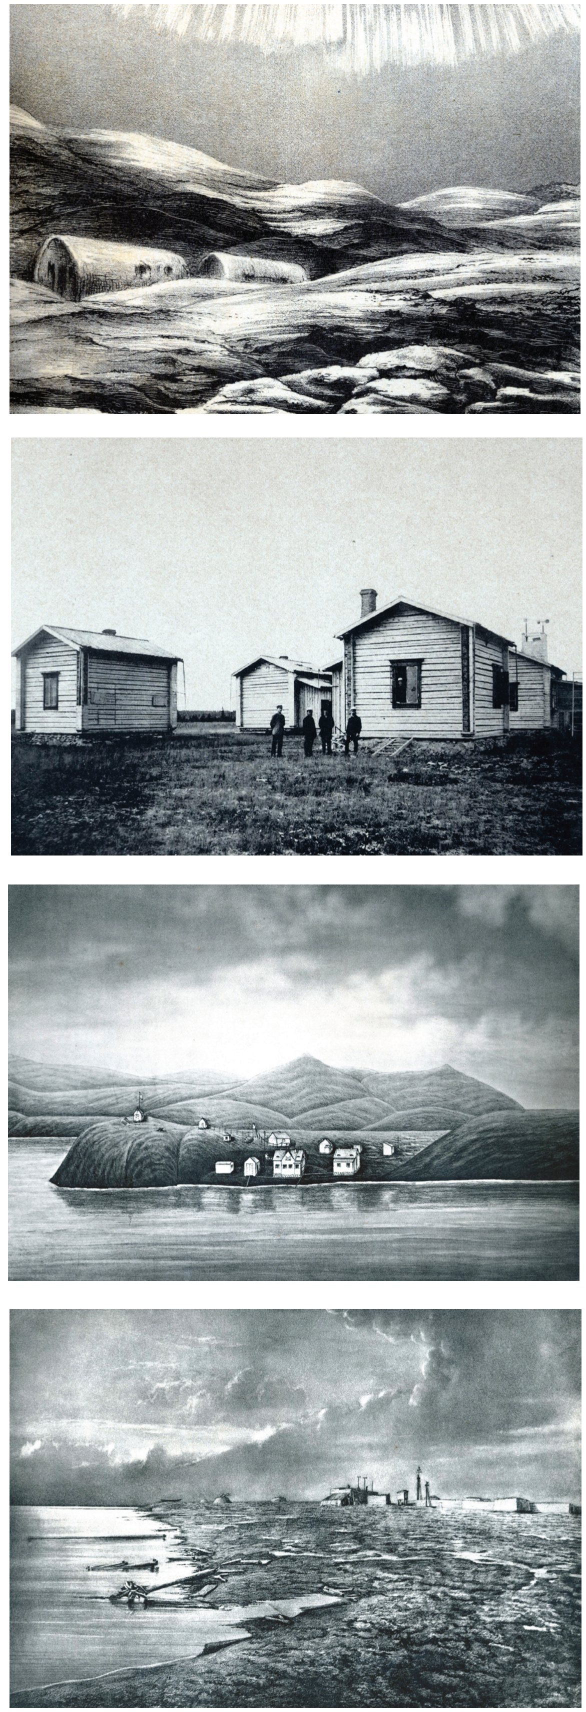

Figure 2. IPY-1 stations and surrounding terrain (from top): Jan Mayen, Sodankylä, Malyye Karmakuly, and Sagastyr.

The tubes were then closed with brass caps. Thermometers at the ground surface were installed horizontally, usually on two small brackets. Surface instruments were often buried in snow and were susceptible to breakage when the snow was removed each time they were read. Instruments on the surface and at 40 cm were read hourly, while the deeper ones were read less frequently (either 3x or daily). Thermometers were calibrated at a range of temperatures against standard instruments at the Central Physical Observatory and verified more frequently at the station at the 0°C calibration point.

The Sagastyr station was established on a small island on the northern edge of Lena River delta. A. Bunge, one of the expedition scientists, noted the dynamic effects of the river upon the terrain in the delta (Lenz 1886a). Old islands were continually being eroded and new ones created. The ground was generally composed of sandy soils overlaid with peat, the thickness of which Bunge suggested was proportional to the length of time the place was undisturbed. The vegetation around the station was dominated by mosses and lichens, with sparse dwarf-shrubs (mostly *Salix polaris*). The data record was interrupted in the summer of 1883 due to meltwater infiltrating from the surface and refreezing in the tubes at deeper levels which prevented the extraction of the thermometers. The location was also moved at this time to an area less susceptible to the building-induced snow drift that was problematic during the first year. Several reported changes of equipment produced small inhomogeneities in the record, but these had minimal influence on the interpolated mean annual ground temperature (MAGT) at particular depths.

The expedition to Malyye Karmakuly was dispatched hurriedly and was not prepared for as thoroughly as the others (Barr 1985). Here, soil temperatures were measured at the standard depths in gravelly soil characteristic of the island.

Wooden tubes rather than glass were used. Continuous snow cover at the measurement site was registered from 6 October 1882 to 25 May 1883. The measurements at 160 cm were interrupted on 30 May, again due to the infiltration and freezing of meltwater, as was the case in Sagastyr.

The metadata for Sodankylä is sparse. The earth thermometers were located about 20 m south of the buildings shown in Figure 2, on flat grassy terrain about 300 m from the Kitala River. Instruments at the surface and 40 cm were read hourly; others were read at least daily but the interval was not clear in the report. In the second year, observations were taken three times daily (0600, 1400, and 2200). Training

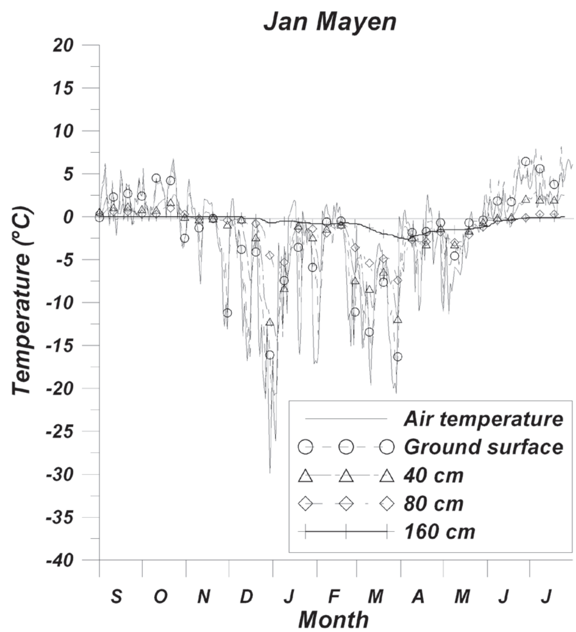

Figure 3. Air and ground temperatures observed at Jan Mayen, 1882–1883. Markers are placed at 10-day intervals throughout.

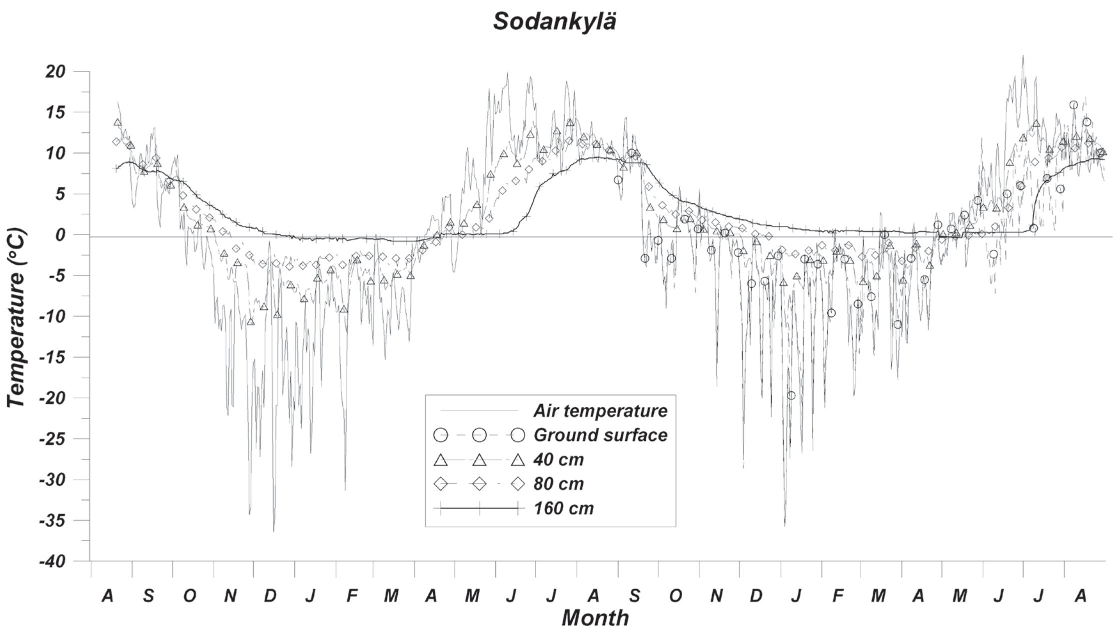

Figure 4. Air and ground temperature measurements at Sodankylä, 1882–1884. Note the difference between the years, which is especially clear in the 160 cm temperature curve. During the second year, the temperature at this level remained above freezing, but then did not warm appreciably until 7 July, nearly four weeks later than in 1883. This is a hallmark of a warmer, snowier winter followed by a cold spring.

and equipment, including glass tubes and thermometers, were provided by the Central Physical Observatory in St. Petersburg. The methods followed at Sodankylä most likely resembled those used at Sagastyr.

At Jan Mayen, rather different procedures were used. Temperatures were recorded at 6 levels down to 1.56 m depth, but the thermometers were graduated in whole degrees and read once per day at 1130. The thermometers were constructed such that they could be buried vertically in the ground while their scales remained above the surface where they could be read. Frozen ground was encountered at 80 cm depth. The expedition's standard thermometers were verified at the Kew Observatory in Great Britain, and they were, in turn, used to calibrate the earth thermometers at the station. We have interpolated the Jan Mayen data to match the standard depth intervals used at the other three stations.

The four stations were located where distinct types of climate and permafrost occur in the Arctic, from seasonal freezing to low temperature permafrost. At Jan Mayen and Sodankylä, the climate can be generally characterized as maritime type, with relatively warm winters and cool summers, even though both are geographically within the Arctic. The milder climate at these stations is due primarily to the dynamics of the atmospheric circulation over the North Atlantic and the influence of the warm ocean currents of the Atlantic Drift. The climate of Fennoscandia is more sensitive to fluctuations in large-scale circulation of the sort indicated by the North Atlantic Oscillation (NAO) (e.g., Thompson & Wallace 2001). The climate at Malyye Karmakuly, and especially Sagastyr, tends toward the more severe arctic-continental type with low temperatures and high amplitude variability. At the latter station, the Siberian high-pressure area is an important factor in winter, which tends to limit the influence of warm advection from the West.

Analysis

Four time series plots of ground temperature data were produced and these are briefly interpreted with respect to mean SAT and other key factors. Differences between subsequent years are pointed out. Gaps in the data were interpolated between other depth levels with data using standard polynomial interpolation.

Jan Mayen

The mean annual air temperature (MAAT) below -2.0°C that was registered at Jan Mayen was enough to form a thin layer of frozen ground (Fig. 3). Despite this there is a sharp attenuation of climatic signal with depth which implies that this layer is unstable to climatic fluctuations. It is possible that the ground at 150 to 200 cm depth was frozen for more than two years, meaning that permafrost was present. This would be consistent with the fact that frozen ground was encountered below 80 cm during the placement of the earth thermometers, but it is also possible that this layer could thaw completely during a warmer year. An interesting feature is the prolonged presence of a zero-degree curtain at 160 cm.

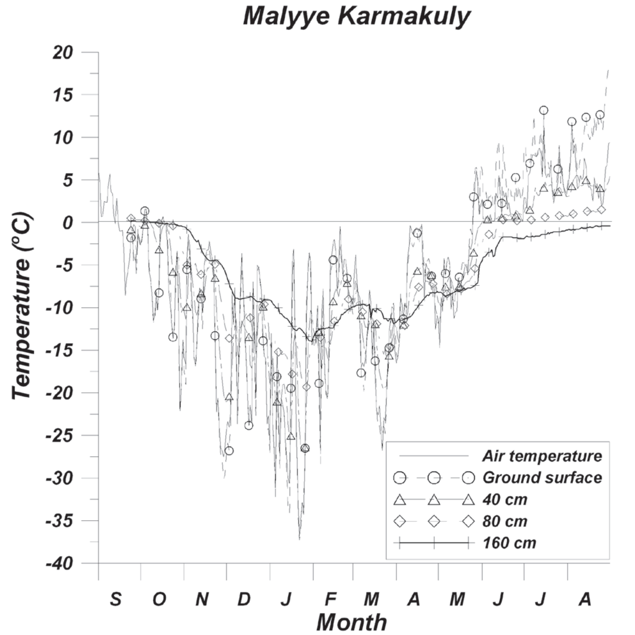

Figure 5. Air and ground temperature observations at Malyye Karmakuly, 1882–1883.

Assuming that there was no instrumental error involved, one possible explanation is that there was a massive body of ground ice present below the study site.

Sodankylä

Despite its position above the Arctic Circle, the climate at Sodanklyä is relatively mild, with MAAT just below 0°C. Even though MAAT during IPY-1 was slightly above the value of the reference climatology (1968–1997) the winter cold signal was enough to create seasonal freezing during the two years of observation. The depth of freezing was down to 165 cm during the first winter and 190 cm during the second (Fig. 4). The difference can be attributed to the fact that the cold climatic signal expressed as Degree-Days of Freezing (DDF) of the second winter was less than 80% of the first winter. This resulted in less penetration of cold into the ground.

A marked difference in meteorology between 1882–83 and 1883–84 was noticed by both scientists and the local inhabitants, who considered 1882–83 much more representative of the typical climate than the following year. The second winter was warmer than the first, but the spring and early summer were much colder. There were also 201 days of rain or snow precipitation during the second year compared to 134 days during the first, which could also have affected the ground temperature regime (GTR).

Malyye Karmakuly

Malyye Karmakuly is located on the west coast of Novaya Zemlya, where North Atlantic circulation patterns also influence the climate, but to a somewhat lesser extent than in Fennoscandia. The MAAT observed in 1882–83 was -6.6°C, which is 1.4° below the reference climatology value of

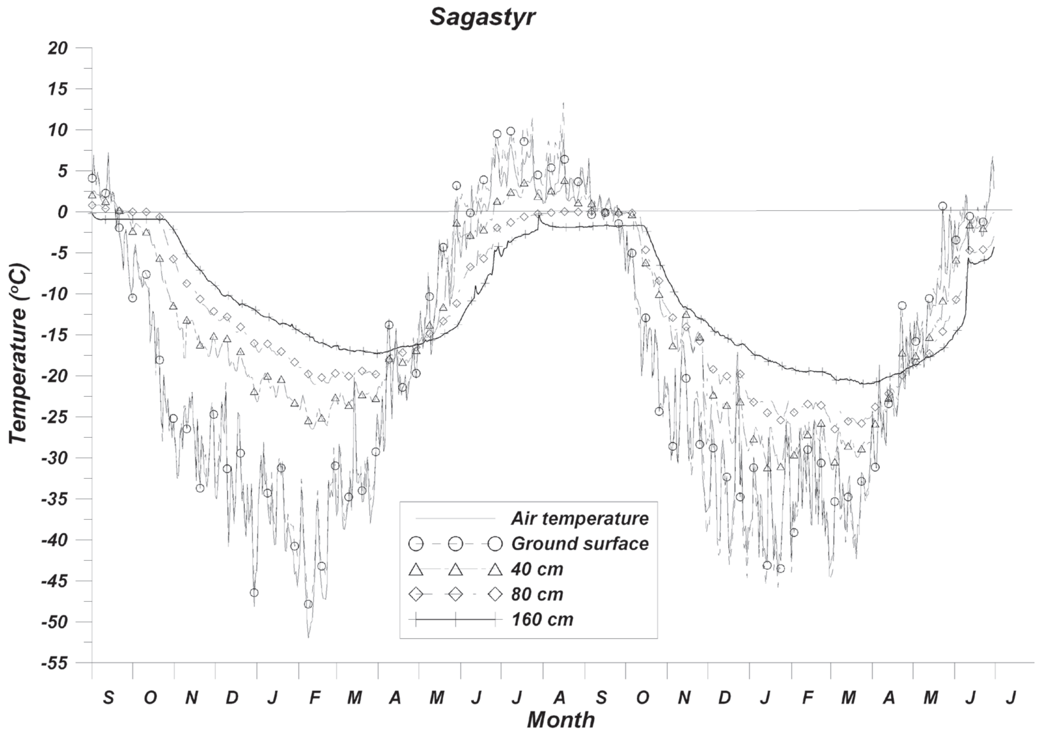

Figure 6. Air and ground temperature measurements at Sagastyr, 1882–1884. While there were differences in the meteorology of the two years, the difference in GTR is primarily due to the reduction in snow cover resulting from the relocation of the instruments away from an area of building-induced snow drift.

-5.1°C. The GTR at this location was more favorable for the formation of permafrost than either Jan Mayen or Sodankylä. This is because of the lower MAAT and greater range of air temperature expressed as Mean Annual Amplitude (MAAA) here. The mean annual ground temperature (MAGT) at 160 cm was -6.0°C at this location, but daily values were still highly sensitive to synoptic meteorology. There was no zero-curtain feature like in the locations discussed previously. Based on the ground temperature gradient, the interpolated permafrost depth was about 12 m in 1883.

Sagastyr

The overall pattern of variability in SAT anomalies at Sagastyr over the two year period was similar to the pattern observed at Sodankylä. The second winter was warmer than the first, especially February, while the spring was cooler. Notwithstanding the warmer winter, MAGT was lower during the second year. This is most likely the result of the drastic change in snow cover that resulted from the shift in location. During the first year, the depth of the snow drift next to the thermometers reached nearly 2 m compared to an accumulation of ~25 cm in the open tundra. The GTR at the second location was quite different due to much less snow cover. MAGT the second year was more than 3.0°C colder even though MAAT was 0.6°C warmer. This clearly demonstrates the critical role snow cover plays with respect to the GTR.

It is also quite interesting to note that SAT in all seasons at Sagastyr was apparently much colder than the mean of the recent climatology (1968–1997). There were no positive anomalies in the entire 22 months of record, and 18 months were more than one standard deviation below the reference means. SAT records at every other IPY-1 station in the Northern Hemisphere showed fluctuations about the mean of the reference climatology that were generally consistent with month-to-month variations in the large-scale atmospheric circulation patterns, particularly the NAO. The nearest modern station with data comparable to Sagastyr was Tiksi, about 200 km south, but an average displacement of more than ~2.5°C in the reference anomaly values would be required to bring Sagastyr observations into line with the rest of the IPY-1 monthly anomalies.

Discussion

There were distinct differences in GTR evident between the IPY-1 stations studied. Both SAT and ground temperatures decreased toward the north and east, consistent with regional climatology. The GTR at Jan Mayen and Sodankylä was much warmer than either Malyye Karmakuly or Sagastyr where MAGT ranged between -5°C and -10°C. Expected exponential attenuation of the temperature signal with depth and delayed phase shifts proportional to depth below the surface can be seen in the data.

If the GTR data from IPY-1 are broadly representative, then we can see that permafrost landscapes situated in the Atlantic-maritime climate zone would have been more sensitive to climate fluctuations even at that time than those toward the East with a more polar-continental type climate. This speculation is supported to some extent in that marked changes in permafrost landscapes were reported during the climate warming that occurred in this region early in the 20th century (Jensen 1939, Wood & Overland, in prep.). This region has certainly experienced changes in vegetation, hydrological regime, and geomorphologic processes during the recent period, and this process would likely expand in the case of increased warming as the boundary of the less-sensitive region to the eastward shifted in response.

We also note that the month-to-month fluctuations in SAT and GTR during the winter were often consistent with large-scale variability in atmospheric circulation. In February 1883, for example, the NAO index was 2.4 and the SAT anomaly distribution over the Atlantic and northern Europe closely resembled the canonical pattern (e.g., Hurrell 1995). Positive SAT anomalies occurred at Jan Mayen, Sodankylä, and Malyye Karmakuly; the effect on GTR is particularly evident at the latter station. However, the effects of increased westerly advection did not extend as far as Sagastyr, where SAT was especially low during this month. It would be reasonable to expect that GTR in Fennoscandia and northern Russia would be sensitive to those fluctuations in atmospheric circulation that produce well-known SAT anomaly patterns in winter.

Historical data such as these we have been discussing are particularly interesting now in light of the large environmental impacts that have been observed in the Arctic and elsewhere associated with a warming climate. The practical use of this type of data, however, is encumbered by a number of well-known issues, not least of which is the lack of comparable site-specific modern data. Even without the ability to make direct comparisons, we can certainly use historical information to study questions suited to the material and also to discover where new investigations might be leveraged by historical resources.

Abstract

Some effective engineering measures (crushed-rock-based embankment, crushed-rock cover, U-type crushed-rock embankment, and thermal pile in the embankment) have been used to mitigate the impact of engineering disturbance on the thermal regime of permafrost and to avoid permafrost thawing and surface subsidence affecting railway performance. A network of 43 automated sections was installed in 2004 along the Qinghai-Tibet Railway to monitor at regular intervals the ground temperature at different locations (in the embankment shoulders and slope foot and in the permafrost underneath the embankment and away from the embankment) for studying the thermal regime of permafrost. The thawing front location in the embankment and ground underneath the embankment also can be monitored based on temperature data. In addition to this network, 12 subsidence benchmarks and one 20 m deep pile as a reference benchmark in each section were also installed for monitoring the surface subsidence of the railway embankment. Recent monitoring results of two years showed that the roadbed was stable during observed periods. Under the crushed-rock-based embankment and the embankment with thermal piles, the permafrost temperatures decreased and permafrost tables were raised noticeably; but the temperature of permafrost under the embankment with a crushed-rock revetment was slightly decreased, and the permafrost table was basically unchanged.

Keywords: embankment performance; monitoring network; permafrost conditions; Qinghai-Tibet Railway; subsidence; temperature.

Introduction

Surface disturbance from engineering construction and other human activities can cause significant permafrost warming and thawing by altering the surface energy balance. Permafrost thawing can result in ground surface subsidence, which can disrupt infrastructure stability and operations in cold regions (Smith & Burgess 1999, Nelson et al. 2001). As a consequence, understanding, evaluation, and anticipation of changes in permafrost under engineering construction are of great scientific interest.

Of the 1142 km of the Qinghai-Tibet Railway (QTR) from Golmud to Lhasa, about 542 km go through continuous permafrost regions. In the 542 km of continuous permafrost regions, there are 275 km in warm permafrost (mean annual ground temperature is higher than -1.0°C), with 134 km of high ice content (including ice-rich frozen soil, saturated-ice frozen soil, and ice with soil), and 171 km in cold permafrost (mean annual ground temperature is lower than -1.0°C), with 97 km of high ice content (Wu et al. 2004). Widespread, warm, ice-rich permafrost along the QTR is easily subject to thaw settlement caused by climate warming and engineering construction, which can affect the stability of highways or railways in permafrost regions (Wu et al. 2004, 2005a, Cheng & Wu 2007). To prevent ground ice near the permafrost table from thawing caused by climate warming and engineering effects, some effective measures, such as crushed-rock-based embankments, crushed-rock cover, and substituting a bridge for embankments, were applied to cool the permafrost under embankments (Ma et al. 2002, Cheng 2005, Wu et al. 2006). The results of permafrost variation during the QTR construction indicated that these measures could effectively reduce the thermal impact of climate warming and engineering disturbance (Wu et al. 2005b, Ma et al. 2006, Cheng et al. 2007). However, under the long-term effect of climate warming and thermal disturbance of engineering, whether these measures can maintain the long-term effect of cooling the permafrost is an important issue for roadbed stability in permafrost regions along the QTR.

The main objective of this article is to introduce the long-term monitoring system of permafrost condition and embankment performance along the Qinghai-Tibet Railway. We first discuss the principles of the long-term monitoring system setup, then the systematic composition and monitoring methods. We focus on roadbed deformation and variation of the permafrost table under embankments with various engineering measures. The relationship between roadbed stability and permafrost variation under embankments caused by the thermal disturbance of engineering were investigated.

Principles of Monitoring Network Setup

The goal of the long-term monitoring network for the Qinghai-Tibet Railway in permafrost regions is mainly to monitor permafrost changes, including artificial permafrost table, permafrost temperature, freezing and thawing process under embankments with and without engineering measures and under the natural surface, roadbed deformation and the variation of seasonal freezing depth under the embankment in seasonally frozen soil areas and thawed areas of permafrost regions. The principles of the long-term monitoring network setup mainly included the following factors:

Permafrost thermal stability

Permafrost thermal stability is one of the most important factors in roadbed stability, including the mean annual ground temperature (MAGT) of permafrost and the frozen soil types (ice content). The permafrost regions along the Qinghai-Tibet Railway are divided into four areas by the MAGT: (1) extremely unstable areas of warm permafrost where the MAGT is higher than -0.5°C, (2) unstable areas of warm permafrost where the MAGT ranges from -0.5°C to -1.0°C, (3) basically stable areas of cold permafrost where the MAGT ranges from -1.0°C to -2.0°C, and (4) stable areas of cold permafrost where the MAGT is lower than -2.0°C. Each area defined by the MAGT could be further divided into two sub-areas by ice content near the permafrost table: (1) ice-rich permafrost areas including ice-rich permafrost, saturated ice permafrost, and ice layer with soil; and (2) ice-poor permafrost areas. We focused on establishing some monitoring sections in warm, ice-rich permafrost areas, where many measures were applied to decrease the permafrost temperatures under embankments.

Engineering measures

The application of engineering measures for the Qinghai-Tibet Railway was to effectively cool the permafrost temperature under embankments. Under the effect of climate warming and engineering construction, the long-term impact of engineering measures on permafrost under embankments is closely related to roadbed stability.

Some measures that were focused on included (1) crushed-rock-based embankment with length up to 142 km, (2) embankment with crushed-rock cover with length up to 156 km, (3) U-type crushed-rock embankment; (4) embankment with thermal piles, and (5) general embankment.

The goals of the permafrost monitoring network on the QTR were to investigate permafrost variations (under the natural surface and the embankments) and surface deformation of the embankment. So, the monitoring network is divided into two parts: one is to investigate the variation of active layer thickness—the soil temperatures at the ground surface as well as near the permafrost table and the MAGT under climate warming; the other is to investigate the variation of the permafrost table—the temperature under the embankments and the total deformation on railway surface under the effect of the railway.

Monitoring Sites Description

According to the principles of the monitoring network setup, 43 monitoring sections were established in 2004, including the monitoring of road surface deformation and permafrost temperatures under the embankment and natural surface. In each section, the permafrost temperatures under both the right and left shoulders of the embankment, under the embankment slope foot, and under the natural surface away from the railway were monitored. Additionally, 12 deformation benchmarks were installed on the road surface for each section. All of these instruments comprised the deformation monitoring system in each site. Meanwhile, two weather stations will be established at the Kaixinling and Tanggula Mountains in 2008. Together with a weather station at Beiluhe basin, they will consist of a weather system in the whole monitoring network along the Qinghai-Tibet Railway.

These 43 monitoring sites along the 542 km of the QTR, from Xidatan to Anduo, span about 3.4 latitudinal degrees and about 2.6 longitudinal degrees on the eastern Qinghai-Tibet Plateau (Fig. 1). The elevation of these sites vary from 4423 m a.s.l. at Xidatan site to 5080 m a.s.l. at the Tanggula Mountain site, with an average elevation of about 4713 m a.s.l. All monitoring sites are located in the permafrost region except the XD1 site, located in seasonal frozen soil areas near the northern limit of permafrost. Among the sites located in permafrost regions, the QH1 and ZH1 sites are in thaw areas of the permafrost region, and the ZR1, XQ1, and WT1 sites are in degraded areas of the permafrost region, where the MAGT is higher than 0°C. These observed sites are distributed in various terrains, including high altitude mountains, high plains, and basins from north to south of the plateau. In the high altitude mountains along the QTR, that is, the Kunlun Mountains, Kekexili Mountains, Fenghuo Mountains, Tanggula Mountains, and Touerjiu Mountains, the MAGTs are lower than -1.5°C or -2.0°C, the active layer thickness ranges from 1.2 m to 2.0 m, the permafrost thickness is larger than 60 m, and ice-rich permafrost exists from the permafrost table to 10 m deep below the ground surface. In the high plain along the QTR, that is, the high plain of the Chumaer River, the MAGTs range from -0.5°C to -1.5°C, the active layer thickness ranges from 2.0 m to 3.0 m, the permafrost thickness is lower than 50 m, and ice-rich permafrost is widespread from the permafrost table to 10 m deep below the ground surface. In the basins along the QTR, that is, the Beilu River, Wuli, Tuotuo River, Buqu River, Zajiazangbu River and Anduo, the MAGTs are higher than -0.5°C, exceptionally lower than -0.5°C, most of the active layer thickness is larger than 3 m, but some is exceptionally lower than 2.5 m, permafrost thickness ranges from 10 m to 25 m, and thaw area is widespread.

The areas in the high plain and in the basin are key sections for monitoring permafrost variation under the embankment and the total deformation of road surface due to warm, ice-rich permafrost.

Measuring Methods

Soil temperature measuring method

Soil temperatures were measured in three embankment locations: from the road surface to 20 m deep through the borehole at the right and left shoulders, from the natural surface to 8 m deep through the borehole at the embankment slope foot, and from the natural surface to 18 m deep through the borehole at a place away from the railway (Fig. 2). All measurements were obtained by a string of thermistors installed with the interval of 0.5 m from each other along the borehole, except at the places away from the railway. There the thermistors were installed at depths of 10, 20, 40, 80, 120, 160, and 200 cm from the surface to 2 m deep, and with the interval of 0.5 m from 2 m to 18 m deep. These thermistors, with sensitivities of ±0.05°C, were made by the State Key Laboratory of Frozen Soil Engineering (SKLFSE). The in situ measurement data acquisitions were automatically conducted by the Datataker of DT500 series (made in Australia). Well-trained technicians and professionals manually download the data from the Datataker every two months, and they check the operational condition of the equipment, including power, communication, etc., every month.

Deformation measuring method

Total deformation of embankment surface monitoring consists of two parts in each site. One part is constructed of 12 thin-steel benchmarks inserted 20 cm deep from the embankment surface. The other part is constructed of standard piles, as a reference benchmark, buried 20 m deep under the embankment near the deformation benchmarks (Fig. 3). Relative elevations of the deformation benchmarks and the reference benchmark are measured by electronic theodolite. The absolute heights are calculated by comparison of the elevation differences between deformation benchmarks and the reference benchmark. The deformation measurements of the embankment surface are conducted on day 20 of every month by well-train technicians and professionals, strictly following the standard guideline.

Estimation method of active layer thickness and permafrost table

Active layer thickness (ALT) under the natural surface or the artificial permafrost table under the embankment can be estimated by soil temperature data measured by the methods mentioned above. The ALT can be estimated by various methods: mechanical probing, temperature measurements, visual measurements, etc. (Brown et al. 2000). The soil temperature measurement method is available in our study. The maximum thawing depth can be shown by the profile of the soil temperature versus the depth-mapped base on the data of the daily soil temperature during any time extent, commonly several months from August to November. The

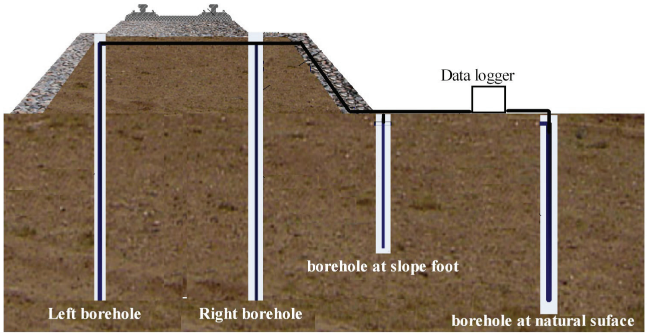

Figure 2. Section of the permafrost temperature observed site; depth of borehole at both left and right shoulders is 20 m, at the slope foot is 8 m, and at the natural surface is 18 m. Generally, the borehole at the natural surface is away from the railway.

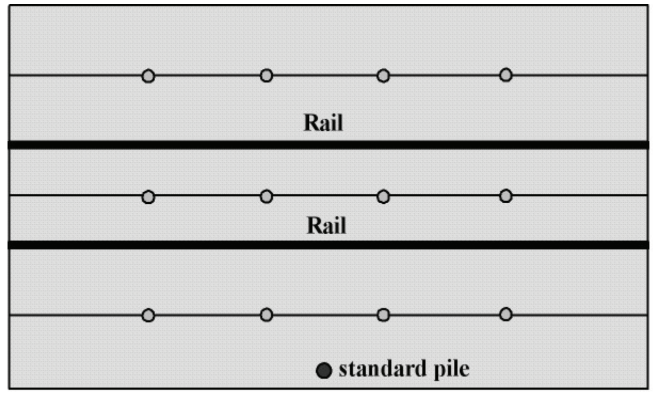

Figure 3. Planform of thin-steel benchmarks setup of the deformation in embankment surface in each section. Grey solid circles are thin-steel benchmarks of deformation, and black solid circles are standard piles as a reference benchmark of deformation.

deepest intersection between the profile mentioned above and the 0°C axes is the deepest depth of soil thawing in summer, which is the active layer thickness from the ground surface. The artificial permafrost table under the embankment is estimated by the same method.

Results

Permafrost variation and deformation for general embankment

Table 1 shows the variation of the artificial permafrost table under the general embankment and deformation of the embankment surface. During the period of observation, the artificial permafrost table rose, ranging from 0.55 m to 0.9 m under the right shoulder of the embankment and from 1.1 m to 2.9 m under the left shoulder of the embankment for KM1, CR2, CR5, LD1, WL3, and WQ1 sites; the artificial permafrost table dropped, ranging from -0.35 m to -4.1 m for CR1, YH1, YH2, DB1, RR1, and AD3 sites. However, the sections where the artificial permafrost table dropped are located in extremely warm permafrost regions where mean annual ground temperature is high, up to -0.5°C, except at the CR2 site. This indicates that extremely warm permafrost could gradually thaw if special design methods are not used.

However, deformation of the embankment surface seems to be unrelated to the variation of the artificial permafrost table (Table 1). The amount of average deformation at the sections of CR1, CR5, WQ1, and AD3 is larger than 20 mm, and only CR1 and AD3 sites found that the artificial permafrost table dropped during observed periods. Drilling data show that the deformation of embankment surface obviously depends on ice content of permafrost. The ice content of permafrost is more than 30% for these sites.

Permafrost variation under crushed-rock-based embankment

Table 2 shows the variation of the artificial permafrost table under a crushed-rock-based embankment. During observed periods, the artificial permafrost table under the embankment rose except at the left shoulder of the WL1 and TG1 sites, ranging from 0.05 m to 3.35 m. The artificial permafrost table under the left shoulder of the embankment was still deeper than the permafrost table under the natural surface. These results indicate that using a crushed-rock-based embankment is effective in raising the artificial permafrost table under the embankment. The cause of the artificial permafrost table under the left shoulder of the embankment for WL1 and TG1 sites is unclear, and probably is related to the crushed-rock-based embankment construction.

Permafrost thawing under embankments resulted in subsidence of the embankment. For WL1 and TG1 sites, the average deformation at the left shoulder of the embankment surface was more than 10 mm—up to 15 mm and 32 mm, respectively, during observed periods. For other sites, the average deformation is lower to 2 mm, indicating that the roadbed is stable.

The monitoring results before 2006 testified that the artificial permafrost table was not only raised, but also the temperatures had a trend of decreased permafrost temperatures under the crushed-rock-based embankment (Wu et al. 2005b, Ma et al. 2007), indicating that it is a good engineering measurement to avoid permafrost thaw.

Discussion and Summary

The network that monitors permafrost conditions and embankment performance along the QTR began to run in 2005, and some very useful data have been obtained successfully, including variation of the permafrost temperature, active layer under the natural surface, artificial permafrost table, temperature under the embankment, and total deformation of railway surface. These helpful data can be used to investigate and analyze the relationship between roadbed stability and permafrost variation under the embankment. The data about active layer can be used to investigate spatial features of active layer thickness along the QTR. These data are useful also for understanding the response of permafrost and active layer to climate warming and engineering construction.

To check permafrost variation in the early stage of the QTR operation, we first analyzed the obtained data of these 43 sites. The results of two recent years showed that

All signs are the same as that in Table 2. * means the value under roadbed centerline. <0 means artificial permafrost table entered into embankment.

the total roadbed deformation was smaller than 10 mm, which indicates roadbed stability. Under the crushed-rock-based embankment and the embankment with thermal piles, permafrost temperatures were noticeably decreased, and the permafrost table was noticeably raised. Under the embankment with crushed-rock revetment, permafrost temperatures were slightly decreased, and the permafrost table was basically stable. However, the following problems deserve more attention:

- For all observed sites, the permafrost temperatures were uneven due to the radiation difference of the two embankment slopes. The permafrost table depth under the sun-side slope of the embankment is greater than that under the shade-side slope, and the permafrost table slope inclining to the sun-side slope of the embankment could be deformed possibly, resulting in roadbed crack.
- The thaw layer between the upper permafrost and the seasonal freezing layer occurred under the embankment in the warm permafrost areas where the MAGT is higher than -0.5°C. The thickness of the thaw layer ranged from 50 cm to 150 cm with an average of 85 cm, which could potentially result in larger deformation of the roadbed.
- The frozen layer which would not thaw within a year formed under the left shoulder (shade-side) of the embankment in both of the seasonal frozen soil areas and the thaw areas of permafrost regions. This frozen layer formation beneath the left side of the embankment could be an inducement to roadbed damage.
- The permafrost temperatures under the slope foot of the embankment were higher than those under the natural surface. Under the thermal effect of the railway, the active layer thickness under the slope foot of the embankment was larger than that under the natural surface. Rainfall could accumulate here possibly because of the lateral thermal influence.

Acknowledgments

Many technicians contributed greatly during construction of the permafrost monitoring network along the QTR, and the authors are very thankful. This research was funded by the Outstanding Youth Foundation Project, the National Natural Science Foundation of China (Grant No. 40625004).

Freezing/Thawing Index Variations During the Last 40 Years Over the Tibet Plateau

Tonghua Wu, Lin Zhao, Shuxun Li, Changwei Xie, Qiangqiang Pang, Wengang Zhang
Cryosphere Research Station on the Qinghai-Tibet Plateau, Cold and Arid Regions Environmental and Engineering Research Institute, Chinese Academy of Sciences

Abstract

This paper presents the freezing/thawing index variation over the Tibet Plateau based on the analysis of the mean monthly air temperature and ground surface temperature data from 101 meteorological stations during the period of 1961 to 2000. The statistical results showed that the mean annual air and ground surface freezing indices equal 959 and 780 degree-days, respectively, and that the mean annual air and ground surface thawing indices equal 2494 and 3532 degree-days, respectively. The multivariate regression analysis results indicated there is a high correlation between the freezing/thawing index and the latitude and elevation on the plateau. On a decadal scale, the annual air freezing indices indicated a decrease of 146 degree-days during the last four decades. As to the annual ground surface freezing indices, the values indicated a decrease of 95 degree-days. Moreover, the annual air thawing index displayed an increase of 209 degree-days, and the annual ground surface thawing index also displayed an increase of 150 degree-days since 1961. The decrease of freezing index and the increase of thawing index may be responsible for the permafrost degradation in recent years on the plateau.

Keywords: freezing index; permafrost; thawing index; Tibet Plateau.

Introduction

In permafrost regions, the annual air and ground freezing and thawing indices are of great significance in predicting and mapping permafrost distribution (Nelson & Outcalt 1987) and active layer thickness (Nelson et al. 1997, Shiklomanov & Nelson 2002, Zhang et al. 2005). Both of the indices are also important parameters for engineering design in cold regions (Steurer 1996). Generally, the annual freezing and thawing indices are defined as the cumulative number of degree-days below and above 0°C for a year (Permafrost Subcommittee 1988). Among the four main types of freezing and thawing indices which have been used, the annual freezing and thawing indices may be representative of the freezing and thawing climatology (Legates & Willmott 1990). A recent study also demonstrated the validity of approaching the freezing/thawing index by means of calculations of mean monthly air temperature data, which is originally defined based on daily observations (Frauenfeld et al. 2007).

This paper aims to provide the variations of annual air and ground surface freezing/thawing indices from 1961 to 2000 on the Tibet Plateau. The estimation of the annual freezing/thawing index would contribute to an understanding of climate change and variations in ground thermal regime on the plateau.

Data and Methods

We collected the mean monthly air and ground surface temperature data at 101 meteorological stations from 1961 to 2000 on the Tibet Plateau (Fig. 1). The air temperature is based on the observations at 1.5 m above the ground, and the

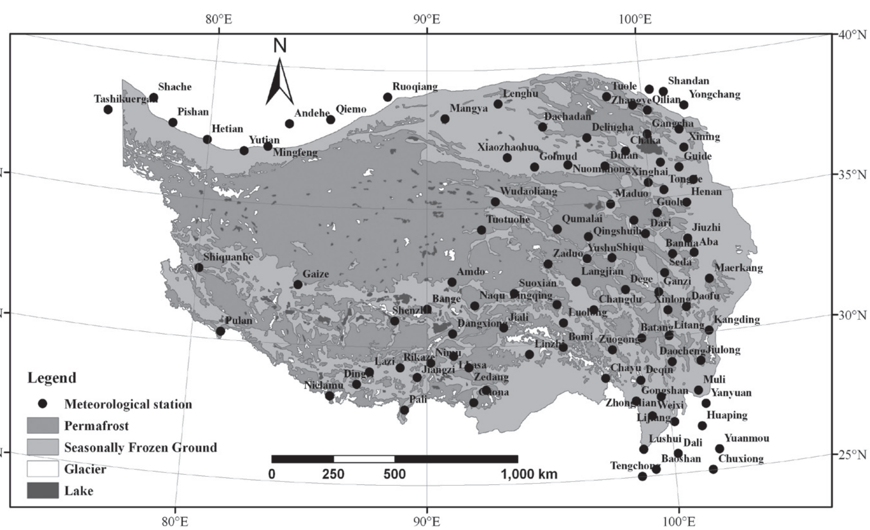

Figure 1. Permafrost distribution and the locations of meteorological stations on the Qinghai-Tibet Plateau.

ground surface temperature is based on the measurements at 0 cm of earth surface.

The annual air and ground surface freezing indices are calculated as the following equations (Frauenfeld et al. 2007). The duration in estimating the freezing index includes those months when temperatures were below 0°C degree:

$$FI_a = \sum_{i=1}^{M_F} \left|\overline{T}_{ai}\right| \cdot D_i, \ \ \overline{T}_{ai} < 0\,^{\circ}\mathrm{C} \tag{1}$$

$$FI_s = \sum_{i=1}^{M_F} \left|\overline{T}_{si}\right| \cdot D_i, \ \ \overline{T}_{si} < 0\,^{\circ}\mathrm{C} \tag{2}$$

where FI_a and FI_s are the annual air and ground surface freezing indices; M_F are those months when the mean monthly temperature is below 0°C; D is the number of days in the month of M_F.

Similarly, the annual air and ground surface thawing indices are calculated as the following equations. The duration in estimating the thawing index includes those months when temperatures were above 0°C degree:

$$TI_a = \sum_{i=1}^{M_T} \overline{T}_{ai} \cdot D_i, \ \ \overline{T}_{ai} > 0\,^{\circ}\mathrm{C} \tag{3}$$

$$TI_s = \sum_{i=1}^{M_T} \overline{T}_{si} \cdot D_i, \ \ \overline{T}_{si} > 0\,^{\circ}\mathrm{C} \tag{4}$$

where TI_a and TI_s are the annual air and ground surface freezing indices; M_T are those months when the mean monthly temperature is above 0°C; D is the number of days in the month of M_T.

The FI_a, FI_s, TI_a, and TI_s are calculated for each year from 1961 to 2000. Then the decadal values of those indices are obtained for avoiding great interannual fluctuations (Thompson 1963, Shur & Slavin-Borovskiy 1993).

Results

Variations of air and ground surface freezing indices

Among the 101 meteorological stations, there are 26 stations where monthly mean air temperature and monthly mean ground surface temperature are above 0°C. Therefore, the remaining 75 stations are selected for the calculation of freezing index on the plateau. The statistical results indicated that the mean annual air freezing index during the 40 years was 959 degree-days and that the mean annual ground surface freezing index was 780 degree-days. The maximum value of air freezing index occurred at Wudaoliang station, which is located at the hinterland of the plateau, equaling 2450 degree-days. The maximum value of ground surface freezing index also occurred at Wudaoliang station, which equals 1792 degree-days. The minimum value of air freezing index occurred at Lhasa station, which is located in the south of the plateau, equaling 97 degree-days. The minimum value of ground surface freezing index occurred at Zhongdian station, which is located in the southeast of the plateau, equaling 42 degree-days.

The calculated annual air and ground surface freezing indices showed a close correlation with the altitude (h) and the latitude (φ). As shown in Figures 2 and 3, validation with FI_a and FI_s from field data shows good correlation (R_{af}=0.916 and R_{sf}=0.943). We used the multivariate regression method to determine the function between air and ground surface freezing indices and the latitude and elevation. The analyses of variance indicated a high significance level (Tables 1 and 2).

$$FI_a = 8029.077 - 192.541\varphi - 0.738h \tag{5}$$

$$FI_s = 6513.638 - 162.230\varphi - 0.537h \tag{6}$$

located in permafrost regions where there is seasonally frozen ground. The data showed an obvious decrease in the air and ground surface freezing indices since the 1960s.

On a decadal scale, the average values of air freezing index in the 1960s, 1970s, 1980s, and 1990s are 1047, 960, 928, and 901 degree-days, respectively. As a signal of climatic warming on the plateau, the air freezing index on the plateau indicated a decrease of 146 degree-days during the past 40 years. While the average values of ground surface freezing index in the 1960s, 1970s, 1980s, and 1990s are 838, 785, 753, and 743 degree-days, respectively. The ground surface freezing index on the plateau also showed a decrease of 95 degree-days since 1961. This conclusion coincides with the general opinion of greater warming in winter than in summer on the plateau during the last 40 years.

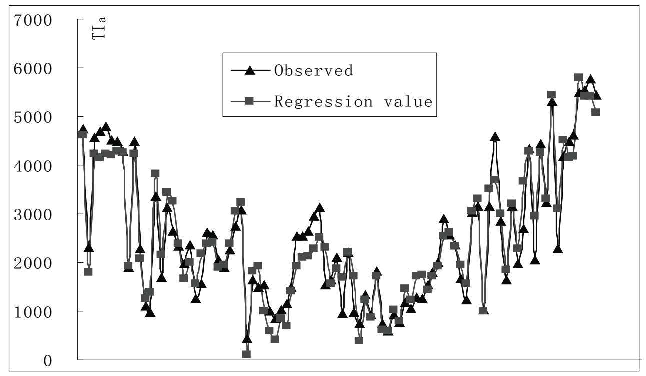

Figure 4. Regression analyses for the air thawing indices.

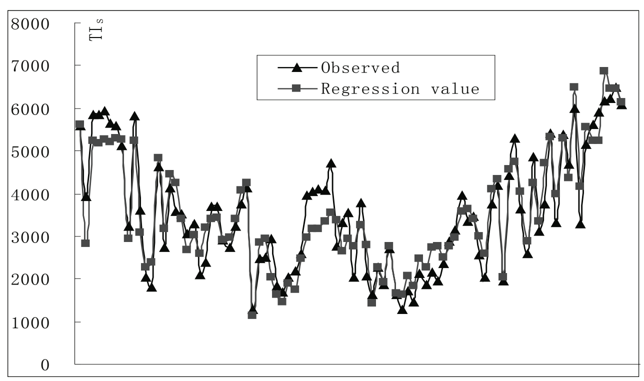

Figure 5. Regression analyses for the ground surface thawing indices.

Variations of air and ground surface thawing indices

We also excluded 9 stations where air temperature and ground surface temperature showed great difference with the other stations. Most of them are located in the southeast of the plateau with a low elevation and high monthly temperature. The remaining 92 stations were selected to calculate the thawing indexes on the plateau. The averaged air thawing index on the plateau is estimated at 2494 degree-days, and the averaged ground surface thawing index is estimated at 3532 degree-days. The minimum value of air and ground surface thawing indices also occurred at the hinterland of the plateau, while the maximum value occurred in the northwest of the plateau, where the West Kunlun Mountain range is situated.

Similar to the freezing index, the calculated annual air and ground surface thawing indices also showed close correlation with the altitude (h) and the latitude (φ). As shown in Figures 4 and 5, Validation with TI_a and TI_s from observed data also shows good correlation (R_{at}=0.961 and R_{st}=0.937). We also used the multivariate regression method to determine the function between air and ground surface thawing indices and latitude and elevation. The analyses of variance indicated a high significance level (Tables 4 and 5).

$$TI_a = 11971.781 - 157.441\varphi - 1.370h \tag{7}$$

$$TI_s = 13130.046 - 161.442\varphi - 1.366h \tag{8}$$

Table 6 implies the interdecadal variations of air and ground surface thawing indices (degree-days) at nine stations. The data show an obvious increase in the air and ground surface thawing indices since the 1960s.

On a decadal scale, the average values of air thawing index in the 1960s, 1970s, 1980s, and 1990s are 2433, 2472, 2488, 2584 degree-days, respectively, which indicate an increase of 209 degree-days in the last 40 years. Similarly, the average values of ground surface thawing index are much higher than the air thawing index. The ground surface thawing indices in the 1960s, 1970s, 1980s, and 1990s are 3448, 3485, 3539, 3657 degree-days, respectively, which show an increase of 150 degree-days. Compared with the variations of air and ground surface freezing indices, the amplitude of changes in thawing index on the plateau was much less than that of freezing index.

Changes of permafrost and active-layer thickness

The observation results of borehole temperature data from sporadic permafrost regions and discontinuous permafrost regions both indicated that permafrost on the Tibet Plateau has undergone significant degradation during the past 40 years (Cheng & Wu 2007). From the 1970s to the 1990s, the ground temperature in sporadic permafrost regions and seasonally frozen ground regions has risen by 0.3–0.5°C, while the permafrost temperature in discontinuous permafrost regions has risen by 0.1–0.3°C. The permafrost where mean annual ground temperature was 0–-0.5°C has been accelerating in warming and thinning (Jin et al. 2000, Wang et al. 2000).

In the recent 10 years, the thickness of the active-layer on the Tibet Plateau showed an increasing tendency, with increasing velocity approximating 3.1 cm/yr in discontinuous permafrost regions and 8.4 cm/yr in sporadic permafrost regions (Wu et al. 2005).

To a great extent, the recent changes of permafrost and active-layer thickness could attribute to the significant decrease in the air and ground surface freezing indices and great increase in the air and ground surface thawing indices.

Conclusions and Discussion

We calculated the freezing and thawing indices based on monthly air temperature and ground surface temperature data on the Tibet Plateau, provided that the freezing and thawing indices can be reliably calculated based on monthly data. The calculation results showed that the 1961–2000 air and ground surface freezing indices which represent the cold-season temperature climatology displayed a drastic decrease, while the thawing indices which are reminiscent of the warm-season temperature climatology showed a significant increase on a decadal scale. Meanwhile, the freezing and thawing indices on the plateau both illustrated close correlation with latitude and altitude. The analysis provided a basis for estimating the temporal and spatial variations of permafrost distribution and active-layer thickness on the plateau.

All of the calculations conducted above are based on the validity of using monthly air temperature data and ground surface temperature data to obtain freezing and thawing indices. Although the idea of utilizing monthly rather than daily temperature values to calculate the freezing and thawing indices is already an acceptable method in estimating degree-days variations (Nelson & Outcalt 1987, Zhang et al. 1996, Brown et al. 2000), the precision of using monthly data is still not assessed on the plateau until now. This would be the focus of our following work.

Acknowledgments

We are grateful to the Cryosphere Research Station on the Qinghai-Tibet Plateau, Chinese Academy of Sciences for obtaining the monthly data. This study was supported by the 973 Key Projects for Basic Research (No. 2007CB411506 and No. 2007CB411505) and the Chinese National Science Foundation (No. 40471026 and No. 40701029).

Hydrological Dynamics of the Active Layer in the Permafrost Region, Qinghai-Tibetan Plateau

Changwei Xie, Lin Zhao, Yongjian Ding, Tonghua Wu
Cold and Arid Regions Environmental and Engineering Research Institute, Croyosphere Research Station on the Qinghai-Tibet plateau, Chinese Academy of Sciences

Abstract

Due to recent climate warming, the heat energy absorbed by the ground surface of the permafrost in the Qinghai-Tibetan plateau region has increased, thereby, leading to a continuous rise in ground temperature and the persistent increase in the thickness of the active layer. In recent years, with an increase in the thickness of the active layer, a large amount of shallow water diffused downward and thus resulted in the migration of water, enriching deeper horizons. Water infiltration carried much heat and increased heat storage in the deep subsoil; hence the freezing time was delayed. The positive feedback relation between the increase in active layer thickness and the water-heat transfer toward the deep soil exerted a profound influence on surface water resources.

Keywords: active layer; changes; hydrological effects; permafrost; Qinghai-Tibet Plateau; water-heat coupling.

Introduction

Traditionally, the active layer has been defined as the surficial layer above permafrost which thaws during summer (Burn 1998). The active layer serves as an energy-water exchange passage between the permafrost and the outer atmosphere. It is also a most sensitive zone for the response of permafrost to climate change. The Qinghai-Tibetan plateau (QTP) is a concentrated, distributed region of continuous permafrost at the word's highest altitude. Under the background of recent global warming, the active layer of permafrost has been affected by a series of changes, such as increase in thickness, vegetation degradation, and swamp drainage. These changes exert a profound influence on the regional ecosystems, hydrological environment, and even engineering construction (Ding et al. 2000). The increase in the thickness of the active layer of permafrost on the QTP has been verified by the data observed in the past few decades, and an increasing trend in active-layer thickness has been even more obvious in recent years. Such a trend is roughly consistent with the changes of the permafrost in other arctic regions (Osterkamp & Romanovsky 1997, Tarnocai et al. 2004). Studies show that in a 20-year period from the 1970s to the 1990s the active layer thickness has increased by 80–100 cm in the Chumar River valley (Tong et al. 1996). It has also been demonstrated that the increase in active-layer thickness was significantly larger in the high-temperature permafrost region than in the low-temperature permafrost region; the mean thickening rate of active layer in the <-1.5°C low temperature region was 3.1cm/yr, while that in the >-1.5°C high-temperature region was 8.3 cm/yr, and the largest thickening rate was 12.6 cm/yr (Wu et al. 2005). Existing studies and observation data show that the rise in the ground temperature of permafrost and the increase in the thickness of the active layer are a basic trend explaining the variations in permafrost in the QTP at present. Permafrost as an impermeable stratum adjusts the regional hydrological processes mainly through the dynamic changes of the active layer. The increase trend of active-layer thickness will inevitably lead to the lowering of the freeze-thaw surface and water drawdown in the active layer, which enhances precipitation infiltratration into deep subsoil, reduces surface runoff, and increases subsurface flow (Yang, et al. 2000).

Several questions need to be answered about this deepening. For example, what is the internal mechanism for the hydrological process variations caused by the thickness changes of the active layer under the present global warming background? What are the influences of the increase in active layer thickness and the rise in ground temperature on water-heat transfer processes? What is the feedback mechanism for the water-heat coupling process to the dynamic changes of the active layer? In response to the water-heat changes in the active layer of permafrost in QTP region, since the 1970s the cryosphere research station on the Qinghai-Tibetan plateau, Chinese Academy of Sciences, has selected more than ten observation sites. They are distributed within a 5 km section on both sides of the Qinghai-Tibetan Highway, from the northern limit of the permafrost-Xidatan to the southern limit of permafrost-Liangdaohe (Table 1). Of these, six sites have a continuous record of 8 years and 4 sites have an observation history of two years.

Temperature of the active layer was measured by a Pt resistance probe with an observation error of ±0.1°C. Soil moisture content was measured by TDR probe, with an observation error of ±0.5%. The buried depths of the probes were different at different sites, and the maximum buried depth of the probes exceeds by 20 cm the largest active layer depth at the observation site. The data were recorded automatically at one hour intervals by a data logger. This paper attempts to analyze the influences of the increase in active layer thickness, the rise in ground temperature on the water-heat transfer processes, and the impact on the regional hydrological environment.

Water-Heat Changes in Active Layer During the Freeze-Thaw Processes

Ground temperature changes

According to the annual freeze-thaw processes, the annual variations in the active layer can be divided into four stages: summer thawing stage, autumn freezing stage, winter temperature-falling stage, and spring temperature-rising stage (Zhao et al. 2000). In this environment, during the summer thawing stage the interior of the active layer had a positive ground temperature gradient, the ground temperature was significantly higher in the shallow layer than in the deep layer, the active layer and the underlying permafrost were in a heat-absorbing state, and the internal temperature exhibited a rising trend. Generally, several days after the atmospheric temperature reached the annual maximum value, the ground temperature below the depth of 10 cm also reached the annual maximum value. With an increase in active layer depth, the time at which the annual ground temperature in different horizons reached the maximum value was delayed. As the climate turned cold and the ground surface temperature fell below 0°C, the active layer entered the autumn freezing period and the ground temperature gradient became negative. The ground temperature was higher in the deeper layer than in the shallower layer, the active layer started to release heat to the atmosphere, and the ground temperature started to drop. Other studies have shown that both the positive and negative ground temperature gradients in the active layer could be maintained for more than 100 days, while the period of no ground temperature gradient lasts only 10–30 days or so in the autumn freezing process and spring temperature thawing period (Ding et al. 2000). Figure 1 is the pattern of annual ground temperature variations at different depths in the active layer of permafrost at the CN1 observation point on the QTP in 2003. The thickness of the active layer in 2003 was 147 cm.

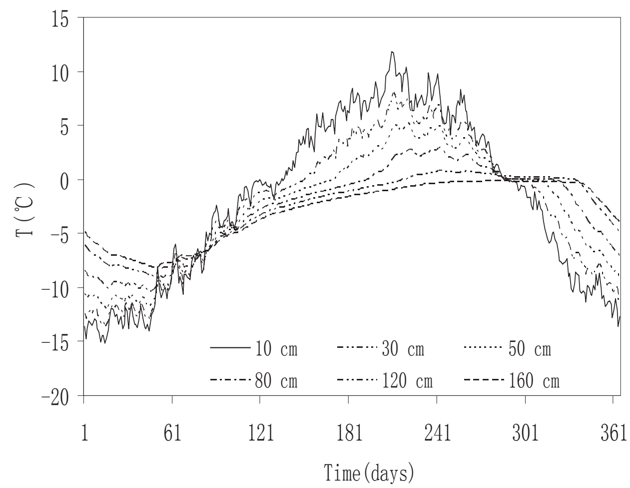

Figure 1. Pattern of annual ground temperature variations at different depths in the active layer of permafrost at CN1 point on the QTP in 2003(the temperatures at 12 levels were measured and the graph showed the data of 6 levels).

Figure 2 shows the ground temperature isoline in the active layer of permafrost at the CN1 observation point in 1999 and 2006. The observation point is located at the north slope of Mt. Fenghuoshan on the QTP, where continuous permafrost exists. It can be seen that the curves are wide near the 0°C isoline, suggesting that the transformation of the two phases of ice and water during the thawing and freezing course is a slow process, and during the process the soil temperature is prolonged at 0°C. But as the soil is entirely thawed or frozen, the isoline density obviously increases, and the ground temperature variation with time significantly speeds up. It can be seen from the annual variation of the 0°C isoline that about 100 days or more were required for the active layer to thaw entirely, but to freeze-back to the surface only required 10 days or so. The statistical results at different observation sites on the QTP show that the thawing time was far larger

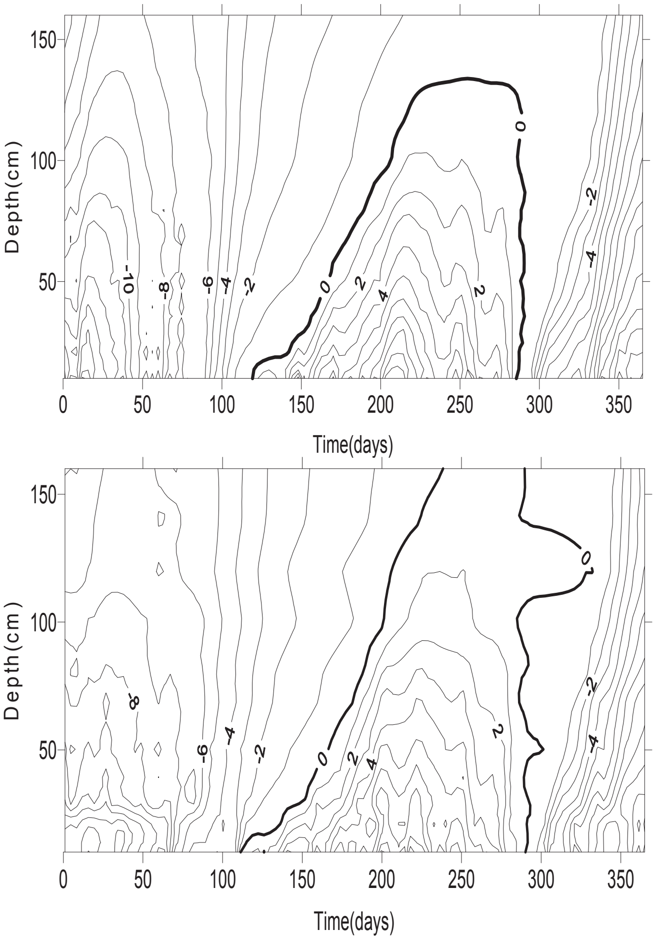

Figure 2. Ground temperature isoline at the different depth in the active layer of permafrost at CN1 observation point on the QTP in 1999 (upper) and 2006 (lower).

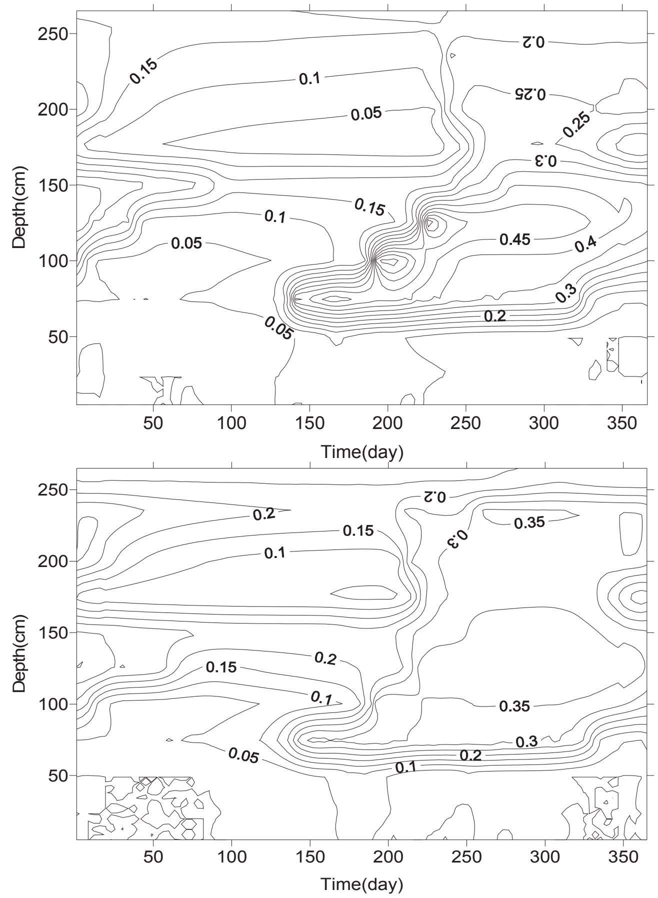

Figure 3. Soil water isoline at different depth in the active layer of permafrost at CN2 observation point on QTP in 2000 (upper) and 2006 (lower).

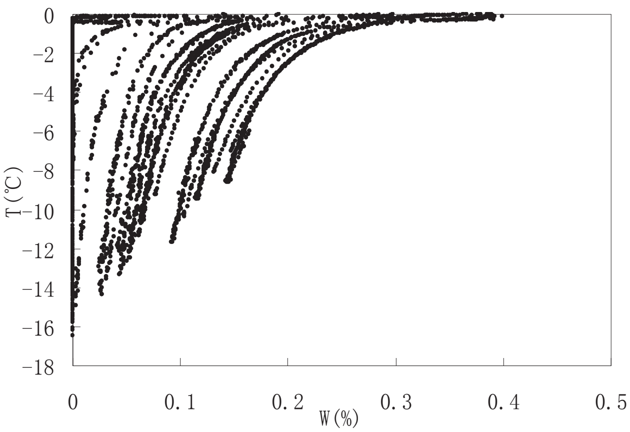
than the freezing time, but in some other places, such as in northeastern China, the freezing time of the active layer is approximately as long as the thawing time (Zhou et al. 2000).

Water change during the thawing process

As the frozen soils started to thaw, the solid water changed into liquid water and was redistributed in the active layer. In the meantime, activities of precipitation and evaporation, etc., in the active layer took place. Due to the limitations of the equipment, the soil water study in this paper was confined to the changes in liquid water; solid water cannot be discussed. Figure 3 shows the soil water isoline at CN2 in 2000 and 2006. It can be seen that the density of isolines during the soil freezing or thawing periods is very high. Water content changes rapidly near the thawing or freezing front. During the thawing period the soil water content increases rapidly, while in the freezing period it decreases quickly. The correlation statistics of soil temperature and water data at different depths and different observation points show that as the ground temperature drops belows 0°C, soil water gradually increases, with increasing ground temperature, and reaches a maximum value at a ground temperature of 0°C. As the ground temperature exceeded 0°C, soil water tended to decrease with increasing ground temperatures (Fig. 4). It can be seen from Figure 4 that the water contents at different horizons in the active layer all reached a maximum value at a ground temperature of 0°C; as the soil temperature exceeded 0°C, soil water tended to decrease, and such a trend was quite obvious in the shallow soil layer.

This phenomenon can be explained as follows: first, instrumentation can only measure liquid water as the frozen solid water gradually melts and the ground temperature gradually approaches 0°C, the percentage of liquid water continuously increases until it is entirely changed into liquid water. The changes in water content in 0°C soil are mainly caused by this process. Second, it results from the water-heat coupling action during the thaw-freeze period of the active layer. The simultaneous transfer process of water and heat in the active layer is called the water-heat coupling process. In this process, material (water) and energy are transferring simultaneously (Zhao et al. 2000). The temperature gradient is an important factor controlling the soil water transfer.

As soil is entirely thawed, gravity promotes water infiltration; when the ground temperature gradually rises to form a ground temperature gradient, water will migrate



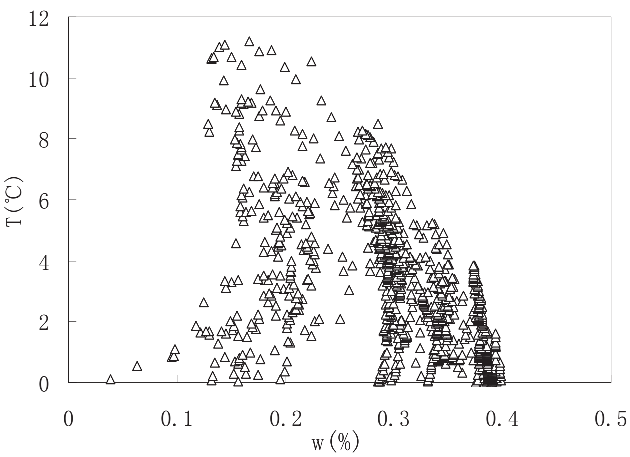


Figure 4. The scatter diagram showing the change trend of water content when soil temperature is below 0°C (upper) and above 0°C (lower) in the active layer of permafrost on QTP (CN1 observation point in 1999).

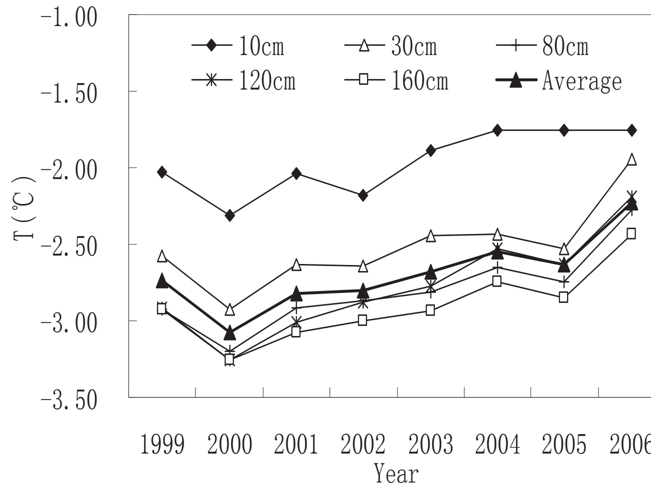

Figure 5. Change of the ground temperatures at different levels during 1999–2006 in CN1 observation site (the temperatures at 12 levels were measured and the graph showed the data of 5 levels and the average value of 12 levels).

to the ground surface; this results in water concentration at the freezing front. Soil water migration in any form is accompanied by heat transfer. This can be clearly seen from the isoline changes in Figures 2 and 3.

Water-Heat Changes and Their Hydrological Effects in Recent Years

As the thickness of the active layer increased, the temperature in it also continuously rose. Taking the CN1 site as an example, the temperature in the active layer at this area has been recorded since May 1998. The statistics of annual mean temperature at different horizons show that the temperature at various horizons rose at different rates over the last 10 years (Fig. 5). The ground temperature at the bottom of the active layer exhibited a steady temperature-rising trend, while that of the shallow layer was more variable.

As viewed from the fluctuated variations of ground temperature at different horizons, in September the rising trend of ground temperature close to the permafrost table could not be affected by the annual fluctuation changes of air temperature, while the variations in the upper active layer apparently coincided with the fluctuation changes of annual mean air temperature. Of course, viewed from the annual mean value of ground temperature, the ground temperature at the bottom of the active layer could be affected by annual air temperature fluctuations.

In December, the general trend of the ground temperature fluctuation changes in the deep layer was consistent with that in the shallow layer. The main reason for this is that the downward transfer of surface heat is a slow process. When the thawing reaches a maximum value in September, the temperature at the lowest part of the active layer still changes. Statistical data reveal that the mean ground temperature in the active layer at the CN1 observation point increased by 0.4°C since 1998, the rising amplitude of ground temperature was significantly higher in the deep layer than in the shallow layer (Fig. 5). The largest rise in temperature occurred at a depth of 120 cm. The freezing time at this depth also significantly changed. It can be seen from Figure 2 that soil at a 120 cm depth froze in the middle of September 1999, and the duration of ground temperature higher than 0°C was 71 days. In 2006, this duration increased to 124 days, while the freezing period was delayed to the end of November, and the thickness of the active layer exceeded the initial observed depth.

Measured data indicate that the 120 cm depth was the horizon with the highest moisture content, and it also had the highest heat storage. Climate warming leads to an increase in energy input in the active layer, but energy storage delays the freezing time of the region with the highest water content. If the annually received energy is persistently greater than the released energy during the freezing period, the winter freezing front cannot reach the bottom of the active layer and therefore a discontinuous layer can be formed in the active layer. The presence of the discontinuous layer will further promote the downward migration of water and thus change the spatial distribution pattern of water in a permafrost region. This is one of the most striking feedbacks of the water-heat coupling process.

Analysis on the vertical profile in the active layer in recent years shows that the water distribution in the active layer has changed and is triggered by a rise in ground temperature. The downward transfer of originally stored water in the dry and shallow soil layer caused the downward migration of the water-enriching zone. A comparison of water isolines of 2000 and 2006 at CN2 point is shown in Figure 3. It can be seen that in 2000 the soil water-enriching zone was located at a depth of 100–150 cm, and the maximum water content was 60% or so (volumetric ratio). As the depth of the active layer increased from 235 cm in 2000 to 270 cm in 2006, the soil water content in the 100–150 cm layer decreased below 40%, while the water content in the 200–250 cm soil layer, which originally had a lower water content, greatly increased, thereby forming two soil water-enriched zones. As a rule, the increase in active-layer thickness led to soil water migration from the shallower layer to the deeper layer, and the downward migration of water carried more heat to the bottom of the active layer. Therefore the freezing time of the bottom of the active layer was delayed and the thickness of the active layer further increased.

Conclusion

It can be seen from the above analysis that under the background of climate warming the increase in active-layer thickness and the rise in ground temperature are favorable to downward migration of soil water. In turn, the water heat coupling action causes a positive feedback to active-layer changes. The intensification of the downward migration trend of soil water will inevitably lead to a decrease in surface runoff yield and an increase in regional groundwater storage. The decrease in surface soil water content strengthens the infiltration of precipitation; on the other hand it promotes soil water loss to evaporation. In one word, the rise in ground temperature in the active layer and the increase in active-layer thickness are unfavorable to the storage of surface water resources in the permafrost, and they likely have a negative effect on regional runoff yield. Of course, this final point needs further study.

Abstract

Thawing permafrost as a major source of climate feedback could accelerate climate change by releasing methane (CH_4) into the atmosphere. However, current estimation of CH_4 emissions from thawing permafrost or northern wetlands has large uncertainty. The Atmospheric Infrared Sounder (AIRS) on EOS/Aqua platform provides a measurement of global CH_4 in the mid-upper troposphere. Based on more than four years' AIRS data in high northern hemisphere, it is found (1) a significant CH_4 increase when the surface temperature becomes above the freezing point; (2) a decreasing trend of -1.3 ppbv/year in Canada-Alaska and -3.9 ppbv/year in Siberia from August 2003 to 2007; (3) a lower CH_4 in 2005; and (4) a possibly large unknown source in Siberia between Jan to March. This study demonstrates that a long-term monitoring of CH_4 using AIRS and other satellites will enable us to better study the CH_4 trend and its relation with thawing permafrost.

Keywords: AIRS; High Northern Hemisphere; methane; northern wetlands; thawing permafrost.

Introduction

As one of the most important greenhouse gas next to carbon dioxide (CO_2), CH_4 is about 20 times more powerful at warming the atmosphere than CO_2 by weight, and plays an important role in atmospheric chemistry. CH_4 is highly variable in the northern hemisphere, and its concentration over the globe has been observed to rise dramatically since the preindustrial era (Dlugokencky et al. 1995). However, the increase rate of CH_4 varies significantly, for example, an anomalous increase of the growth rate of CH_4 was observed in 1998, and the anomalous increase of the growth rate of CH_4 was partially attributed to wetland emission (Dlugokencky et al. 2001). As the largest single source wetlands emission contributes CH_4 around 100–230 Tg/yr (IPCC, 2001), which represents ~20–45% of total methane emissions (~500 Tg/yr). However, the emission of CH_4 from wetlands is dominated by climate, and as demonstrated from model simulations, ±1°C changes in temperature could lead to ±20% changes in the CH_4 emission from wetlands, and ±20% changes in the precipitation alter CH_4 emission by about ±8% (Walter et al. 2001).

The permafrost thaw beneath wetlands and lakes may enhance methane production and emission by biological decomposition of organic matter previously sequestered in permafrost. i.e., permafrost degradation may lead to environments that produce methane. Since the Arctic is vulnerable to climate changes, the accelerated thawing of subarctic peatland permafrost, as observed in the discontinuous permafrost zone of northern Canada (53–58°N) over the last 50 years (Payette et al. 2004), may lead to the increase of CH_4 emission to the atmosphere. Field measurements showed that CH_4 emission from mires increased by about 22–66% over the period of 1970 to 2000 and this increase was associated with the permafrost and vegetation changes (Christensen et al. 2004). The world's northern wetlands as a much larger source of CH_4 were observed to release more CH_4 into the atmosphere than previously believed. For instance, Walter et al. (2006) observed a large emission through ebullition from Siberia thaw lakes, which increases present estimates of CH_4 emissions from northern wetlands by 10 to 63%. The thawing permafrost along the margins of the thaw lakes is the primary source of CH_4 released from the lake. Since the impacts to CH_4 emissions from northern wetlands and thawing permafrost are hard to isolate, later in this paper we just refer to emissions from these regions in the High Northern Hemisphere (HNH) as emissions from wetlands/thawing permafrost.

Current ground-based measurements of CH_4 emissions and CH_4 concentration in the atmosphere are sparse and not representative at large scales, particularly in the subarctic wetlands and permafrost regions. Sampling of the vertical variation of CH_4 in the atmosphere is much more sparse than current ground-based measurement. Therefore, space-borne measurements are crucial, as they provide the large spatial and temporal coverage needed to help us better understand the variation of CH_4 and its relation with surface emission in hemispheric scale. CH_4 in the middle atmosphere to near the tropopause region was observed from Halogen Occultation Experiment (HALOE) measurement on Upper Atmosphere Research Satellite *(*UARS*)*, and its most sensitive region is in the stratosphere to near tropopause (Schoeberl et al. 1995, Park et al. 1996). CH_4 total columns were recently observed by the SCanning Imaging Absorption spectroMeter for Atmospheric CHartographY (SCIAMACHY) instrument on board the European Space Agency's environmental research satellite (ENVISAT) (Frankenberg et al. 2005). Compared with SCIAMACHY which uses the absorption spectra of solar radiation in the near-infrared, AIRS is a nadir cross-track scanning infrared spectrometer on EOS/AQUA with 2378 channels at high spectral resolution (Aumann et al. 2003), and is most sensitive to CH_4 in the middle to upper troposphere. Moreover, the sensitivity of SCIAMACHY in the HNH is worse than that in lower latitudes due to large solar zenith angles at high latitudes. A combination of both AIRS and SCIAMACHY may provide more information on the CH_4 than either of them separately, but to combine these two data sets to derive CH_4 requires taking into account their difference in spatial resolution and many other aspects and is outside the scope of this paper.

This paper attempted to utilize AIRS observation of CH_4 from August 2003 to 2007 to investigate its seasonal variations and trend in the HNH, particularly in Canada, Alaska, and Siberia which are mostly underlain by wetlands and permafrost. The relation between AIRS CH_4 with surface temperature is also investigated. Through a combination of AIRS data with model simulation, a trend in the past four years was derived. This study demonstrates the value of satellite observations of CH_4 to the study of the effect of permafrost on climate change. However, it is still preliminary considering some uncertainties and caveats in current retrieval, the limited validation in the HNH and only a few years' data available.

Data and Method

AIRS on EOS/AQUA is a nadir cross-track scanning infrared spectrometer with about 200 channels near the absorption band of CH_4 around 7.6 μm at high spectral resolution ($\lambda/\Delta\lambda = 1200$, ~0.5 cm^{-1}), and the noise equivalent change in temperature (NeΔT), referred to 250K target temperature, ranges from 0.14K in the critical 4.2 μm lower tropospheric sounding wavelengths to 0.35K in the 15 μm upper tropospheric sounding region (Aumann et al. 2003). The spatial resolution of AIRS is 13.5 km at nadir, and in a 24-hour period AIRS nominally observes the complete globe once per day and once per night. In order to retrieve CH_4 in both clear and partial cloudy scenes, 9 AIRS pixels in the footprint of an Advanced Microwave Sounding Unit (AMSU) pixel are used to derive the cloud cleared radiance in this field of regard (FOR), from which the retrieval is made with the spatial resolution of about 45 km. The atmospheric temperature profile, water profile, surface temperature and surface emissivity required as inputs in CH_4 retrieval are derived from other AIRS channels.

A detailed description of CH_4 retrieval from AIRS can be obtained from Xiong et al. (2007), in which over 70 AIRS channels sensitive to CH_4 but less sensitive to water vapor and HNO_3 are selected for CH_4 retrieval. The most sensitive region is in the middle to upper troposphere at about 300–400 hPa in the HNH. Validation using *in situ* aircraft observations of NOAA Earth System Research Laboratory, Global Monitoring Division (ESRL/GMD) shows the bias of the retrieved CH_4 profiles is -1.4% ~ +0.1% and its rms difference is about 0.5–1.6% (Xiong et al. 2007). In this paper, the AIRS data in the retrieval are in 3 x 3 degrees in latitude and longitude.

Data of *in situ* observation of CH_4 mixing ratio at the Marine Boundary Layer (MBL) at Barrow, Alaska are obtained from *ftp://ftp.cmdl.noaa.gov/ccg/ch4/in-situ/brw* (GLOBALVIEW-CH_4, 2005). The global CH_4 concentration data from transport model simulations, as reported by Houweling et al. (2006), were obtained using a source scenario (S3) as input to the atmospheric transport model TM3 (Heimann & Körner 2003). Model simulations have been performed on 3.75° x 5° for the period 2001–2004 with meteorological fields derived from the NCEP reanalysis (Kalnay et al. 1996).

Due to the change of information content inherent in the infrared observation, which is related to the atmospheric temperature-moisture profiles, the averaging kernels have to be used to convolve the model data as below (Rodgers 2000, Xiong et al. 2007):

$$\hat{x} \approx Ax + (I - A)x_a \tag{1}$$

where $\hat{x}$ is the convolved CH_4 mixing ratio profile, x is the profile from model simulations, and x_a is the first-guess profile ("*a priori*"), which is a function of latitude and pressure but does not vary with time and longitude (Xiong et al. 2007). I is the identity matrix, and A is the averaging kernels (Maddy & Barnet 2007). Difference between AIRS observation with the model convolved data will reflect the biases between satellite observation and the model simulation (as a "truth") but taking into account the retrieval scale associated with the variation of information content in satellite observation. To analyze the seasonal variation of CH_4 from August 2003 to 2007, the average needs to be removed for both AIRS and model data. Thus, the difference between AIRS observation and model convolved data after removing their mean values individually will remove the systematic bias between AIRS and the model. By using the model data in 2004 only and the averaging kernels from every satellite observation from August 2003 to 2007, we obtained convolved data using Equation (1). Such data can be used as a "baseline," which considers the retrieval scales but no annual variation in the "truth," to drive the trend of CH_4 from its difference with AIRS observation.

Results and Discussion

Spatial and vertical distribution of CH_4 in the HNH

In the HNH, the ground surface is usually frozen and covered by the snow in the winter and early spring, so emissions of CH_4 from the wetlands/permafrost are very low, if not zero, during this period. As snow starts to melt in the late spring, soil temperature increases above the freezing point, and vegetation grows quickly into the summer; hence, CH_4 emission starts to increase in the late spring or early summer. The maxima of CH_4 emission occurs around July (Zhuang et al. 2004)., and the most CH_4 emissions from wetlands/thawing permafrost occur in June, July and August (JJA). For example, Figure 1 shows the averaged distribution of AIRS CH_4 at 200–300 from June to August 2004 in North America and Eurasia, respectively. It is evident that CH_4 is enhanced in Siberia and Canada-Alaska, which are mostly underlain by wetlands and permafrost. For further analysis, we chose two regions in Canada-Alaska (60–70°N, 165–90°W) and Siberia (50–70°N, 75–170°E).

The seasonal variation of mean CH_4 profiles averaged in Canada-Alaska and Siberia from 2004 to 2007 is shown in Figures 2a and 2b, respectively. Since the sensitivity of AIRS is low in the lower troposphere and stratosphere, the profiles shown are from 150 to 500 hPa only. Here, only the daytime profile (from the ascending node at 1:30pm LST) of each day is used, as the information content of AIRS in daytime is relatively larger than that in the nighttime (Xiong et al. 2007). Evidently, CH_4 starts to increase from June to August in both Canada-Alaska and Siberia. However, the maxima of CH_4 occurs in early spring in Siberia, which is possibly due to the leakage of natural gases, and worthy of further study. In late spring, CH_4 observed from AIRS is low, which is consistent with ground-based measurement of CH_4 in Barrow, Alaska. As indicated by Dlugokencky et al. (1995), the reason for the low CH_4 in late spring can be attributed to the break-down of atmospheric inversion in the HNH, allowing dilution of northern air with the air from the upper level.

Seasonal variation of CH_4 in the HNH from August 2003–2007 and its relation with surface temperature

Figure 3 shows the seasonal variation of CH_4 at 300 hPa (after removing the average) from AIRS observation and models from August 2003 to 2007. Here the model data are fixed in 2004, and then convolved using the averaging kernels corresponding to each AIRS observation. One common feature at both regions is the increase of CH_4 in June every year. The period for the increase of CH_4 has a good correlation with the increase of surface temperature (*Tsurf*). The decrease of CH_4 in the summer also follows the decrease of surface temperature, but with a delay of about 2–3 weeks.

Compared to the model convolved data in 2004, CH_4 from AIRS in Canada-Alaska is much higher than that from the model, which may be associated with the large forest fires in 2004. In Siberia, the maxima of CH_4 from AIRS occur mostly from January–March each year, and they are much higher than those from model convolved data. This large difference between AIRS and the model indicates a possible unknown, strong source occurring in the winter to early spring in Siberia. One possibility is the gas leakage in Siberia, and this gas leakage or other sources are not well characterized in the model, if they are included at all.

Trend of CH_4 in the HNH and its relation with surface temperature

Figure 4 shows the difference of the seasonal variation (after removing the mean) of AIRS CH_4 minus the model convolved data and the trend. Since most emissions occur from May to October, the data in this period (red) are fitted

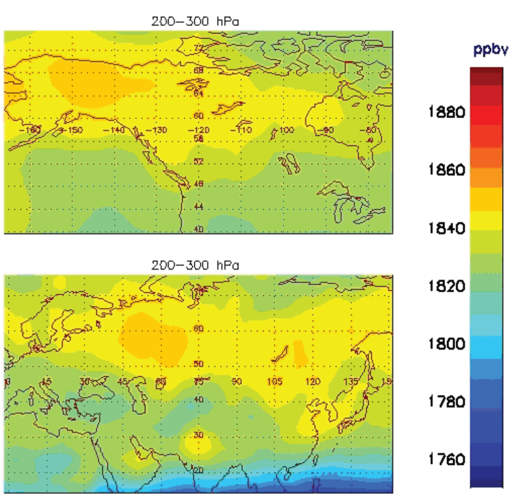

Figure 1. Seasonal averaged distribution of AIRS CH_4 in layer 200–300 hPa in June, July and August 2004 over North America (upper) and Eurasia (right). Enhancement of CH_4 CH_4 is evident over Canada-Alaska and Siberia which are underlain by wetlands and permafrost.

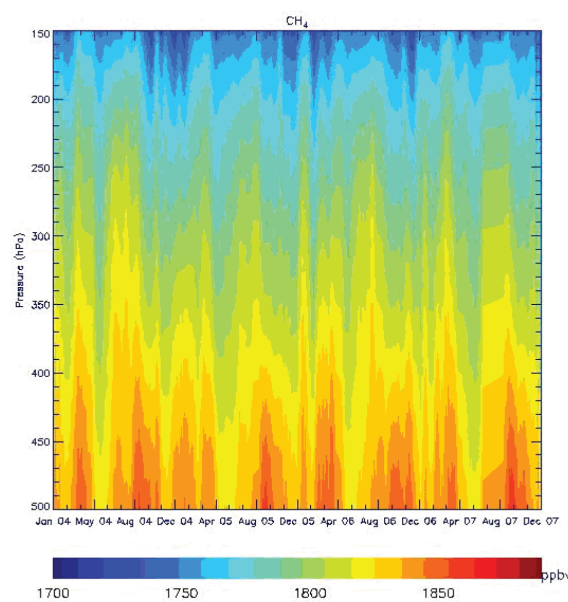

Figure 2a. Seasonal variation of CH_4 profiles (using daytime data from ascending node only) from 2004 to 2007 at Canada-Alaska.

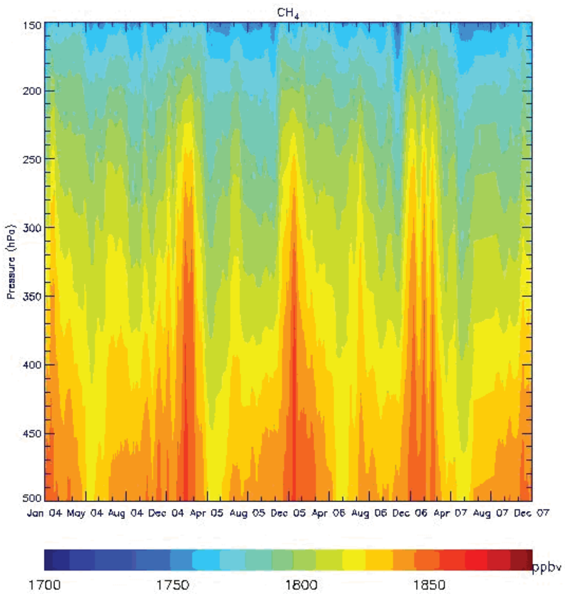

Figure 2b. Same as Figure 2a, but in Siberia.

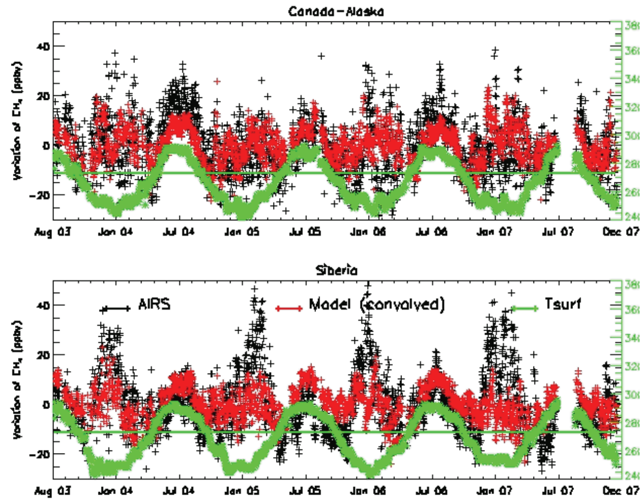

Figure 3. Seasonal variation of CH_4 (300 hPa) from AIRS (black), model convolved (red), and surface temperature (Tsurf, green) at Canada-Alaska and Siberia. There is a good correlation between CH_4 and Tsurf in the summer.

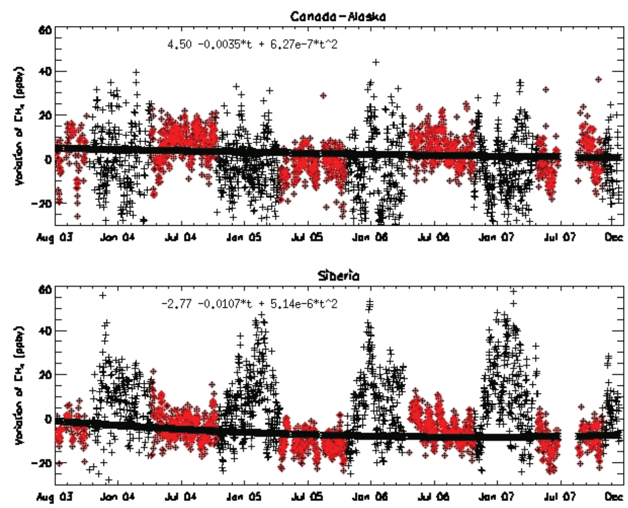

Figure 4. Trend of CH_4 (300 hPa) derived as the difference of AIRS observation minus the model convolved data (model data are fixed to 2004) at Canada-Alaska and Siberia. Black solid lines are the second-order polynomial fitting to their differences from May to October (red), and the legends are the equations.

using a second order polynomial of date (starting from Aug. 6, 2003), as shown in the solid line. The equations are given in the legends of Figure 4. The CH_4 trend is about -1.3 ppbv/year in Canada-Alaska and -3.9 ppbv/year in Siberia.

We note that in Figure 4, in the summer of 2005, CH_4 is biased lower than the fitting in both regions. This indicates that CH_4 emission in 2005 is smaller than that in 2004 and 2006. If this argument, based on satellite observation, is reasonable, lower CH_4 in 2005 may exist in the ground-based observation since its variation has a closer link with surface emission than CH_4 in the mid-upper troposphere observed by satellite. Therefore, we analyzed the seasonal variation of CH_4 measured by NOAA/ESRL/GMD in Barrow, Alaska and the surface temperature retrieved from AIRS. The hourly CH_4 observed at MBL were used to compute the daily average in Figure 5 (upper panel). In agreement with AIRS observation, CH_4 at the MBL in the summer of 2005 is lower than that of 2004 and 2006. Analysis of surface temperature provides more evidence to lower emission of CH_4 from high northern wetlands/thawing permafrost in 2005 as the surface temperature from June to September in 2005 is lower than that at 2004 and 2006 (Fig. 5). Further study of the trend of CH_4 emission from high northern wetlands/permafrost from model simulations may help to validate whether this observed trend from AIRS is reasonable.

Uncertainty analysis

It is important to keep in mind some uncertainties and caveats in current AIRS retrievals and limited validation made in the HNH. As addressed in Xiong et al. (2007), the uncertainty of CH4 retrieval corresponding to a noise equivalent bias in AIRS radiances can be evaluated by putting a noise equivalent bias to the observed radiance in CH4 channels, and then comparing the differences in their retrieved profiles. As an example, Figure 6 (upper left panel) shows the mean retrieved bias resulted from a noise equivalent bias based on two days' AIRS data (in 3 x 3 degree) in the HNH above 50°N. These two days are chosen randomly, and one is Aug. 10, 2004 (summer) and another one is Feb. 15, 2005 (winter). The largest bias is 24.9±6.0 ppbv at 350–400 hPa, and below 600hPa the bias is less than 10 ppbv. The standard deviation for all cases, represented by the error bar in the figure, is mostly less than 10 ppbv. A similar methodology is used to estimate the uncertainties of retrieval due to errors in temperature-moisture profiles and surface temperature. The mean CH4 biases resulted from the AIRS temperature and moisture profile biases are mostly less than 10 ppbv. The errors in cloud clearing could be the largest source of uncertainty, however an examination to the variation of AIRS retrieved CH4 within 200 km in the same granule and its relation with cloud amount, and

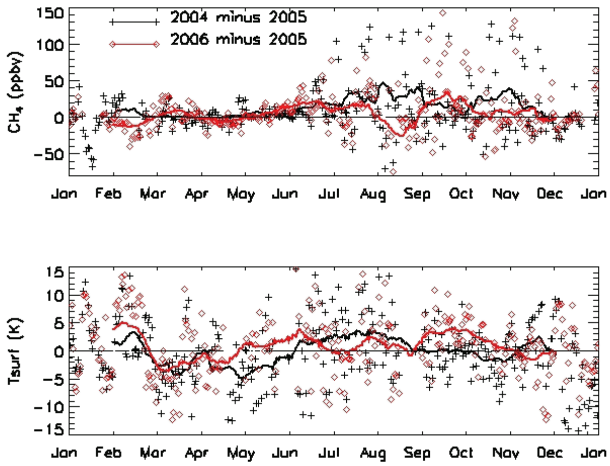

Figure 5. Difference of CH_4 at the MBL in 2004 and 2006 minus that in 2005 in Barrow, Alaska (upper). Lower CH_4 in the summer of 2005 is consistent with the lower CH_4 in the middle to upper troposphere observed from AIRS. Lower panel is surface temperature (Tsurf) in 2004 and 2006 minus that in 2005 at Canada-Alaska. Lower Tsurf from June to September in 2005 may indicate the lower emission of CH_4 from high northern wetlands/thawing permafrost in 2005.

found the difference of CH4 between clear cases (with the cloud fraction less than 0.1) and cloudy cases (with the cloud fraction over 0.8) is usually less than 1.0%. Since the magnitude of the seasonal variation of CH4 (see Fig. 3) is significantly larger than the uncertainties of the retrieval, these uncertainties should not undermine the conclusions.

We noted that there are some correlations between the retrieved CH_4 with the surface temperature and water vapor amount. Therefore, variation of water vapor and temperature profiles make the interpretation of the retrieval results complicated, and the averaging kernels have to be taken into account in the interpretation of the variation of CH_4 from AIRS, and in the comparison of AIRS with model simulation and/or other observations. A better retrieval of CH_4 also depends on a more accurate computation of radiance from the radiative transfer model, and further improvement to current model is required (Xiong et al. 2007).

It is almost impossible to isolate the impact of wetland emissions and emissions from thawing permafrost on the seasonal variation and trend illustrated above; therefore, it is hard to say whether the observed trend is related to the thawing permafrost. This will require long-term monitoring of CH_4 from satellite and more model studies.

Conclusion

Satellite observations using AIRS, show that the CH_4 in middle to upper troposphere increases in the summer in regions that are mostly underlain by the northern wetlands and permafrost, and that this increase has a good relation with the surface temperature. Preliminary analysis using AIRS observation from August 2003 to 2007, in conjunction with model simulation, shows a small but negative trend of CH_4 of -1.3 ppbv/year in Canada-Alaska and -3.9 ppbv/year in Siberia. Moreover, lower trend of CH_4 in 2005 is observed from AIRS which is in good agreement with the lower CH_4 from ground-based observation and lower surface temperature in 2005. These results have demonstrated that AIRS can provide valuable information of CH_4 in the middle to upper troposphere. Further use of AIRS CH_4 appropriately in conjunction with model simulation will provide a way to better estimate source emissions from wetlands and/or permafrost in the HNH. NOAA plans to utilize the Infrared Atmospheric Sounding Interferometer (*IASI*) (2006–2021) and the Cross-track Infrared Sounder (*CrIS*) (2009–2023) to derive atmospheric CH_4 in the same method as used for AIRS for the next 20 years. These long-term observations will be useful to monitor the trend of CH_4 associated with the thawing of permafrost and climate warming.

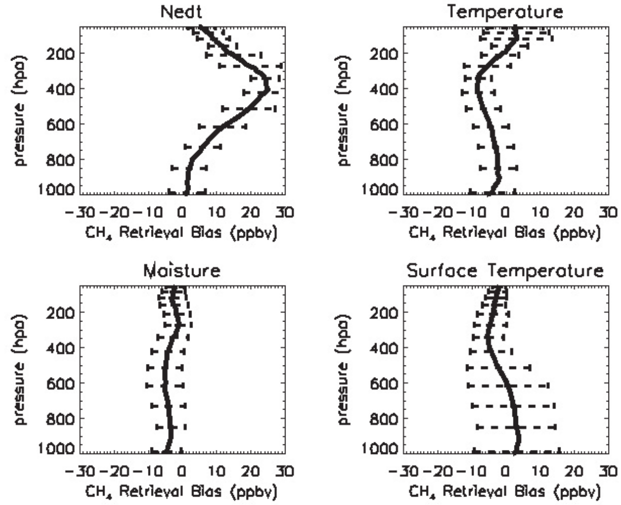

Figure 6. The mean bias of the retrieved CH_4 profiles in the HNH assuming a radiance bias equivalent to the noise of the AIRS *NeΔT* for CH_4 channels (upper left), AIRS biases in temperature (upper right) and moisture profile, and a bias in surface temperature of 2 k. Two days' AIRS data in Aug. 20, 2004, and Feb. 15, 2005 are used. Solid lines are the mean bias, and dashed lines represent the standard deviation.

Numerical Analysis of a Thermosyphon Foundation of High-Voltage Transmission Towers in a Permafrost Region

Xue-yan Xu , Lin-lin Yu, Li-yue Wang
School of Civil Engineering, Harbin Institute of Technology, Harbin 150090, China

Abstract

A new-model thermosyphon foundation (the portion of thermosyphon under ground is wrapped with concrete) is applied in the project, because this special foundation can bear the loads from superstructure, preserving permafrost soil from thawing. Research contents: According to the conditions of permafrost regions and considering global warming, the thermal and mechanical finite element model of thermal pipe foundation is made with the function of thermal and nonlinear mechanical analysis of ANSYS. Temperature distributions are compared between a thermosyphon foundation and a traditional pole foundation. The thermal calculation results indicate that the natural permafrost table rises by 0.5 m, and the inner temperature lowers by 2°C, in comparison to those with a traditional foundation. This proves the distinct permafrost-preserving effect of thermal pipes. In response to the distributions of the temperature fields of ten years in permafrost regions, it is concluded that the permafrost-preserved effect of thermal pipes is in direct ratio to working years. With the increase of areas ratio, pile space, and pile length, a better cooling effect is obtained; when the spacing between thermal pipes is 4 m, the cooling effective is optimum. On the basis of the above thermal analysis, the appropriate design parameters of a thermosyphon foundation are presented.

Keywords: design parameters; global warming; permafrost-preserved effect; temperature fields; thermosyphon foundation.

Introduction

The permafrost area of the Northern Hemisphere is about 25% of the land surface. In China, permafrost is about 22.4% of the country (Zhou et al. 2000). The Direct-Current (±500 kV) Transmission Project will be built from Hu Lun Bei Er to Liao Ning Province, and it will pass across the permafrost region (Daxing'an Mountain Range, A Er Mountainous Region, and the northwest of SongNen Plain). When the project is constructed, disturbed frozen soil and the seasonally thawed layer will have great influence on the thermal regime of the permafrost region. Often permafrost in these regions is ice-rich and makes large deformation for consolidation if thawing occurs. Global warming tends to warm the permafrost in these regions and makes it susceptible to thaw. (Mingyi Zhang et al. 2005). So it is very significant and practical to study the design method to ensure the construction security and the regular service of the project.

So far, in China, systemic test research and numerical calculations have not been conducted on the combination of the bearing capacity of the foundation of the transmission tower with the permafrost-preserving effect.

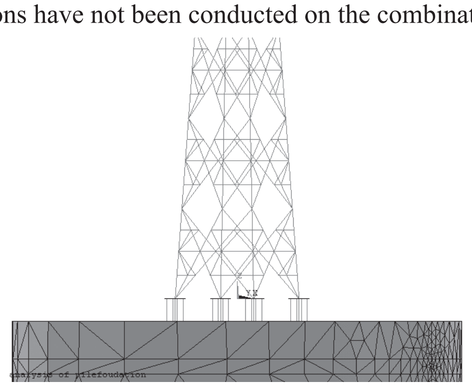

Figure 1. Sketch of the connection of tower and thermosyphon foundation.

In this paper, we consider the effect of global warming on a thermosyphon foundation (one thermosyphon pile under each tower foot, total of four) shown in Figure 1. In order to research the cooling effects of different pile spacing distances with or without a thermosyphon, we have used numerical modeling by ANSYS. Some numerical simulations are carried out during the course of this study. Namely, the temperature fields of a traditional pile foundation and a thermosyphon foundation have been analyzed under the assumption that the average atmosphere temperature will be warmed by 1°C in 10 years.

Governing Equations, Numerical Model, and Boundary Conditions

The thermal convection of foundations is the process of heat transfer. In the analysis, circular cylindrical coordinates are introduced and then the corresponding governing equations as follows (Yuanming Lai et al. 2004).

Energy: $$\rho c \frac{\partial T}{\partial t} + \rho_w c\left(u_z \frac{\partial T}{\partial z} + u_r \frac{\partial T}{\partial r}\right) = \lambda\left(\frac{\partial^2 T}{\partial z^2} + \frac{\partial^2 T}{\partial r^2}\right) + s_3 \tag{1}$$

where c and λ are specific heat and coefficient of heat conductivity separately, T is temperature, t is time, and s_3 is heat source of the whole system.

Continuity and energy:

$$\lambda_f \frac{\partial T_f}{\partial n} - \lambda_n \frac{\partial T_u}{\partial n} = L\rho \frac{\partial \xi}{\partial t} \tag{2}$$

Table 1. Thermal-physical parameters of soil used in numerical simulation.

	Temp. (℃)	-10	-5	-2	-1	-0.5	0	15
Fine sand	ρ(kg/m³)	1680	1680	1680	1680	1680	1680	1680
	W_u(%)	0.44	1.1	1.76	3.3	4.84	22	22
	λ(J/m · ℃ · h)	5760	5760	5760	5760	5760	4680	4680
Marl soil	ρ(kg/m³	1600	1600	1600	1600	1600	1600	1600
	W_u (%)	2.2	5.4	6.3	7.4	8.1	30	30
	λ(J/m · ℃ · h)	5004	5004	5004	5004	5004	2304	2304
Mud stone	ρ(kg/m³)	1890	1890	1890	1890	1890	1891	1890
	W_u (%)	4.4	5.5	6.6	7.7	8.8	35	35
	λ(J/m℃ · h)	8640	8640	8640	8640	8640	5544	5544

$$T_f(\xi(t), t) = T_u(\xi(t), t) = T_m \tag{3}$$

where *f* and *u* indicate frozen state and thaw state separately. *t* is time; *L* is critical heat; ξ is interface between freeze and thaw; T_m is the temperature of freezing front; *n* is normal vector of frozen-thaw interface.

In this study, numerical solutions are obtained using a two-dimensional finite ANSYS model through the function of the thermal and nonlinear mechanical analysis.

According to the engineering geological exploration and requirements of The Direct-Current (±500 kV) Transmission Project, the simplified computational domain including thermosyphon foundation is shown in Figure 2, 18 m depth, 30 m width, the distance between two thermosyphon foundations is 6 m. And there are no thermal flows on boundaries E–F and D–G; that is, $q = 0$.

The thermal-physical parameters of the three kinds of soils (A, B, and C) used in numerical simulation are shown in Table 1.

The temperature at the native surface E–D is changed according to the follow expression:

$$T_a = -1.0 + \frac{1}{50 \times 365 \times 24} t + 10 \sin\left(\frac{2\pi}{8760} t + \frac{\pi}{2}\right) \tag{4}$$

where, *t* is working time of the thermosyphon foundation, and is given in hours for ten years.

The temperature on the sub-permafrost boundary (18 m depth) F–G is -2.5°C.

In this study model, the thermosyphon Φ 89 (7.5 m long totally) is simplified to a 7.5 m long line, and divided into three parts, and the finite width in computation area is concrete in the results Figures 6a–h. The first one is aboveground (1.5 m length), that is, the condensation part; the second one is 3.0 m underground, which is heat-insulating; the third one, the bottom part, namely the evaporation part, is 3.0 m, and when air temperature is higher than the temperature of the thermosyphon foundation, its density of heat flow is 0; on the contrary, it starts to work, and then the density of heat flow changes as the air temperature does, and the refrigerating output per second is changed according to the following expression:

$$q = \frac{T_s - T_a}{R_s + R_f} \tag{5}$$

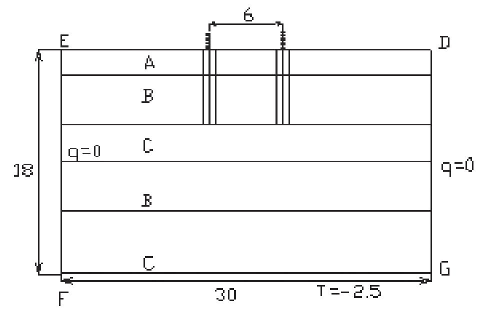

Figure 2. The simplified computational domain. A is fine sand; B is marl soil; C is mud stone (unit: m).

where, q is refrigerating output per second, T_s is average ground temperature, T_a is air temperature, R_s is thermal resistance on the soil-syphon interface, R_f is thermal resistance of the radiator on the air-syphon interface (cooling portion).

$$R_f = 1 / A\alpha \tag{6}$$

where, A is the effective area of the cooling portion of the thermosyphon; α is the heat-release coefficient of the cooling portion of the thermosyphon.

$$R_s = \frac{\ln\left(2r / D\right)}{2\pi\lambda L_e} \tag{7}$$

where, D is the outside diameter of the thermosyphon; L_e is length of cooling portion of the thermosyphon; λ is the coefficient of heat conductivity of the soil; r is the maximum radiator of area influenced by the thermosyphon.

The heat transfer quantity of the thermosyphon bar is expressed as follows:

$$Q = M \Delta T(t) \tag{8}$$

where, Q is heat transfer quantity, M is heat transfer quantity, and it is altered as follows:

$$M = \begin{cases} \dfrac{1}{R_s + R_f} & T_a - T_s \geq 1 \\ 0 & T_a - T_s \leq 1 \end{cases} \tag{9}$$

ΔT(t) is the difference in temperature between soil around the thermosyphon foundation and the inner thermosyphon.

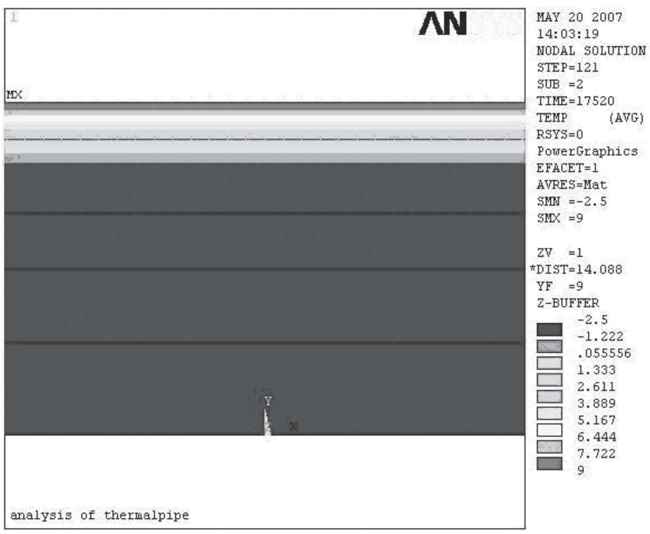
In this analysis, the 10-year simulation starts on July 15, 2007, when the high-voltage transmission tower is applied according to the requirements of the project. We choose the representative calculation results on autumnal equinox and spring equinox. On autumnal equinox, the seasonal thaw layer is the deepest, and the thermosyphon works because of the temperature difference; on spring equinox, the active layer is frozen totally, and the thermosyphon stops working.

Numerical Results and Comparisons

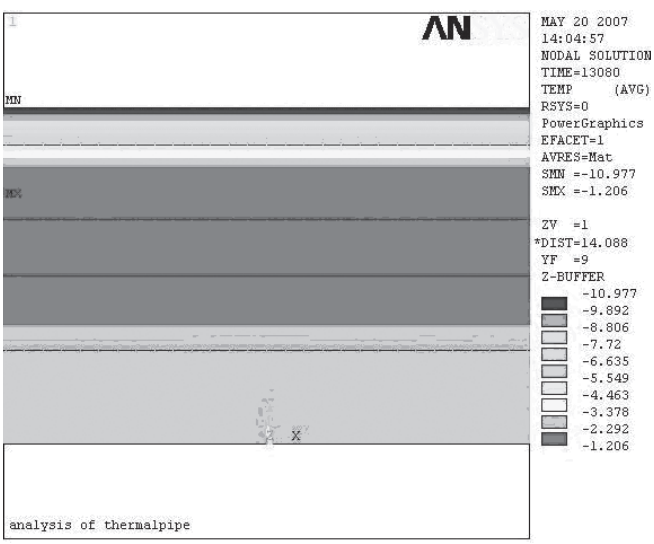
Characteristics of the temperature fields of thermosyphon foundation

The temperature field of (traditional) foundation is shown in Figure 3. It can be seen that the initial temperature distribution is even in the same soil layer. The temperature field in Figure 3 also shows the temperature field of traditional foundation.

Figures 4 and 5 are the temperature distributions of soil next to a traditional foundation and a thermosyphon foundation on autumnal equinox and spring equinox along depth. It is evident that the natural permafrost table rises by 0.5 m and the average temperature decreases by 2°C due to the permafrost-preserving effect of the thermosyphon foundation.



a) Isotherm of autumnal equinox.



b) Isotherm of spring equinox.

Figure 3. Temperature field of (traditional) foundation.

Figures 6a–6f separately display isotherms of the thermosyphon foundation on autumnal equinox and spring equinox in the second, fifth, and tenth working year. From Figure 6b, it can be seen that the isotherms of the thermosyphon foundation change in evidence, which reveals that the thermosyphon has worked; however the affected region is only as big as twice the diameter of the thermosyphon foundation on the first spring equinox after the first cold season.

As shown in Figures 6a, 6d, and 6f, with the working years going, the influenced region surrounding the thermosyphon foundation has become wider and deeper and relative temperatures descend obviously, especially for the soil layers around the bottom of the thermosyphon foundation; so it is demonstrated that the cooling effect becomes more powerful.

From Figures 6a, 6c, and 6e, because of the heat-absorbing effect of the evaporation part of the thermosyphon, there is an approximate elliptic low-temperature (isotherm of -4.2°C to -4.9°C) region, and we can state that cold power stored in the soil near the thermosyphon foundation increases greatly; therefore, the stability of the foundation can be protected effectively from rising air temperatures in permafrost regions.

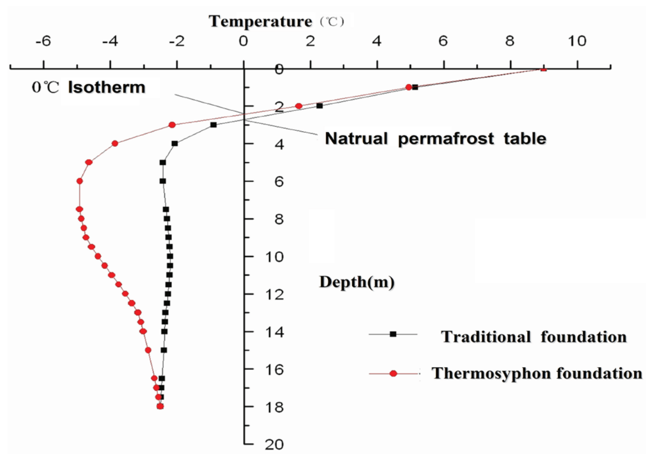


Figure 4. Temperature distributions of the two kinds of pile foundations on autumnal equinox.

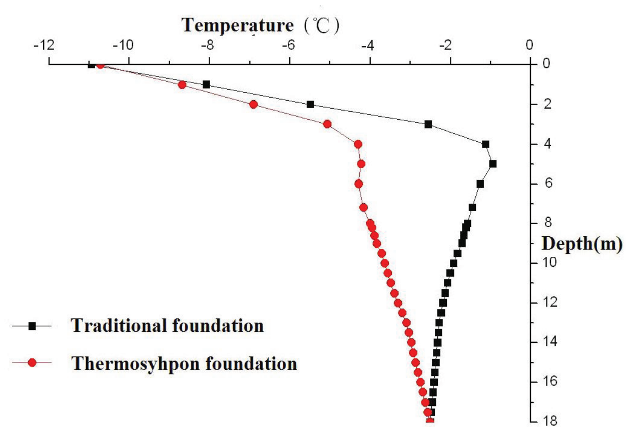

Figure 5. Temperature distribution of the two kinds of pile foundations on spring equinox.

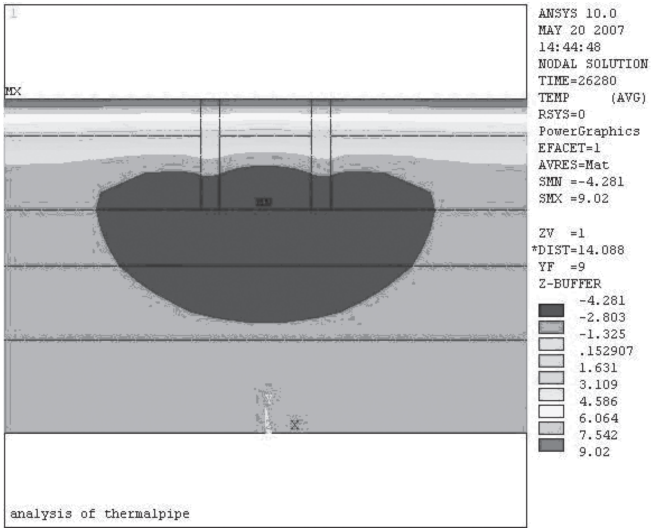
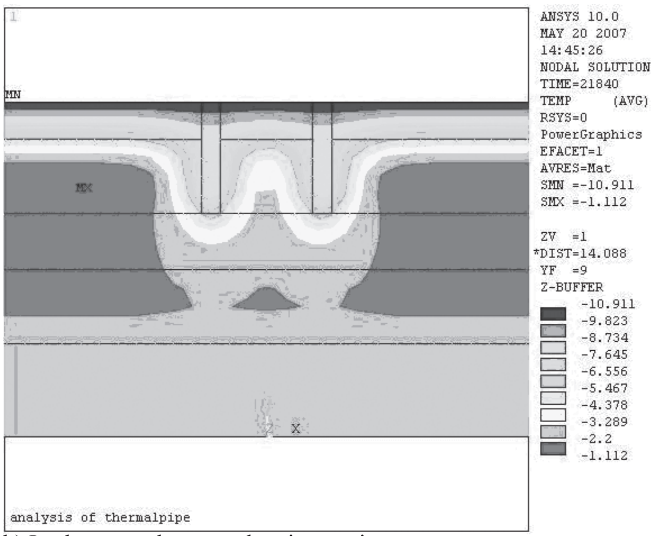
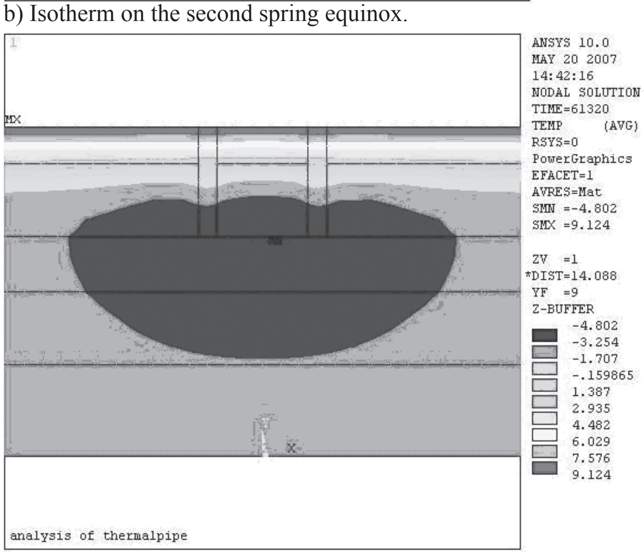
Figures 6a–6f show that it is obvious that the cooling effect of the thermosyphon foundation gets stronger and better as working time goes, per annum. Through each cold season's cooling effect and each warm season's heat-absorbing effect, cooling power gradually increases in the thermosyphon foundation each year, which illuminates that the longer the working time of a thermosyphon foundation, the better the permafrost-preserving effect will be in the application life.



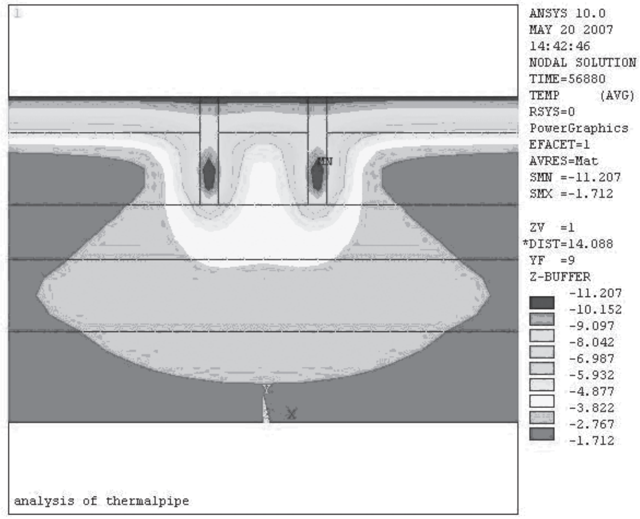
a) Isotherm on the second autumnal equinox.



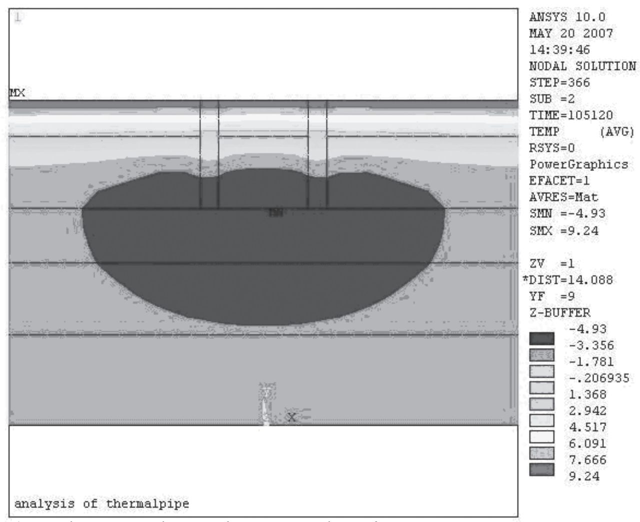
b) Isotherm on the second spring equinox.



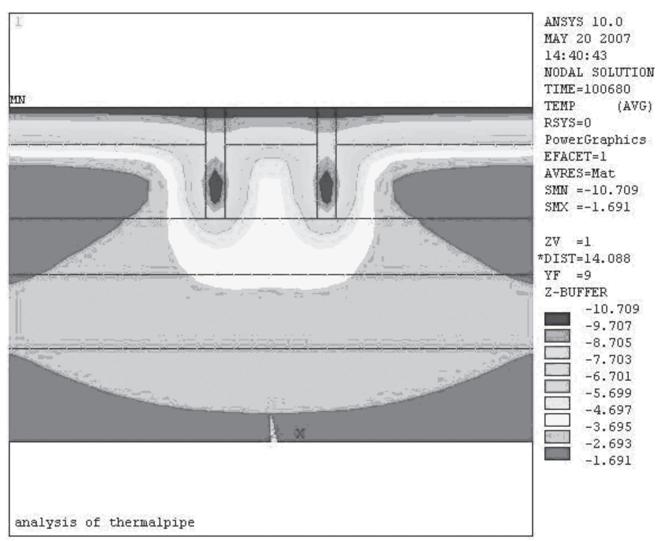
c) Isotherm on the fifth autumnal equinox.



d) Isotherm on the fifth spring equinox.

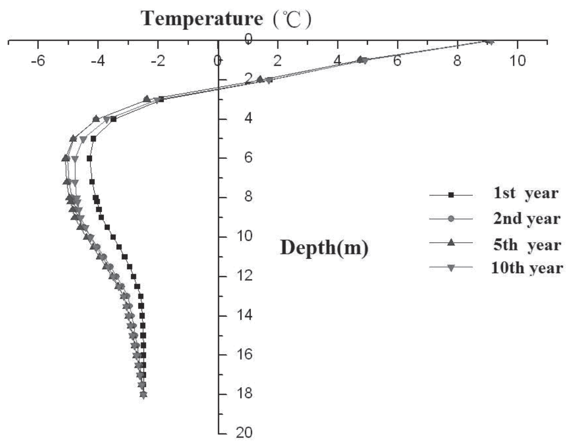


e) Isotherm on the tenth autumnal equinox.

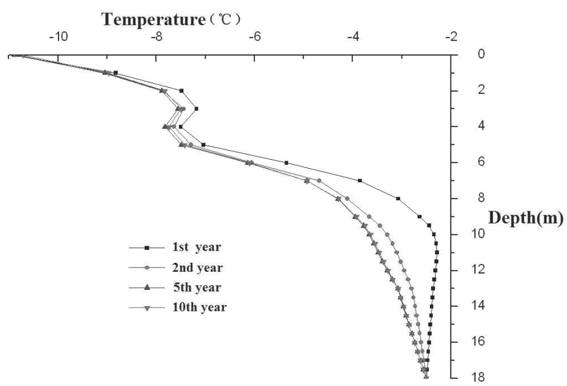


f) Isotherm on the tenth spring equinox.

Figure 6. Isotherms of the thermosyphon foundation in different years (the second, the fifth, and the tenth year taken, for instance).

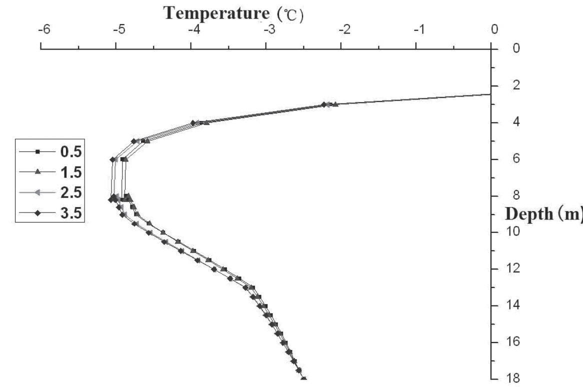


a) Temperature distribution on autumnal equinox.



b) Temperature distribution on spring equinox.

Figure 7. Temperature distributions in different years.



Areas ratio:

Figure 8. Temperature distribution with different ratios of areas (0.5, 1.5, 2.5, 3.5) on the tenth autumnal equinox.

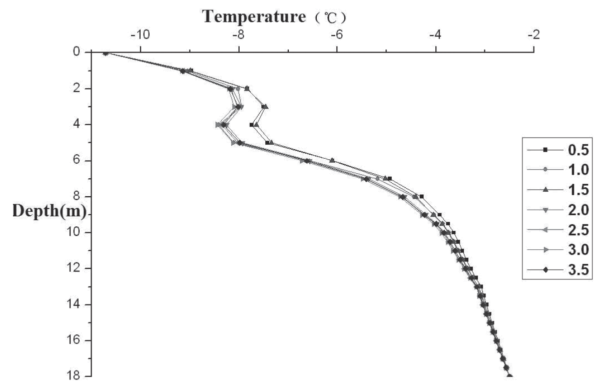


Figure 9. Temperature distribution with different ratios of areas (0.5, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5) on the tenth spring equinox.

Figure 7 is temperature distribution in which is as far as the diameter of thermosyphon foundation away from the foundation, along depth in different years. The average temperature in year 1 is apparently higher than those in other years, and as working time goes, it continuously drops but the falling range becomes smaller and smaller. At the same time, there is a rising trend for the temperature of permafrost due to the influence of global warming. For the cooling effect of thermosyphon foundation, the natural permafrost table keeps in a certain level, so the foundation is safe and steady enough to sustain structures.

The influence of parameters of thermosyphon foundation on temperature field

The article investigates the influence of parameters (areas ratio, length, pile space) of thermosyphon foundation on temperature fields to gain reasonable design parameters. The total calculation time is ten years. Areas ratio is defined with the surface area of the condensation part divided by that of the evaporation part.

Influence of areas ratio on temperature field

Figures 8 and 9 separately show temperature fields that are one diameter away from the thermosyphon foundation with different ratios of areas, such as 0.5, 1.5, 2.5, and 3.5 along depth on the tenth autumnal equinox and spring equinox. It is clear that the temperature of soil layers near to the foundation changes slightly with areas ratio 0.5–1.5, distinctly with 1.5–2.0, less with 2.0–3.5. From Figure 7, we can state that from -3 m to the bottom, namely the evaporation part, the temperature of soil layers near to this part is greatly affected by the variation of areas ratio, and the temperature falling range rises with areas ratio increasing, especially from 1.5 to 2.0, so that we choose 2.0 as the reasonable ratio of areas in the study.

Due to the limitation of the transmission tower structure, the length of condensation part is not appropriate to be changed, so the length of evaporation part varies with 3.0 m, 3.5 m, 4.0 m, 4.5 m, 5.0 m for calculation. Figure 10 represents temperature distributions with different lengths of thermosyphon Φ89 pile along depth on the tenth autumnal equinox, from which we can see that the temperature falling range of soil increases, as well as the cooling efficiency, with the evaporation part becoming longer. Meanwhile, the influencing region is getting wider and deeper. In view of facts such as project cost, design requirements and so on, the article suggests that the reasonable length of evaporation part is 3 m.

The pile spaces for numerical analysis between thermosyphon Φ89 piles are 3.0 m, 4.0 m, 5.0 m, and 6.0 m with areas ratio 2.0, and all these chosen spaces(3.0 m, 4.0 m, 5.0 m, and 6.0 m) are limited by the structural sizes. All these data points are node points in the analysis. Figure 11 shows temperature distributions (below 0°C) of the foundation with different pile spaces along depth. It reveals that when pile space is 3.0 m the cooling effect of thermosyphon founda-

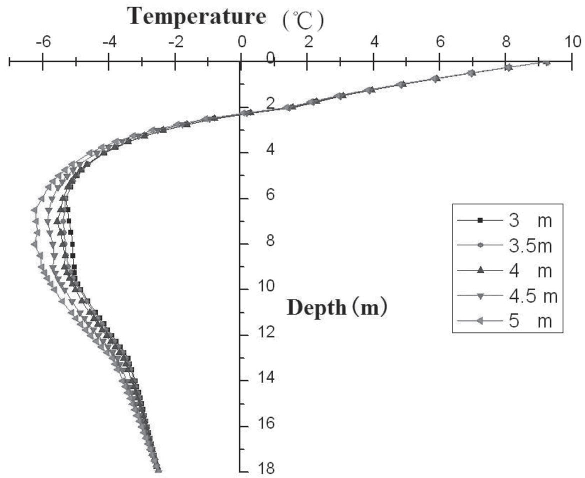

Figure 10. Temperature distributions with different lengths of thermosyphon.

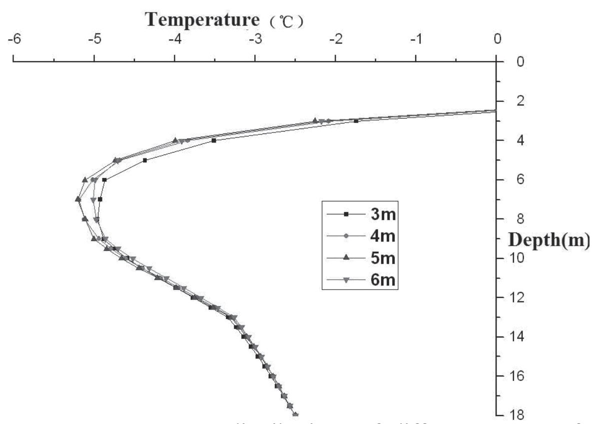

Figure 11. Temperature distributions of different spaces of the thermosyphon.

tion decreases, but increases with pile space getting large; the cooling effect with pile space 6.0 m is not as good as that with 4.0 m or 5.0 m, and 4 m is optimum, because the mutual influence (i.e. group action of piles) between thermosyphon φ89 piles turns strong with small pile space, but if the pile space is too large, there will be a weak region (with relatively high temperature) between two thermosyphon piles. According to the calculation result and the type of transmission tower applied in this project, 6.0 m is the best pile space, and in order to reinforce the cooling effect, it can be considered to add a thermosyphon pile in the central zone of the four ones with the pile space among them about 4.0 m.

To sum up, as a result of the cooling effect, the average temperature of permafrost with the thermosyphon foundation is lower than that with a traditional foundation.

After ten years, the natural permafrost table moves up 0.5 m owing to the thermosyphon foundation. Although ten years of global warming makes permafrost near the ground surface degenerate, from the above analysis and figures, it can be stated that permafrost surrounding the bottom part of the thermosyphon foundation can be refrozen completely in cold seasons; a big central frozen zone is formed with -5.2°C; after the tenth whole warm season the temperature of this zone is even -3.7°C. Therefore, the permafrost-preserving effect of a thermosyphon is strong enough to keep the whole structure stable and resistant to the influence of global warming.

Conclusions

Based on the continuity equation, momentum equation, and energy equation, the temperature characteristics of a thermosyphon foundation of a high-voltage transmission tower in permafrost regions are calculated and analyzed using FEM with the aid of ANSYS, and reasonable design parameters are obtained considering global climatic warming. The results provided a theoretical basis for the design of a thermosyphon foundation. It can be concluded that: (1) Under the stated climatic conditions and the project requirements, the temperature fields of a thermosyphon foundation and traditional foundation compared on autumnal equinox and spring equinox reveal that the natural permafrost table rises by 0.5 m due to the cooling effect of the thermosyphon pile, and the average temperature of soil near to the foundation drops by 2°C, which proves that the thermosyphon foundation has a distinct permafrost-preserving effect. (2) The temperature fields of a thermosyphon foundation in the first year and the tenth year are also compared, and the average temperature in the tenth year is 2.0°C lower than in the first year, which indicates that the cooling effect increases as working years pass. (3) The influence of the design parameters of a thermosyphon—for instance, areas ratio, pile length, and pile space on temperature fields—is analyzed in ten years. The computation results suggest that the temperature of soil layers near the foundation changes slightly with areas ratio 0.5–1.5, distinctly with 1.5–2.0, less with 2.0–3.5, so this paper chose 2.0 as the reasonable areas ratio. In order to satisfy the project requirements and economy, the appropriate length of the evaporation part is taken as 3.0 m. According to the analysis stated above, 4 m is the optimum pile space, and considering the type of transmission tower applied in this project, 6.0 m is the best pile space. In order to reinforce the cooling effect, a thermosyphon pile can be added in the central zone of the four ones with the pile space among them about 4.0 m.

Abstract

Permafrost deposits have affected archaeological excavations in interior and northern Alaska in numerous ways. Here we consider a new geoarchaeological context for Paleoindian sites in eastern Beringia: permafrost-shattered bedrock colluvium which has sealed deep loess deposits within swales between bedrock knobs. These loess deposits contain paleosols with early archaeological materials, including Nenana complex artifacts and Late Pleistocene megafauna. They are often underlain by additional permafrost. In order to discover such deeply buried deposits, it may be necessary to excavate through bedrock colluvium. Under such situations, "permafrost is no excuse." These principles are illustrated by recent excavations at the Little John Paleoindian site in the Alaska/Yukon Borderlands.

Keywords: Beringia; Little John site; Nenana complex; Paleoindian archaeology; permafrost; Pleistocene megafauna.

Introduction

Numerous archaeological excavations in interior and northern Alaska have encountered permafrost conditions either prior to or during excavation, and have been forced to develop methodologies to confront that situation. Permafrost interacts with archaeology in two ways: by creating unique preservation conditions for organic materials, and by creating difficult conditions for excavation to retrieve those materials. In northern Alaska, conditions which allowed for the development of permafrost "freezers" for storing meat and other organic materials by Inupiaq people have also created conditions for organic preservation over periods of hundreds to thousands of years. Excavation in northern Alaskan coastal sites in areas of permafrost (e.g., St. Lawrence Island) often yields not only bone, ivory, and wood, but also food remains and rendered seal, whale, or fish oil, some of which still emits odors when newly exposed. Long-term preservation of such organic residues allows an additional source of materials for radiocarbon dating, although calibrated date corrections to account for the marine reservoir effect frequently add several hundred years to dates, whether produced by standard or AMS methods. Preservation of categories of material culture such as clothing is generally only possible under permafrost conditions, as was the case in the Utqiagvik project in the Barrow region. Human bodies have also preserved in ice, again in the Utqiagvik site, and on St. Lawrence Island. In the former case, soft tissue pathologies (e.g., pneumoconiosis due to soot inhalation) and even evidence of late-life pregnancy could be determined. In the latter case, tattooed symbols were visible, similar to those of the Pazyryk bodies, encased in ice within kurgans (traditional burial mounds) in the Altai and upper Yenisei River regions of westernmost Beringia.

All of these unique discoveries come at a methodological expense. Excavation through permafrost is difficult, and requires the use of specialized archaeological techniques. Traditionally, until 30 years ago, sites were only excavated a few centimeters at a time as the surface was exposed and allowed to thaw. The use of such techniques meant that even some well-known Paleoindian site excavations in interior Alaska were abandoned because of difficulties or slowness of these procedures. The Utqiagvik project experimented with warm water thawing of the surface, and the gradual extraction of organic materials such as clothing from the ice. This technique was extremely successful, and has become the standard in recent years.

The results of ice on archaeological materials embedded in soft sediments such as loess (fine-grained glacial silt) are somewhat an issue of debate. While it is recognized that ice may preserve organic remains, it is also possible that higher permafrost tables result in a greater degree of cryoturbation, frost jacking, and displacement if not destruction of materials. For example, at the Broken Mammoth site near Big Delta in interior Alaska (Fig. 1), there is excellent preservation of organic material (bone, ivory, eggshell) in paleosols at the base of a 2 m loess deposit, dated from 9500 to 12,000 ^{14}C yr BP (Fig. 2); this has been suggested by some to have been at least partly the result of a higher permafrost table in the Late Pleistocene and/or Early-to-Mid Holocene. However, in our view, this preservation is more likely attributable primarily to the calcareous nature of the loess and the depth of the loess, with the latter retarding the downward mobilization of acidic ions in the soil column as a result of rainfall percolating through the coniferous needle mat associated with the contemporary (2–3,000 year old?) closed spruce forest (Holmes 2001, Yesner & Pearson 2002). Today, there is no permafrost present at the Broken Mammoth site, although it is found both to the north of the site (in the vicinity of Richardson) and to the south (in Shaw

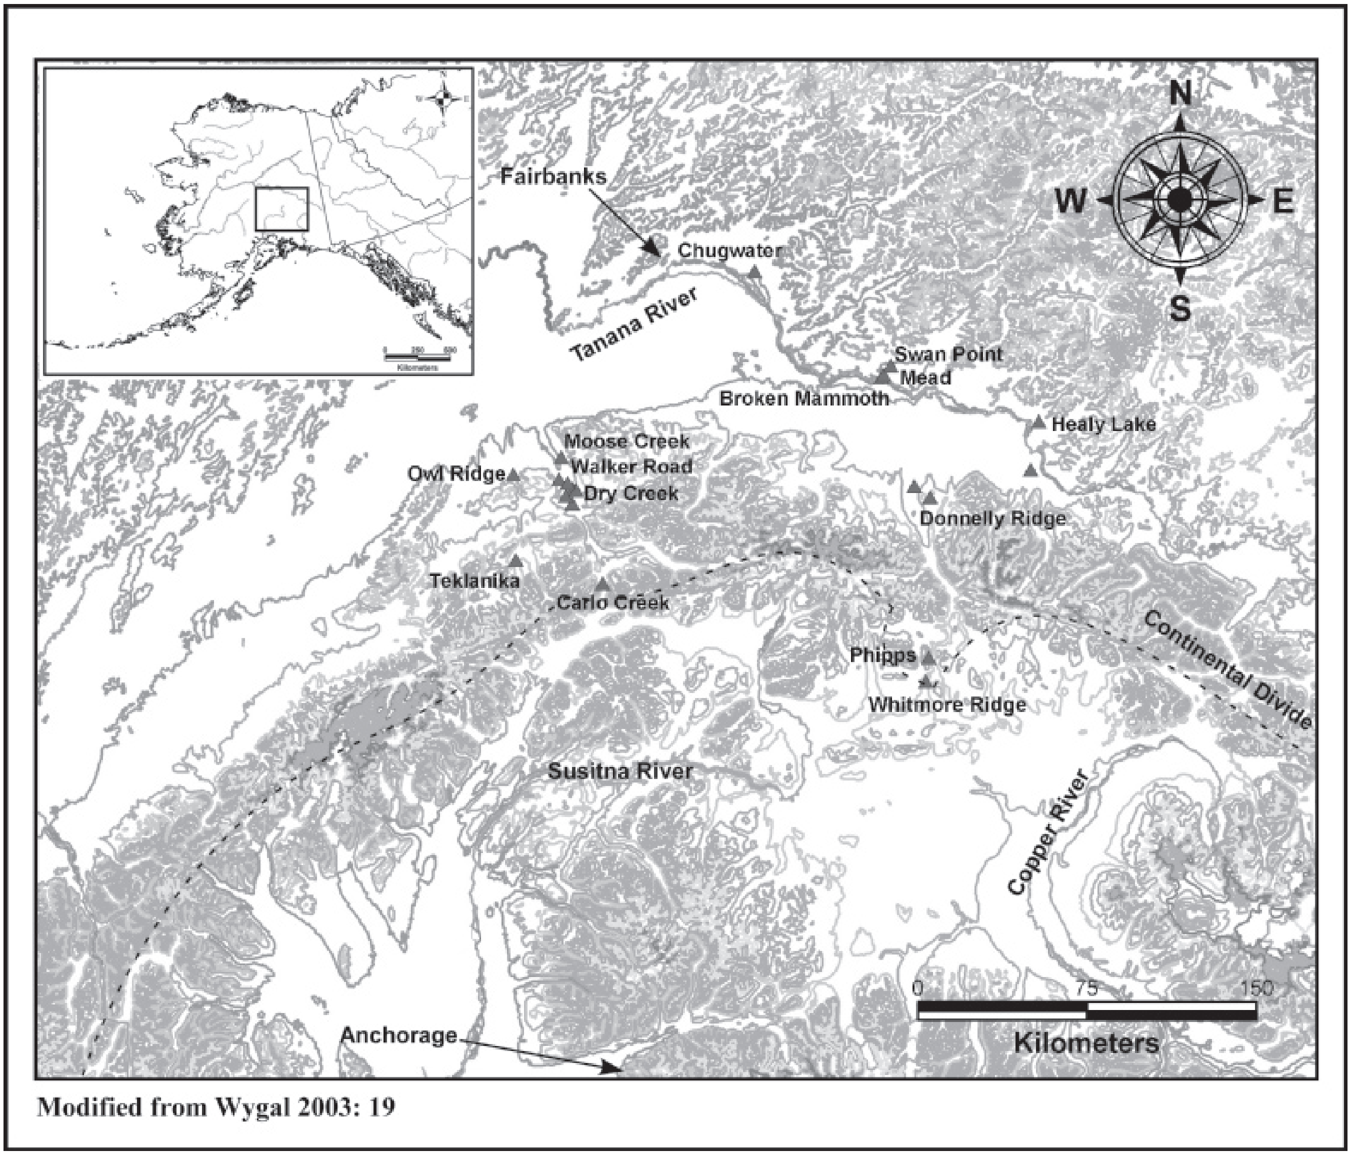

Figure 1. Early sites in Interior Alaska.

Creek Flats). This may be related to the fact that the site is on a south-facing slope, which has produced a microhabitat of relict Beringian flora in the site vicinity, including sage (*Artemisia* sp.). The result is that stratigraphic layers at the site are extremely flat lying, with even relatively thin (<5 cm thick) paleosols traceable horizontally over 30 meters or more. This suggests no previous experience with a higher permafrost table, a condition which differs strongly from Late Pleistocene/Early Holocene archaeological sites found elsewhere in interior Alaska (e.g., the Dry Creek, Walker Road, Moose Creek, Panguingue Creek, Owl Ridge, and Teklanika West sites in the Nenana Valley/Denali Park region; and the Chugwater and Gerstle River Quarry sites in the Tanana Valley region), all of which display evidence of cryoturbation, including distortion of archaeological stratigraphy (Powers & Hoffecker 1989, Hoffecker et al. 1993). Some of these sites also contain gleyed soils which are linked to reduced ions resulting from permafrost table saturation of the soil column.

The Little John Site, KdVo-6

Located just off the Alaska Highway, approximately 2 km due east of the International Boundary, the Little John Site occupies a knoll overlooking Mirror Creek, the easternmost tributary of the Tanana River basin. Unglaciated during the Wisconsin (Rampton 1971), this site contains evidence of human occupation from the Late Pleistocene to the recent past.

The western area of the site exhibits a geoarchaeological context similar to that of northern Alaskan sites or sites in the Tangle Lakes region of interior Alaska, with shallow, gravelly deposits entraining a basal loess layer at no more than 30–40 cm depth, directly overlying frost-shattered bedrock (West 1967, 1996). An archaeological component associated with this thin, shallow loess contains abundant microblades, burins on microblades, several core tablets, and irregular core fragments (although as yet no complete microcores). It also contains numerous scrapers and a limited bifacial industry, which may suggest that it be assigned to the Northern Archaic or the "Late Denali complex." Unfortunately, this area of the site is so far undated, due to a lack of datable organic material.

The eastern portion of the Little John site presents a completely different geoarchaeological context. In terms of paleogeomorphology, this portion of the site represents a swale between two bedrock knobs which has served as a sediment trap throughout the Late Quaternary. Here, a combination of frost jacking and gravitational processes has produced a series of colluvial episodes in which blocks of bedrock have become dislodged and transported into the swale. The last of these episodes, about 10–30 cm below surface, has produced a frost-shattered bedrock "pavement" in some areas which is extremely difficult to excavate through, but which may have helped preserve some of the underlying package of sediments. Underlying this colluvium is at least 30 cm to 40 cm of brunisol strata overlying 40 cm to 60 cm of (probably colluvially reworked) loess containing thick (10–30 cm), darkly stained paleosols. These paleosols also exhibit evidence of B horizon eluviation, indicative of gleyed conditions associated with a formerly higher permafrost table; a similar phenomenon can be seen at the Gerstle River Quarry site in the central Tanana valley to the NW. There are additional lenses of colluvial frost-jacked bedrock found within the loess, including some materials near the base of the loess that are Late Pleistocene or Early Holocene in age. There is also permafrost in some units at the base of the loess. The paleosols within the loess contain a diverse assemblage of culturally modified fauna, with AMS assays to date on three samples dating to 8890 +/-50 RCYBP (Beta 182798), 9530 +/-40 RCYBP (Beta 217279), and 9550 +/-50 RCYBP (Beta 218235). None of these bone samples, however, was from the lowest paleosol stringer within the loess, from which will have dates available shortly from new, stratigraphically-lower bone samples.

Nenana complex materials

The artifact assemblage from the eastern area of the site is assignable to the Nenana Complex or Early Beringian Tradition, previously established for the lower Tanana Valley and Nenana Valley areas (Bever 2006, Easton & MacKay 2007). It contains four teardrop-shaped Chindadn points, two biconvex bifacial knives, other large bifaces, macroblades, a variety of scraper forms, waste flakes, and two chisel-like bone tools; some of these are directly associated with dated fauna (see below). These materials are all characteristic of Denali assemblages in interior Alaska, including both the Nenana and central Tanana valleys.

Zooarchaeological and paleoecological data

Fauna identified to date from the palesol complex (cf. Hutchinson et al. 2007) include the following taxa: bison (cf. *Bison priscus*), elk or wapiti (*Cervus elaphus*), caribou (*Rangifer tarandus),* moose (*Alces alces*), hare (*Lepus sp.*)*,* swan (*Cygnus sp.*) and other as yet unidentified birds, rodents, and canids. This diverse faunal assemblage indicates a broad-spectrum subsistence strategy, similar to that

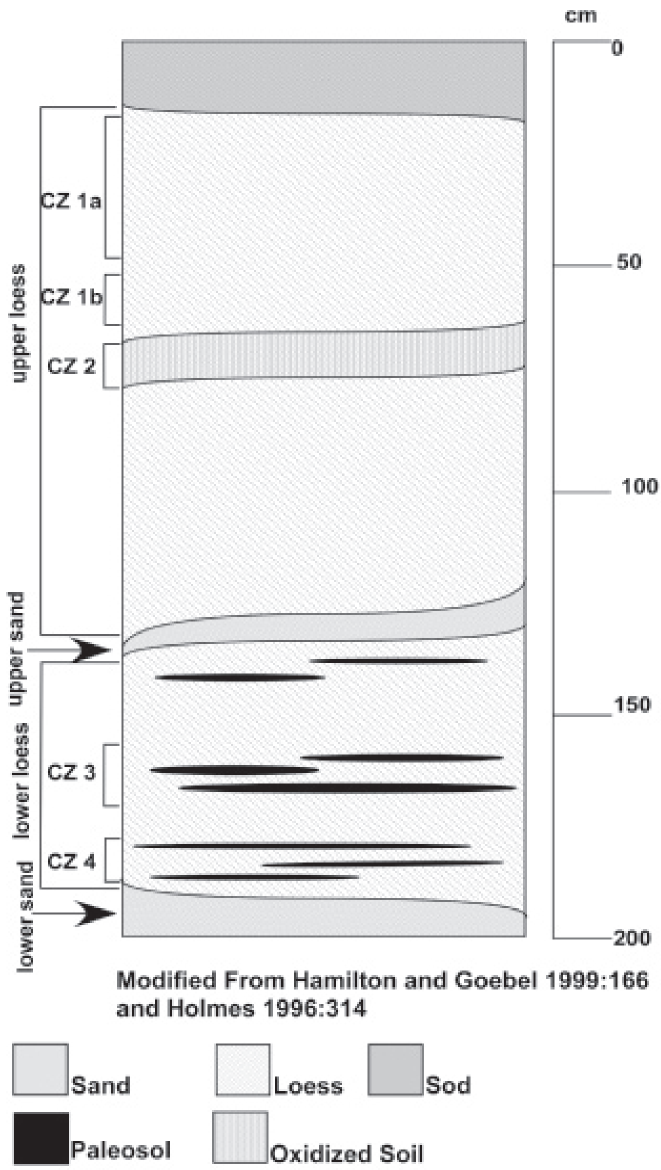

Figure 2. Broken mammoth profile.

displayed at a few other Late Pleistocene/Early Holocene sites in the central Tanana valley and Nenana valley with good bone preservation (Broken Mammoth, Mead, Swan Point, Dry Creek).

A core sample from a lake called *Yihkah Männ'* (~5 km from the Little John site) indicates that a transition from herb tundra ("tundra-steppe") to shrub tundra occurred ~11,000 ^{14}C yr BP, perhaps some 500–1000 years later than in the Tanana Valley (MacIntosh 1997). Occupation of the Little John site may correspond with this transition (cf. Bigelow & Powers 2001, Hoffecker & Elias 2007). The importance of this transition was to provide not only a more mesic, ameliorated environment for human occupation of the region, but also wood resources (especially with the appearance of *Populus* at ~11,000 ^{14}C yr BP) for hunting technology, dwellings, and other purposes. Simultaneously, these mesic conditions allowed soil formation and the entrainment of archaeological materials which might otherwise not have been preserved.

A successive eastward movement of Nenana and Denali culture bearers adapted to the subsistence opportunities offered by the shrub tundra environment of the Tanana Valley may explain the appearance of these complexes in the southwest Yukon. The Little John site extends the range of the Nenana complex to the far southeast edge of Beringia during the terminal Pleistocene.

Summary and Conclusions

Archaeological excavation in interior Alaska has provided data for Early Eastern Beringian archaeological assemblages (~12,000 to 9000 C^{14} yr BP) typically entrained in paleosols within deep loess units deposited on bedrock or river gravel terraces above river floodplains. In the middle Tanana Valley, deep, calcareous loess deposits have resulted in excellent faunal preservation at some of sites (e.g., the Broken Mammoth and Mead sites). New work at the Little John site in the upper Tanana Valley, Yukon Territory, extends the eastern Beringian record another 250 km eastward, and simultaneously provides a new geoarchaeological context within which early (Nenana Complex or Early Beringian Tradition) sites with excellent faunal preservation are found: fine-grained sediments deeply buried in swales between bedrock knobs above the valley floor. Discovery of additional such early sites may, however, be difficult, because such deeply buried deposits may be similarly covered by extensive sheets of colluvially-transported bedrock fragments, a fact of life in a region dominated by permafrost activity.

Acknowledgments

The authors would like to thank Daniel Stone and Rita Eagle for supervising the 2007 field season at the Little John Paleoindian site. The University of Alaska Anchorage and Yukon College provided joint funding for the 2007 excavations, with partial support for graduate students from IPY and EPSCOR initiatives. We also thank the White River First Nation, based in Beaver Creek, Yukon Territory, for permission to undertake excavations on their ancestral lands. The slogan of the Little John project is “Permafrost is no Excuse.”

Stable Isotope Composition of Ice in Seasonally and Perennially Frozen Mounds

Kenji Yoshikawa
Water and Environmental Research Center, Institute of Northern Engineering, University of Alaska Fairbanks

Abstract

Ice-cored mounds develop in regions of continuous and discontinous permafrost. Isotopic composition not only clarifies the growth process of the ice, but also indicates groundwater environments, such as open or closed environments and residual water fraction. Isotope stratigraphy of ice cores from the various types of frozen mounds (open- and closed-system pingos, palsas, icing blisters, frost blisters) can be applied to reconstruct the growth mechanism of each mound. An ice-cored mound in an open hydrological environment (such as an open-system pingo or a frost blister) froze relatively fast (enrichment of isotope ratio) at the top of the ice layer and remained an open environment during the main growth period. However, a major part of the ice (60% or more) was formed in a closed environment by continuous downward freezing. At the end of the growth period, a discontinued groundwater supply and slow freeze-up was followed by Rayleigh distillation. Palsas and closed-system pingos were in a semi-closed environment during the entire period.

Keywords: frost blister; icing blister; ice core; pingo; palsa; stable isotope.

Introduction

Ice-cored mounds are known for their unusual growth process and ice structure. However, a detailed physical mechanism for the formation of such mounds is still poorly understood. This study discusses the isotopic characteristics of ice from ice-cored mounds around Alaska, Canada, and Svalbard. Isotopic composition can indicate the groundwater source and physical environment of the ice development. The stable isotopic composition of ice formation is relatively well-studied for lake ice (Gibson & Prowse 2002), river ice (Gibson & Prowse 1999), and frost blister ice (Michel 1986), especially by Canadian scientists. Clark & Fritz (1997) reviewed well-documented surface and groundwater isotope studies. These well-documented isotopic works are useful in the study of ground ice processes. Isotope stratigraphy can be applied in reconstructing growth mechanisms with a variety of ice-cored-mound signals to understand differences between and the developmental process for these mounds. Definitions for each type of permafrost mound follow the terminology used by the Associate Committee on Geotechnical Research (1988).

Isotope study for permafrost mounds

The term *pingo* is an Eskimo word for a conical, more or less asymmetrical mound or hill, with a circular or oval base and commonly fissured summit. Pingos occur in areas of continuous and discontinuous permafrost, have a core of massive ground ice covered with soil and vegetation, and exist for at least two winters. A pingo has two general types of origin based on hydrological environments: open system (hydraulic) and closed system (hydrostatic). Mackay (1990) reported stable isotope results from one of the closed-system pingos at the Tuktoyaktuk Peninsula area. The isotope value slowly trends lighter, with a $\delta D/\delta^{18}O$ ratio of about 6. Yoshikawa (1993) reported oxygen isotope results from one of the Svalbard open-system pingos. The $\delta^{18}O$ values remain at -13‰ from top to bottom of the ice core except where there is dilation crack ice.

Two basic differences between pingos and seasonal frost mounds are (1) the time necessary for development and (2) the stability of ice conditions. Seasonal frost mounds are less than a decade old because their ice is situated over (or near) the thawing zones. Therefore, ice conditions are unstable in frost mounds.

Icing mounds and icing blisters are formed by hydraulic pressure during winter. These ice formations are usually continuous during the winter. In High Arctic regions, some icing mounds have been reported to exist longer than a decade (Sharp 1942). Excellent stable isotope studies for seasonal frost mounds were reported by Michel (1986) and Clark & Lauriol (1997). Michel (1986) successfully collected frost blister isotope signals as an entire fractionation process at North Fork Pass, Canada. The present study examines several ice cores from the same site at North Fork Pass.

The purpose of this study is to identify and characterize groundwater discharge and freezing processes of the different types of ice-cored mounds in permafrost regions. The source of water, freezing rate, and groundwater pressure are fundamental parameters. Stable isotopes were applied to reveal these parameters in understanding the formation process of the mounds.

Methods

During 2001 and 2006, ice samples from locations in Alaska, Canada, and Svalbard were taken to examine three open-system pingos, one closed-system pingo, two palsas, four icing blisters, and four frost blisters. Table 1 and Figures 1 and 2 show the sample sites and their profiles. In Table 1, the numbers in column $\varepsilon^{18}O_{i\text{-}w}$ are the values for fractionation relationships for ^{18}O in water-ice reactions. Ground ice was obtained using a portable drill core sampler (5-cm diameter stainless steel hollow Stein auger with hand or 1 kW electric drill). Obtained samples were analyzed

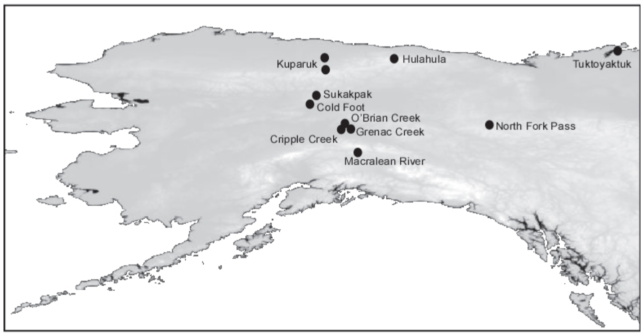

Figure 1. Sample sites in Alaska and Yukon, Canada.

for stable isotopes at the Alaska Stable Isotope Facility at the Water and Environmental Research Center (WERC), University of Alaska Fairbanks (UAF), using Pyrolysis Elemental Analysis-Isotope Ratio Mass Spectrometry (pyrolysis-EA-IRMS) DeltaV system. This method utilizes a ThermoFinnigan MAT high-temperature elemental analyzer (TC/EA) and Conflo III interface with a DeltaV Mass Spectrometer. The pyrolysis reactor consists of a reaction tube packed with glassy carbon/graphite and silver wool. Other TC/EA conditions are as follows: Pyrolysis tube temperature 1450°C, He flow rate 120 mL/min, GC column 3 m 5Å mol sieve and GC oven temperature 75°C to 100°C. Water from ice samples in the amount of 0.2 µL are injected into the TC/EA with a CTC Analytics A200SE liquid autosampler. The sample is pyrolyzed into H_2 and CO gases, then separated chromatigraphically. These gases are then transferred to the IRMS, where the isotopes are measured.

The values $\delta^2H_{V\text{-}SMOW}$ and $\delta^{18}O_{V\text{-}SMOW}$ are reported in reference to international isotope standards. The typical quality control scheme involves analyzing laboratory working standards every seven replicate samples. Each sequence batch is calibrated to NIST standards to confirm quality assurance. NIST standards are analyzed in replicate throughout the sequence.

The freezing of water in a closed system is a good example of Rayleigh distillation (Fig. 3, closed circles). During the closed-system freezing process, ice is progressively enriched; however, such enrichment does not occur in an open-system environment.

Results

The series of the ice-core signature contain a unique isotope value that reveals freezing processes. Figure 4 shows perennial ice-cored-mound results. Closed-system pingos (Mackay 1990) and palsas show a similar gradually decreasing trend of oxygen isotopes. Thus, frozen ice at an early stage is heavier than that at a later stage. The isotopic structure of the palsa is considered a semi-closed hydrological environment, similar to a closed-system pingo. However, an open-system pingo does not have this trend. The values of $\delta^{18}O$ are nearly constant for all sampling points deeper than 2 m at different horizons except for the sample of the upper 2 m of ice. As the water of the open-system pingo continuously comes from sub-permafrost and/or a talik, the value of $\delta^{18}O$ does not change (ca. -16‰) when the water source is constant. However, the early stage of the open-system pingo has complicated signals. This upper layer indicates rapid freezing similar to the frost blister. Figure 5 shows the relationship between δD and $\delta^{18}O$ from various ice-cored mounds and spring water adjacent to the mounds. The local water sources are at the local meteoric water line (LMWL). The freezing process of the mounds follows Rayleigh-type evolution.

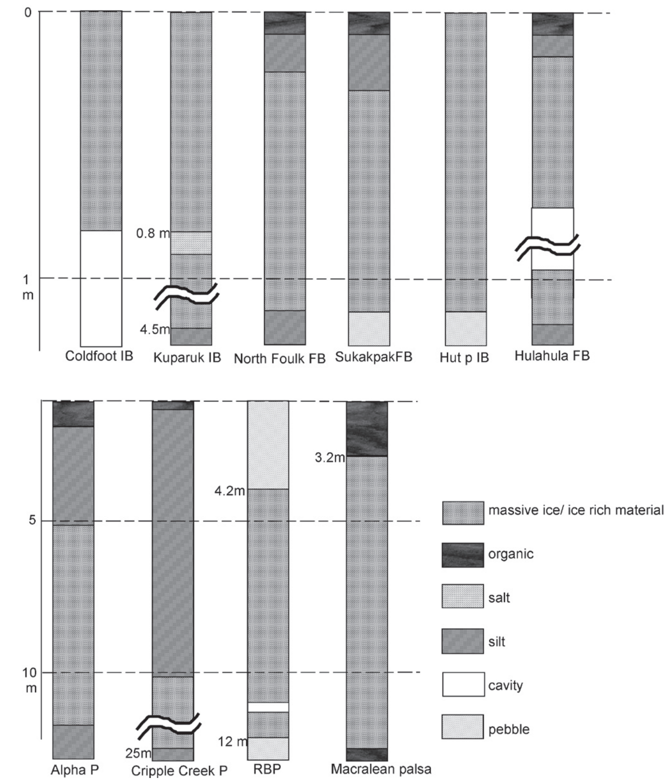

Figure 2. Drill logs for sampling frost mounds (FB: frost blister; IB: icing blister; P: pingo). Palsa samples taken include the organic layer up to 3.2 m, and focus on the ice layer below 3.2 m.

Figure 6 shows seasonal ice-cored mound results. All of the signals have similar trends. At the top of the ice, the isotope value is quickly enriched 2–3‰, which is the equilibrium fractionation factor to the ice. When freezing continues, ice formed from the depleted water preserves this trend of increasingly lighter oxygen isotope values. These mounds are produced through doming of groundwater due to hydraulic pressure. Once the dome shape is established, the downward freezing continues forming ice in a water-filled cavity under closed-system conditions. Some frost blisters are observed in a over several winters. Sukakpak frost blister (Fig. 6) is a good example. This ice core (2 m) indicated two times of enrichment.

During the winter of 2005–2006, one icing blister near Cold Foot (in the south-facing foothills of the Brooks Range) developed 2 m in height and about 30 m in diameter (Fig. 7). The details of ice grain size and C-axis measurements were observed. The upper 20 cm of the icing blister had overflow of white ice with very fine random crystals (<2

The numbers for $\varepsilon^{18}O_{i-w}$ are the values for the difference in 18O between water (spring) and uppermost (oldest) ice. Permafrost conditions are classified by zero annual amplitude permafrost temperature: warm (0° ~ -2ºC), moderate (-2° ~ -4ºC), and cold (< -4ºC). Size is indicated by diameter (D) and height (H) ratio.

mm). The stratification extended from below the overflow ice to the base of the cavity, with three layers of different ice crystal size. The icing blister ice had two major joint thresholds by the iron extraction (Fig. 7b). This chemical extraction indicated discontinuity of the freezing process. Ice crystals have a candle-like, slender, enlongated shape. There were several air bubbles inside the crystals (Fig. 7a). The long-axis orientation demonstrates the direction in which the crystals grew, which was vertically toward the freezing front. Once the dome shape was established, downward freezing stopped at least two times; however, the water-filled cavity froze under the closed system conditions (Fig. 6: IB Cold Foot).

Frost blisters from both the south- and north-facing foothills of the Brooks Range were sampled to the bottom of the ice. Drilling was performed June 2, 2004, at the Hulahula River frost blister to obtain an ice core. Below the 188 cm of ice and overburden was a large water-filled cavity 262 cm in height. This pressured cavity was developed by groundwater artesian water which continues to flow and discharge as a spring (Fig. 8). The isotope signals from this core did not reveal a Rayleigh distillation curve for ice that indicates open-system conditions during freezing in the water-filled cavity.

Sukakpak Mountain (in the south-facing foothills of the Brooks Range) and North Fork Pass, Yukon Territory, Canada, are two of the most well-studied areas for frost blisters (Brown et al. 1983, Michel 1986). For this study, six frost blisters were drilled at these two sites. The frost blisters at Sukakpak Mountain are considered to be at least 5–10 years old, but no more than 20 years old. The locations of previously studied frost blisters from the 1980s (Brown et al. 1983) were confirmed, but the frost blisters have completely disappear.

The grain size and shape of ice crystals in perennial and seasonal ice-cored mounds were different. Seasonal mound ice usually has small, enlongated ice crystals, the average crystal size being 1–5 mm. Perennial mound ice has big crystals (30–200 mm), and there are fewer bubbles observed

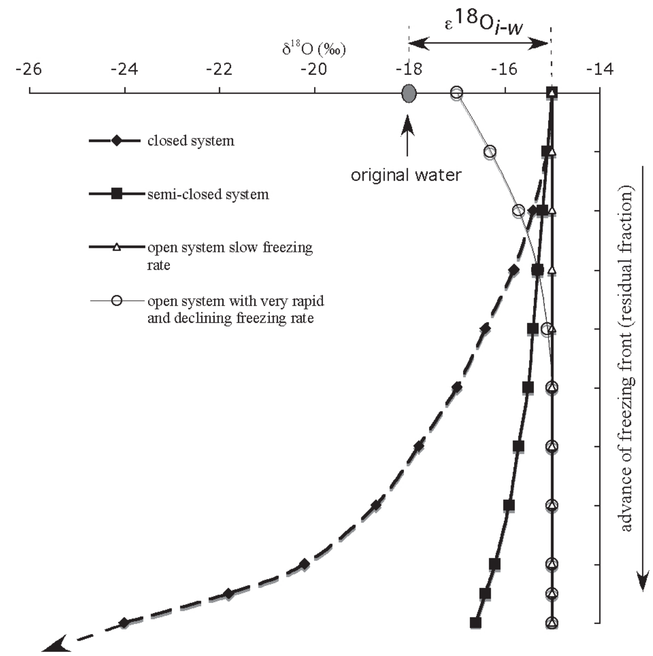

Figure 3. $\delta^{18}O$ versus freezing condition and water source effects (after Gibson & Prowse 1999).

in each crystal. Open-system pingos can be separated into two sections based upon grain size and isotope signals. The upper part of pingo ice is similar to that of a frost blister; the lower part consists of massive ice with bigger crystals.

The petrofabric analyses of icing mounds show that the c-axis orientations are normal for crystal elongations, with crystal growth along the basal plane in an a-axis direction (Pollard & French 1985). Mackay & Stager (1966) reported that in closed-system pingo ice beneath 5.5 m of overburden, the *c*-axis tended to point toward the pingo center. The isotope results also support development of ice formation similar to the petrofabric analyses results. The isotope analysis indicated the last residual water body in the ice core was located at the lower center of the mound. Ice-fabric analysis of the three samples taken from the basal pingo ice shows a changing *c*-axis pattern from the edge of the pingo

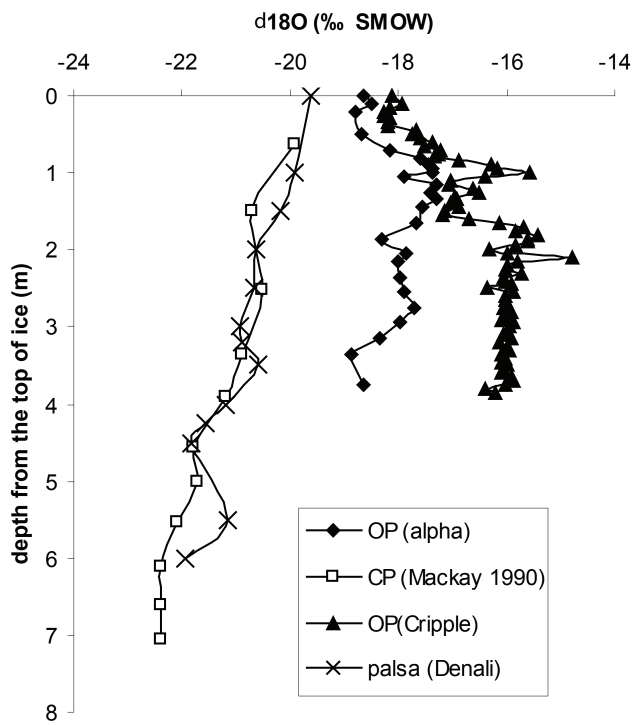

Figure 4. Oxygen isotope results versus ice thickness for perennial ice-cored mounds. Signals from an open-system pingo (OP) are quite different from those of a closed-system pingo (CP) and palsa.

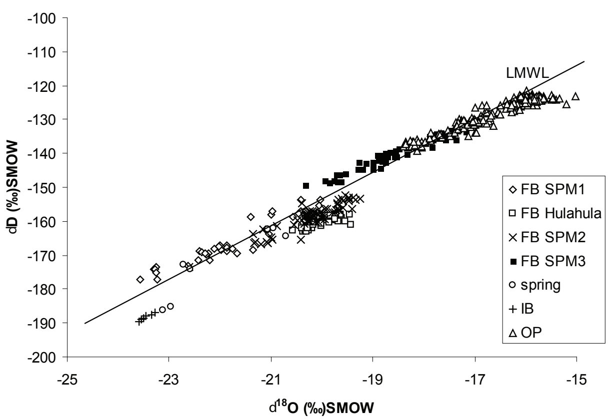

Figure 5. δD and δ[18]O relationship from various ice-cored mounds in Interior Alaska. LMWL is from Fairbanks.

to its center. The lattice orientation apparently coincides with vertically oriented columnar ice crystals. However, usually there is a maximum of four *c*-axis concentrations at the center of the pingo, which indicates that the ice received a strong force after crystallization due to residual water. As a result, pingo ice has significant pressure at the center. The edge of the ice has only a small amount of this force (Yoshikawa 1993).

Discussion

One of the important processes of closed-system freezing is chemical extraction or enrichment. Mackay (1990) reported

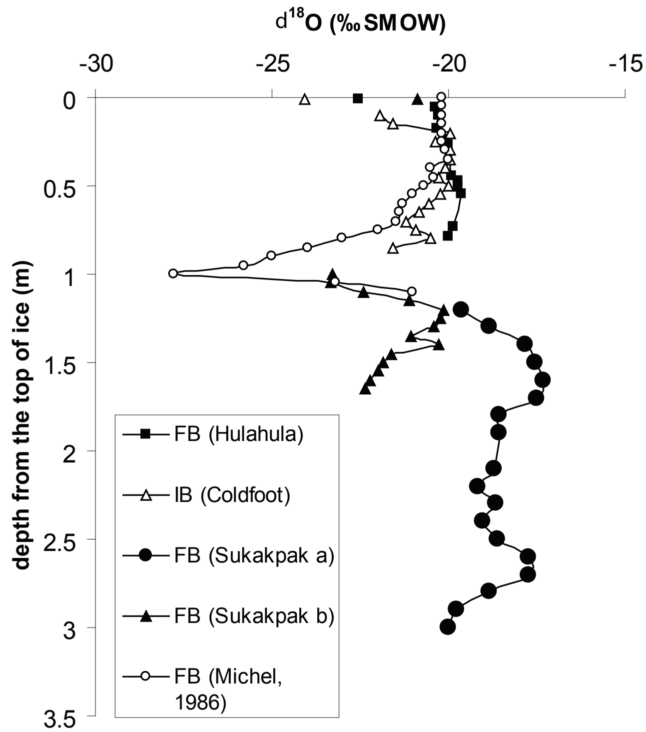

Figure 6. Oxygen isotope results against fraction (ice thickness) of the remaining ice on seasonal ice-cored mounds.

several layers of high ion concentrate in the closed-system pingo ice body. The isotope fraction analysis can detect this layer associated with delayed freezing (residual water) by the descending freezing point. Chemical extraction or salt precipitation during the freezing process is commonly observed in icing formation during the winter period. An icing blister from the Kuparuk River area, which was examined for this study, had developed only a week before the drilling sample was taken. The blister is 50 cm in height and 20 m in diameter. A highly concentrated and pressurized mineral layer was found 80 cm below the surface. This mineral layer is relatively easy to see from the air (Fig. 9). During core sampling 80 cm below the surface, about 5 cm of the cavity was found to have minerals with yellow fine form (bubbles) throughout, rising to the ground surface (Fig. 9, lower right). The majority of the minerals consists of carbon and calcium. Calcium and alkalinity concentrations indicate 14 times enrichment, and total carbon indicated 10 times. Isotope results follow chemical enrichments and indicated closed conditions for freezing both from the top down (Fig. 10, between 25–80 cm) and from the bottom up (Fig. 10, between 80–180 cm). The isotope fractionation demonstrates this freezing process. These enrichments are examined in terms of the Rayleigh distillation model (Fig. 11). The equilibrium-type curve of the fractionation factor (α) is 1.0028 for oxygen and 1.0206 for hydrogen (O'Niel 1968). However, the models show both oxygen and hydrogen, indicating the existence of non-equilibrium conditions (α = 1.006 for oxygen, α = 1.030 for hydrogen) (Fig. 11). The reason for the higher number in the fractionation factor (α)

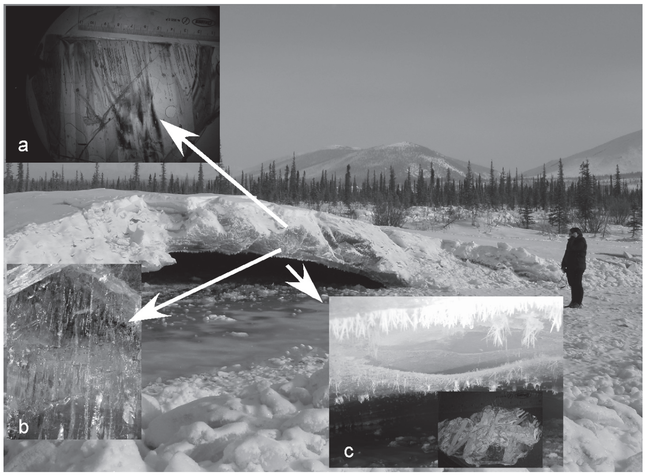

Figure 7. Icing blister transect profile near Coldfoot. Three layers of enlongated ice crystals (a) with bubbles contained in a majority of the ice body. Iron-extracted layer (b) was observed in the lower 20 cm. Needle-shaped crystals develop at the bottom.

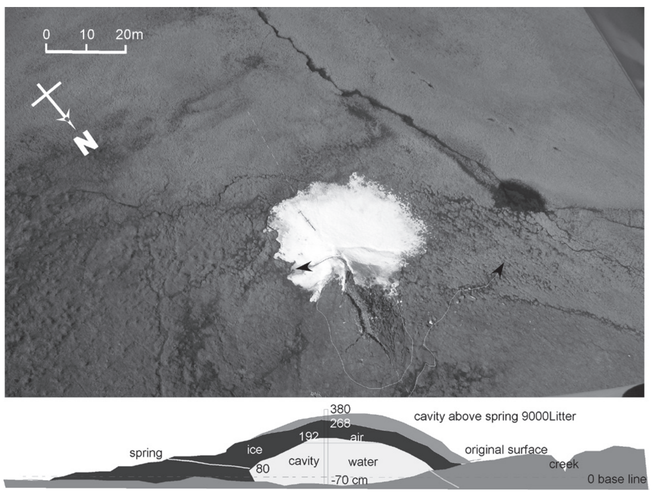

Figure 8. Diagram (lower) and aerial view (upper) of frost/icing blister at Hulahula River.

is unknown. It may be caused by the continual addition of water while freezing, resulting in a partially open system which will affect the fractionation.

The source water for this icing blister has high alkalinity (200–300mg/L) and was observed precipitating during the freezing process. This icing blister is not associated with hydraulic pressure from the groundwater; rather it is formed by hydrostatic pressure caused by freezing of the residual ion-rich water. There are a number of days that reach the freezing (thawing) point during spring months in this area. The unfrozen mineral-rich layer can associate with and move to an unfrozen layer.

Conclusions

Stable isotope signals from different types of ice-cored mounds (open- and closed-system pingos, palsas, icing blisters, frost blisters) were studied in relation to mound formation. An open-system ice-cored mound, such as an

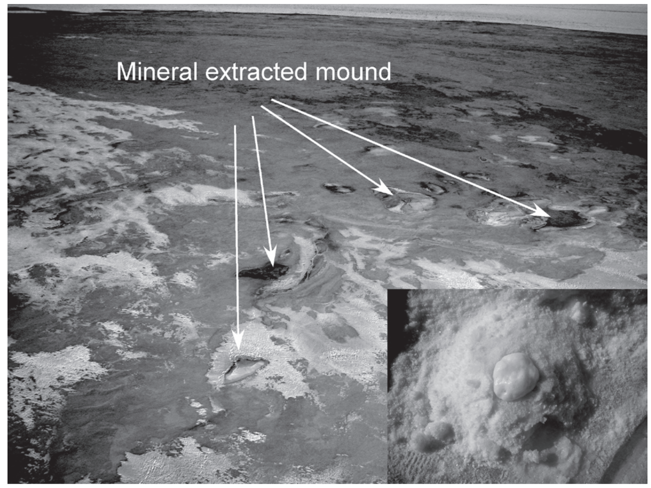

Figure 9. Salt extraction mounds (dark spots) are found at the Kuparuk River icing site during the spring period (April). After the drilling operation, highly concentrated minerals with yellow fine form rose to the ground surface (bottom right).

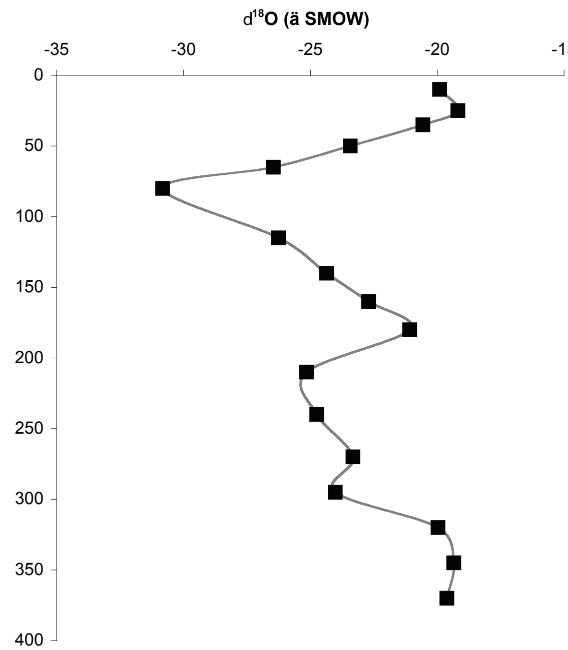

Figure 10. Strong (top down and bottom up) freezing process is observed between 30 cm and 180 cm depth. This is closed-system fractionation, where ice is progressively enriched under Rayleigh distillation of isotope signals and high concentrated ion layer at 80–110 cm.

open-system pingo or frost blister, freezes relatively fast with delayed enrichment of the isotope ratio at the uppermost ice layer. Once the stable freezing point is reached, the isotope value remains the same as that of an open environment.

The ice cores from palsas and closed-system pingos have signals of a semi-closed environment. The reservoir seems much bigger than the other closed-system mounds, but still follows Rayleigh distillation during freezing of the water. Icing blisters and frost blisters have very similar isotopic

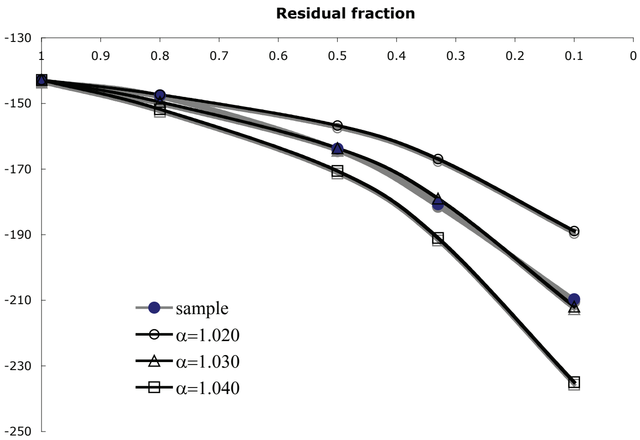

Figure 11. Sample value and calculated δD value for estimation of the fraction.

signals and ice structures. They develop (uplift) relatively quickly with a pressurized water source. The mound consists mainly of ice and water (cavity filling water). The water freezes downward following Rayleigh distillation. However, during the freezing process, especially with an icing blister, the chemical extraction involves dropping freezing point.

This study classifies the perennial and seasonal ice-cored mounds of four different stable isotope types by ice formation: 1) superimposed/crack ice, typically observed open-system condition; 2) upper part of frost blister, open system-pingo ice, rapid freezing with delaying enrichment; 3) open-system freezing ice, constant values of the isotope signals, and 4) semi-closed (or closed) freezing, following the Rayleigh distillation curve. Each of these isotope signals plays a critical role in revealing the growth mechanism of ice formation.

Geography Department, York University, Toronto, Ontario, Canada, M3J 1P3

Abstract

In 2004, a suite of ponds, 71 in total, situated in moraine, coastal, and bedrock-wetland terrains were surveyed, in order to assess their sustainability in a continuous permafrost, polar desert environment. Snow cover, ground thaw, water table, and water quality were measured. In 2005 and 2006, detailed hydrological studies were undertaken on a selection of these ponds. The 2004 results indicate that snow depth, melt, frost table, and water table variations exist between the ponds located in the different geomorphic settings. Electrical conductivity of water varied due to differences in Na^{+}, Mg^{2+} and Ca^{2+}. The 2005 and 2006 results signaled the importance of pond substrate (e.g., texture, colour) in modifying ground thaw, vertical seepage, and evaporation rates. Terrestrial linkages of ponds to late-lying snowbeds, wet meadows, and streams sustain pond levels during dry, warm episodes, but not frost cracks which can divert water from ponds. Ponds in this extensive wetland might show a range of responses to future climate change.

Keywords: climate change; continuous permafrost; extensive wetland; High Arctic; ponds; wetland hydrology.

Introduction

Wetlands are important ecological sites in the High Arctic. They are often the only zones where sufficient grasses and sedges exist to supply northern ungulates, such as muskox and caribou, with sufficient grazing grounds. They also provide food and water for migratory birds and help to cleanse and store water. Permafrost is critical to their existence; it serves to maintain water tables near the ground surface and allows for the growth of hydric vegetation. Despite the ecological importance of wetlands, a limited understanding of their hydrology and chemical status still exits. Progress has been made in understanding small patchy wetlands lying in continuous permafrost terrain (e.g., Woo & Young 2003, Young & Woo 2003a, b), but less information exists about extensive wetlands. Woo & Young (2006) recognize three groups: periglacial polygonal areas (low-centered polygons, ice-wedge cracks), glacial terrain, and coastal zones. A recent study by Woo & Guan (2006) focused on the first type: tundra thaw ponds, lying within a polar oasis environment (warm/dry; see Woo & Young 1997). They found that linkages between ponds and the surrounding landscape were good at the time of snowmelt (shallow thaw), but connectivity dropped off with deep ground thaw and prolonged evaporation.

Here, an extensive wetland-complex, underlain by continuous permafrost and possessing a polar desert climate (cool/wet; see Woo & Young 1997) is examined. It is characterized by numerous ponds, lakes, wet meadows, streams, and dry ground, and encompasses a range of surfaces: glacial terrain, bedrock, and coastal zones. The region is considered ecologically significant to migratory birds (Latour et al. 2005), but a clear understanding of the area's present and future sustainability has not yet been achieved.

Here we report on the characteristics of the typical ponds situated in three broad geomorphic zones (moraine, bedrock, and coastal) in relation to several environmental factors (e.g., snow, sediment, frost, water tables, and water quality). Detailed hydrological studies conducted on a selection of these ponds (small to large in area) during 2005 and 2006 are useful in confirming and understanding these spatial patterns. Finally, our study provides an indication of how these ponds might respond to future climate change.

Study Area

The study area is located in an extensive low-gradient wetland complex situated on the southern shore of Creswell Bay, Somerset Island, Nunavut (72°43′N, 94°15′W). Continuous permafrost exists here, and active layers approach 0.40 m in boggy areas and about 1.0 m in sandy and gravely zones. There are no continuous climate records from Somerset Island, but the area is considered to have a polar desert climate similar to Resolute, Bay, Cornwallis Island (200 km to the north) with its long, cold, dry winters and brief, cool, damp summers (Dyke 1983).

The study encompasses about 23 km^2, and the site contains two contrasting landscapes, the northern part being modified by beach and coastal processes and the southern section showing evidence of glacial and periglacial influence (Brown & Young 2006). Figure 1 provides an aerial photograph, depicting the general area. Letters indicate ponds in the main geomorphological zones (moraine, bedrock, and coastal). Ponds in the moraine area exist both in an upper plateau area (>40 m a.s.l) and at a lower elevation (c.a. 25 m) with the latter fed by a stream draining the upland. Lingering snowbeds are typical of the west bedrock ponds, while major and minor frost cracks running generally east-west across the landscape are typical in the coastal wetland zone (see Fig. 2).

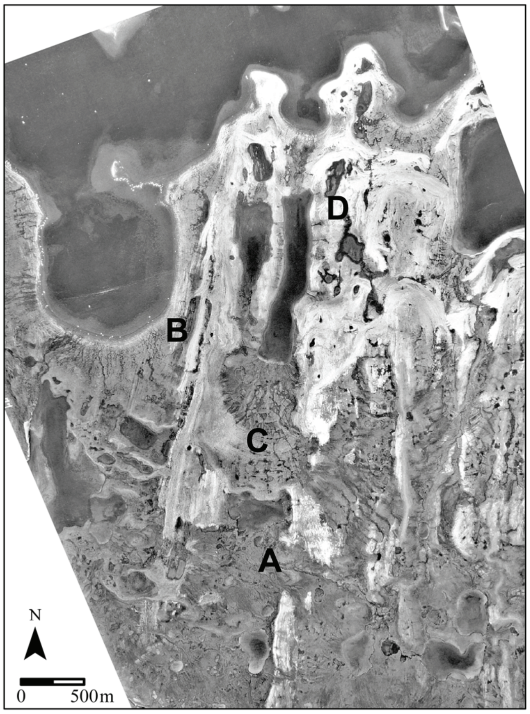

Figure 1. Aerial photograph of the study area: A-moraine zone; B-west bedrock zone; C-coastal area; and D-east bedrock zone. Creswell Bay is at the top of the diagram, and an Automatic Weather Station (AWS) is located near A.

Figure 2. Photographs of typical ponds in the study area: A-Moraine; B-West Bedrock; C-Coastal and D-East Bedrock pond. Note frost crack adjacent to Coastal pond and late-lying snowbed beside the West Bedrock pond.

In 2005 and 2006, at least three ponds (small, medium, and large) were selected from each zone for detailed study (late May to early August).

Methodology

Fieldwork 2004

Ponds dominate the landscape, so an earlier map of this region (Brown & Young 2006) was used as a guide to select the study ponds. In total 71 ponds ranging in size (small-median 510 m^2, medium-median 1,710m^2, and large-median 11,624 m^2) were examined. Due to logistical constraints (traveling by foot), we selected eight of these ponds to conduct detailed snow surveys in early June 2004. These ponds represented the three main geomorphic areas: in total, four moraine ponds with one situated on the upper plateau; two coastal ponds; one west bedrock pond and one small east bedrock pond. Snow surveys (i.e., snow depths, density) were conducted at each pond site. A physically-based snowmelt model described by Woo & Young (2004) was used to model melt for the ponds in 2004. Meteorological information (net radiation, incoming and outgoing solar radiation, air temperature, relative humidity, precipitation, and wind speed and direction) obtained at the AWS was used to drive the model.

During the post-snowmelt period, a comprehensive survey of the 71 ponds was conducted from July 18–July 25. The ponds occurring in the main geomorphic regions: moraine, west and east bedrock, and coastal are examined here. Position and area of ponds was determined using a Garmin 12 XL GPS (±3 m). The frost table divides the zones between thawed and frozen ground and provides an indication of water storage and seepage potential. Development of the thaw zone usually develops rapidly after the snow cover is depleted, but is also influenced by temperature gradients, surficial materials, and ice content. At each pond site, frost table position was measured by probing with a frost rod (±5 mm) until frozen ground was encountered. Three measurements at each pond site were made: 1 m from shore, 1 in the center of the pond, and then 1 between the center of the pond and the shore. Water table, the height of the water level above or below the ground surface, was determined adjacent to frost table measurements with a metric ruler (±5 mm). Estimates of water and frost tables for each pond at the time of sampling were averaged prior to analysis (see Fig. 4). Presence of plants (i.e., type and amount) was recorded, and a soil core of the near-shore sediment was obtained (250 cm^3). This soil sample allowed volumetric soil moisture to be determined, and was used to assess organic content (loss on ignition), soil color, and grain size (Sheldrick & Wang 1993).

Water quality information is helpful in determining relative water sources and periods of dilution and drying. The pH and water temperature were measured with a Hanna #18424±0.01 type meter. The electrical conductivity was measured with an YSI 30 ±0.1 µS/cm meter. A water sample was obtained from each pond, kept cool and returned to the York University Biogeochemistry Laboratory. Here the samples were analyzed for major cations (Ca^{2+}, Mg^{2+}, Na^+, and K^+) using a Spectra-10 Atomic Absorption Spectrometer, and laboratory standards and blanks were run to ensure quality control. The means and standard deviation of samples are reported. A Student t-test with unequal variance ($\alpha = 0.05$) was used to assess differences between ponds and aid in the discussion.

Fieldwork 2005, 2006

A detailed water balance framework was employed to investigate the hydrology of typical ponds (small to large) lying within the three broad geomorphic zones. Similar to 2004, snow surveys were conducted to determine initial pond and catchment's snow amount (in snow water equivalent units). Snowmelt was modeled and confirmed in the field with ablation measurements. In August 2004, perforated and screened water wells were placed along transects at each study site, dissecting both the pond and its catchment. Water tables were measured routinely in these wells at least every other day in 2005, 2006. Frost table was measured adjacent to these wells twice a week. Groundwater movement was estimated using the Darcy's approach. Soil moisture was measured both indirectly (Theta Probe) and directly (gravimetrically). Evaporation loss was determined using the Priestley-Taylor approach, with meteorological data supplied from the main AWS, and a portable AWS station which roved between the pond sites. Pond shrinkage was accounted for in the evaporation estimates. Streamflow both into and out of the moraine zone was estimated using the velocity-area approach. Retreat of a late-lying snowbed, which continued to supply moraine ponds with meltwater after the main melt period, was quantified on a daily basis. All ponds and their catchments were surveyed with a Total Survey Station in July 2005. In 2005 and 2006, no measurements were made of west bedrock ponds. Here, logistical and time constraints prevented these types of detailed measurements.

Results and Discussion

July 2004 was colder than 2005 and 2006, and much rain fell towards the end of July. In 2005, rain events were more frequent but of shorter duration than in 2006. Poor conditions during the early part of the season in 2006 resulted in greater rain and snow.

Environmental factors

Snowfall in the High Arctic usually occurs from September until May. Spatial variation in snow coverage and variations in the timing and duration of melt is important in the initiation of water for runoff, in defining the pattern and timing of ground thaw, and for providing waters for evaporation and/or infiltration.

Table 2 indicates the range of snow water equivalent (SWE, mm) for the study ponds in 2004. Initiation and duration of melt is also shown. For comparison, snow data from medium-sized ponds (2005, 2006) are also presented. Snow amount varies amongst the different pond types and within the same zones due to subtle differences in topography. However, snow amounts are still higher than that observed for a polar oasis environment (Woo & Guan 2006), but timing of melt and duration is generally later and longer. Hence, these ponds experience a polar desert climatic regime.

Ponds in the lee of slopes (e.g., a moraine pond-258 mm w.e.) can accumulate much snow, being sheltered from high winds. Other ponds on exposed ridges (e.g., west bedrock pond-58 mm w.e) have less snow due to steady winds redistributing snow. Topographic depressions (east bedrock-124 mm w.e.) provide shelter from wind and are effective in capturing much snow. Table 2 indicates that snow accumulation patterns are typical from one year to the next, though variations in amount can exist. Melt duration also varies amongst the sites. Some pond sites with shallow snow become isothermal and melt out earlier (e.g. west bedrock, 2004) than other sites with much snow (e.g. moraine, east bedrock, 2004).

Soil texture and organic content are important factors in the evolution of ground thaw and storage capacity. Fine soils (e.g., silts/clays) with high organic contents can hold considerable ground ice and can store much water, delaying thaw as ice melts and energy is consumed in evaporation. Once vegetation and organic materials start to dry out, they can serve as an effective insulator delaying the thaw of ice further and even encouraging permafrost growth. While coarse soils can contain ground ice, these soils and areas with little vegetation or organic cover will generally experience enhanced thaw (e.g., Woo & Xia 1996; Young & Woo 2003a). Figure 3 provides an assessment of grain-size distribution and organic content of surveyed ponds (small to large).

Table 1. Summary of climatic conditions.

Year/Month	Ta (°C)	PPT (mm)	Thaw Days
2004			
July	3.8	37.7	117
2005			
June	1.2	8.1	36
July	4.8	31.8	145 (121*)
Aug.	5.0	6.7	15
2006			
June	0.6	47.0	15
July	5.6	21.2	138 (till JD 207)

*Thaw days up until JD 207 (July 26).

Table 2. Range of snow conditions for study ponds: SWE (mm), initiation and duration of melt; 2005 and 2006 data are for medium-sized ponds.

Year/Ponds	SWE (mm)	Initiation of Melt	Melt Duration (days)
2004			
Moraine	77-258	June22 (JD 174)	6-9
Coastal	101-108	June 21 (JD 173)	8
East Bedrock	124	June 21 (JD 173)	9
West Bedrock	58	June 10 (JD 162)	11
2005			
Moraine	148	June 7 (JD 163)	10
Coastal	163	June 4 (JD 155)	9
East Bedrock	258	June 8 (JD 159)	14
2006			
Moraine	115	June 12 (JD 163)	10
Coastal	122	June 11 (JD 162)	9
East Bedrock	163	June 12 (JD 163)	11

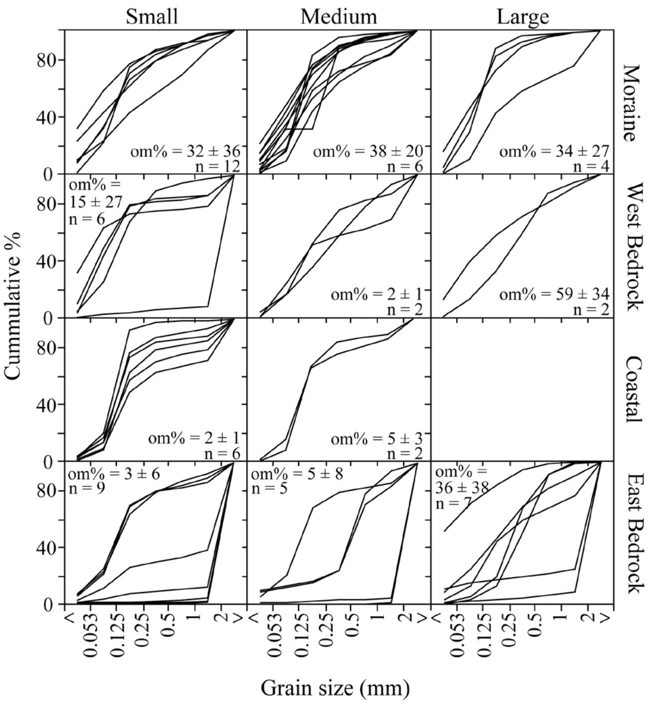

Figure 3. Grain size analysis and % organics (±standard deviation, and sample size [n]) of soil samples obtained at surveyed ponds (small to large).

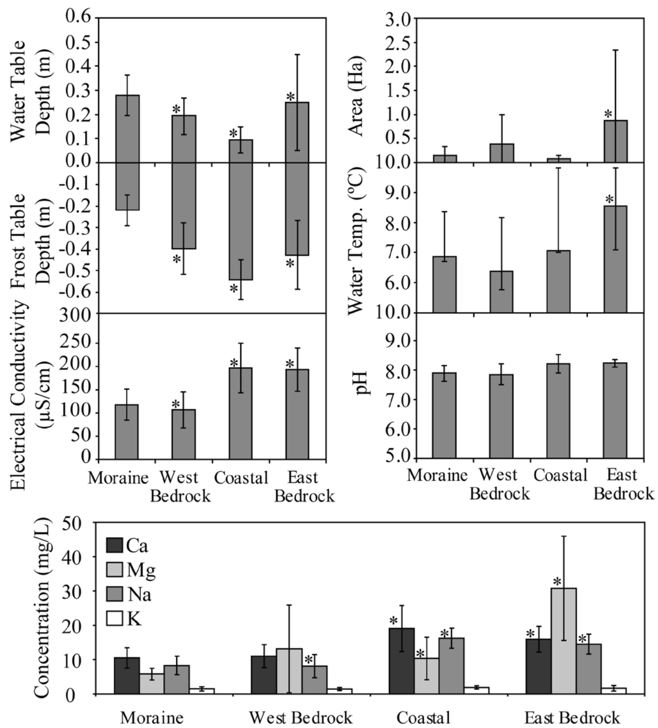

Figure 4. Selected environmental factors of all surveyed ponds. Significant differences of coastal and bedrock ponds to moraine ponds are indicated by an asterisk (*). Analysis is based on Student T-tests (α=0.05). Standard deviation bars are plotted.

Moraine ponds have a high amount of fines, while coastal ponds comprise fine sands and have the most uniform soil texture. West bedrock pond substrates are generally coarse, and soil texture is most variable in the east bedrock ponds. This reflects a longer period for these ponds to accumulate fine sediments through the dissolution of rocky material.

Moraine pond soils contain high organic contents, arising from extensive wet meadows with grasses and sedges surrounding most ponds in this area. In small and medium ponds (both bedrock types and coastal), organic percentages are low, reflecting the sparse vegetation coverage around these pond-types. However, as pond size increases, organic content also rises. The slow accumulation of fines in these areas eventually gives rise to a prolific wet-meadow community.

Environmental response

Figure 4 indicates a range of environmental factors which were measured over a short time span (mid-July to early August 2004). All ponds surveyed (small to large) are grouped here for analysis. A similar diagram for "small" ponds emerged, but these results are not reported here. The data indicate that we sampled more "large" east bedrock ponds, with some much larger than the other ponds.

The position of the frost table defines the position of the water table and can influence the presence of both surface and subsurface flow. Moraine ponds had the shallowest thaw (0.2 m) at the time of sampling, an observation which is supported by process studies in 2005 and 2006 (see Fig. 5). The frost table is deepest in the coastal ponds and is indicative of the coarser soils here and the lack of vegetation. Frost tables in the west and east bedrock ponds are all deeper than moraine ponds, arising from their coarser substrate, which enhances deeper thaw and vertical seepage. Some east bedrock ponds also possess black (blue-green algae) substrates (e.g. 5YR 2.5/1). This dark surface triggers two processes. Radiation penetration through clear pond water can be absorbed by this dark surface (α = 0.10, 2005), and the heat generated can then be used to warm the water and enhance evaporation, leading to lower water levels. It can also accelerate ground thaw and vertical seepage by elevating the thermal gradient at the water/substrate interface (see Oke 1987).

Water table is an important indication of the balance between water inputs and losses in a pond. High water tables may encourage runoff and sustain evaporation, and its persistence throughout a dry summer is indicative of lateral water inputs (i.e., surface and/or groundwater). Low water tables in the absence of rain can suggest an isolated system where vertical processes dominate; evaporation and/or seepage to the subsurface. Landscape alterations, such as erosion of a pond rim or an enlarged drainage outlet, may also encourage pond drainage and desiccation (e.g., Woo & Guan 2006).

Figure 4 indicates that water tables in the moraine ponds are greater than the other ponds. This is a reflection of the materials (greater % of fines and organics) which give rise to shallow frost tables, ensuring elevated water tables (Young & Woo 2003a). This area, especially the low-lying area, also received much water from a stream which drained the upland area. Several ponds in this area were also adjacent to late-lying snowbeds which continued to supply this area with meltwater long after the seasonal snowpack had disappeared (Fig. 5).

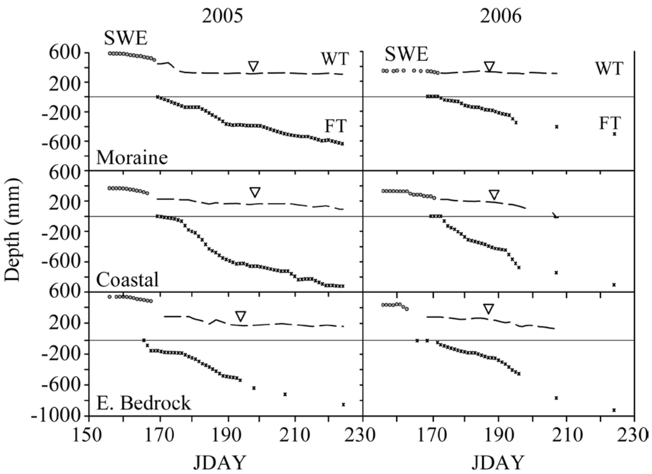

Figure 5. Seasonal patterns of frost and water table at the medium-sized ponds in 2005 and 2006.

Coastal ponds have the lowest water tables, owing to the higher proportion of coarser materials here and less vegetation, two factors which promotes deeper thaw and vertical water seepage. Frost cracks which dissect this zone serve as "sinks" during dry episodes, channeling water out of the ponds by setting up a hydraulic gradient (i.e., reversal of flow). Groundwater outflow from these ponds was estimated to be 1.3 x 10^{-2} m^3/d per unit m in 2005 and 2.8 x 10^{-2} m^3/d per unit m in 2006.

Water tables are higher in the east bedrock ponds. Many ponds occur in slight topographic depressions which are effective in trapping and sheltering much snow. Deeper snow prolongs melt, and delays ground thaw and evaporation losses. In warm years, ground-ice melt from the surrounding rocky catchment helps to maintain water levels (e.g., 2006).

All ponds are slightly alkaline owing to the underlying bedrock materials: limestone and dolostone. Water temperatures are the highest in the east bedrock ponds due to the dark substrate of most ponds here, which readily absorbs radiation and warms the waters. This pattern was similarly repeated in 2005 and 2006. Cooler water prevails at the other sites, which suggests frequent additions of cool water; i.e., stream water recharging ponds (e.g., moraine), and/or meltwater from late-lying snowbeds (e.g., west bedrock).

Electrical conductivity of the bedrock ponds and the coastal ponds are significantly different than the moraine ponds. Deeper thaw and shallower water tables ensure that waters have prolonged contact with the substrate, allowing additional solutes to be absorbed. Nearness to the sea allows salts and aerosols to be easily carried by sea breezes, fog, and rain, helping to elevate levels. Electrical conductivities are dampened in moraine ponds owing to high water tables, which are maintained by shallow ground thaw and the continual recharge by stream water and melting of late-lying snowbeds. West bedrock ponds have slightly lower electrical conductivities than the moraine ponds. Steady meltwater inputs from snowbeds, which lie in the breaks-of-slopes above many of these ponds, is effective in diluting pond waters.

Higher electrical conductivity values at the east bedrock and coastal pond sites can be attributed to higher values of Ca^{2+}, Mg^{2+}, and Na^+ at these sites. Elevated values of Ca^{2+} and Mg^{2+} reflect the bedrock type and greater ground thaw. Na^+ is much higher at the bedrock ponds owing to its nearness to the ocean and occurrence of sea breezes. The west bedrock ponds are on the west side of a NE-SW bedrock ridge lying adjacent to an inlet of Creswell Bay (see Figs. 1, 2). Winds blew from the NW in 2004, about 40% of the time and likely were effective in transferring sodium into these ponds.

All sites had low values of K^+, less than 5 mg/L. This is a common occurrence, given that any available K^+ is readily taken up by plants.

Response to climate change

The recently published ACIA (2005) suggests that arctic regions will be significantly affected by climate warming, with increases in precipitation (likely rainfall) and warmer temperatures. It is postulated that these ponds, despite occurring within a small landscape, will likely respond differently to these anticipated changes. For example, warmer and drier summers might mean the disappearance of many of the late-lying snowbeds which now feed several ponds both in the moraine and bedrock zones. These late-lying snowbeds are vulnerable to short-term changes in climate (Woo & Young 2003) and can disappear from the landscape, depriving downslope areas and ponds of water (Brown & Young 2006). Given the likelihood that these snowbeds will be vulnerable to shifting and changing climatic conditions, then it is probable that the electrical conductivity levels and solutes will also shift. The electrical conductivity levels of west bedrock ponds are now similar to moraine ponds largely due to the diluting effect of the late-lying snowbeds. However, with no additional meltwater inputs in the summer period, these waters will become more comparable to east bedrock ponds where electrical conductivity values are twice as high.

The ponds able to sustain themselves the best will be the low-lying moraine ponds. The occurrence of fine soils with much organics is able to promote ground ice and shallow thaw. Continual discharge of stream water into this zone, along with melting late-lying snowbeds, ensures elevated water tables, and buffers most of these ponds against warmer and drier summers.

Coarse and darkened substrates encourage ground thaw and vertical seepage. If water supplies are not sufficient to overcome losses, then many of these types of ponds might disappear. One other possibility is that emergent grasses may start to encroach and transform ponds into wet meadows. This process was observed for a small pond near Eastwind Lake, Ellesmere Island, in 2005. Others have noticed similar trends (e.g., Smith et al. 2005).

It is postulated that large ponds in all areas will likely sustain themselves in a warmer climate. They often have more fine material than smaller ponds and are linked to both wet meadow areas and smaller ponds which can funnel water into their watersheds during melt and rainfall events.

Summary and Conclusions

This pond survey undertaken in 2004 reveals the following:

(1) Within a polar desert wetland-complex, there can be significant differences in the types of ponds existing. Response of the ponds in terms of water table position, ground thaw, and water quality is strongly controlled by the substrate type, topography (level versus depression), and linkages with other water sources (streams, frost cracks). Ponds found in moraine areas tend to have fine substrates, higher water tables and shallower ground thaw than ponds occurring in coarse textured areas (e.g. coastal, east bedrock), unless additional sources of water are available (e.g., west bedrock ponds-meltwater from late-lying snowbeds). Higher conductivities and solute levels are common in the coastal and east bedrock ponds where water inputs are limited.

(2) It is likely in a warmer/drier climate that the ponds which possess a greater percentage of fine materials and organics and receive additional contributions of water aside from snowmelt and rainfall (e.g., stream water recharge, meltwater from late-lying snowbeds, groundwater inflow) will be able to sustain themselves in the future. It is the "isolated" ponds, shallow and poorly defined ponds (wind-swept), and/or ones with coarse and/or dark substrates which will be the most susceptible to demise.

(3) It is expected that the low-lying moraine zone of this wetland-complex will remain little changed; ponds receive multiple sources of water and have much fine sediments and organics to minimize thaw and maintain relatively high water tables. The coastal and east bedrock ponds, especially small ones, will be the most vulnerable. Years with low snowfall, little rain, and warm summers may see many of these ponds dry up and/or be overtaken by emergent grasses.

(4) The west bedrock ponds can be considered to be in "transition." Presently, they behave much like moraine ponds. Water tables are elevated despite coarse bedrock, with water being supplied by melting late-lying snowbeds. However, these snowbeds are vulnerable to warm/dry years and can be severely reduced in size or disappear completely from the landscape (Brown & Young 2006, Woo & Young 2006). In the long-term, climate warming will likely result in the disappearance of these snowbeds, and when this occurs, west bedrock ponds will begin to behave like the east bedrock ponds.

Acknowledgments

Funding for this project was provided by NSERC and NSTP. Logistical support from PCSP is gratefully acknowledged. Excellent field assistance was provided by Dan Thompson and Markus Anastasiades. Laboratory assistance by Jackson Langat is also appreciated. The authors are grateful to an anonymous reviewer whose suggestions have improved the paper.

Abstract

To further understand the degradation process of permafrost on the Qinghai-Tibet Plateau (QTP) and its environmental impacts, a Sino-German joint team conducted a pilot research project in the interior and on the eastern and western parts of the QTP. Preliminary results show that characteristics of surface landscapes have important influences on heat and mass transfer in soils. Major differences between cold (<-4°C) permafrost in the Tianshuihai Lake region and warm (>-1°C) permafrost in the interior and eastern QTP lie in their features of lithology, ice content, and ground temperature. The ecological environments in the Tianshuihai region have changed greatly in the past 30 years: large areas of vegetation have degenerated or vanished with considerable surface soil salinization. Extensive occurrences of small pingos, unsorted circles, sand wedges, and polygonal ground, and other periglacial phenomena were identified in the Tianshuihai area. Geophysical surveys indicate that topography, vegetation, and surface moisture conditions have substantial impact on the permafrost table and ground ice.

Keywords: environments; permafrost; Three Rivers Sources; Tianshuihai area; vegetation.

Introduction

The Qinghai-Tibet Plateau (QTP) is considered the third largest cold region on earth and is the source region of most major rivers in Asia (Zhou 2000). The source region of theThree Rivers (Yangtze, Yellow, and Lancang-Mekong) is in the interior and on the eastern part and feeds about 6×10^{10} m^3 of water per year into the three rivers. The water flow volume in the source of each of the Three Rivers respectively accounts for 49%, 15% and 1% in the total volume of each river (Li et al. 2006). The cold-region hydrological processes, especially the modification of hydrologic cycling by climate warming, have attracted increasingly more public attention in recent years. To understand the degradation of permafrost and its environmental impact in the source regions of the Three Rivers in the interior and eastern QTP, as well as in the Tianshuihai region in the Western Kunlun Mountains on western QTP, a series of preliminary research and field investigations have been conducted.

The source region of the Three Rivers is in the continuous and discontinuous plateau permafrost zones, where cold climate and permafrost produce a special hydrologic cycle, cryogenic phenomena, and fragile ecological environments (as shown in Fig. 1). The changes in cold-region ecological environments have directly impacted the water storage. Major ecosystems, such as the paludified alpine meadows, grasslands, and steppes degraded markedly between the 1970s and 1990s (Cao et al. 2006). Degradation of permafrost and ecological environments represented by aeolian desertification has been accelerated since the 1990s because of persistent regional droughts and overgrazing (Cheng & Wang 1998, Wang et al. 2000, Yang et al. 2004, Jin et al. 2007). In recent years, the aggravated ecological environment in the source region of the Yellow River has been seriously impacting its regional sustainable development, and could be one of the primary reasons for the decreasing runoff of the Yellow River from Qinghai Province, and for the increasing soil and water erosion (Kang 1996, Cheng et al. 1998). Thus, permafrost degradation modes and processes, and their ecological impacts are subjects of major research (Jin et al. 2006).

The distribution and degradation of permafrost in regions along the the Qinghai-Tibet Highway and Railway have been studied in more detail using meteorological measurements and the established long-term monitoring systems (Li et al. 2005, Wu et al. 2005, Jin et al. 2006, Cheng & Wu 2007). However, these observation systems are close to regions frequently and significantly impacted by human activities, and vast regions in the west and east remain unknown due to difficult access to and subsequent paucity of data.

The active layer is the crucial link between the climate and permafrost during the permafrost degradation process and can buffer climatic impact on permafrost. However, other than along the Qinghai-Tibet Highway, the heat, moisture, and mass transfer processes in permafrost soils had not been studied in detail (Li & He 1990, He 1991, Li et al. 1998). There also are remarkable differences between cold (<-4°C) permafrost in the Tianshuihai Lake region in the western Kunlun Mountains and warm (>-1°C) permafrost in the interior and eastern parts of the QTP.

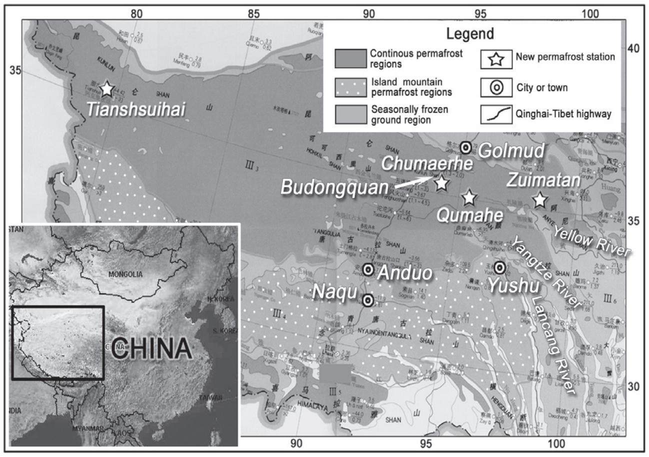

Figure 1. The extent of permafrost on Qinhai-Tibet Plateau in China and the positions of new permafrost stations established on QTP in the Sino-German joint research project.

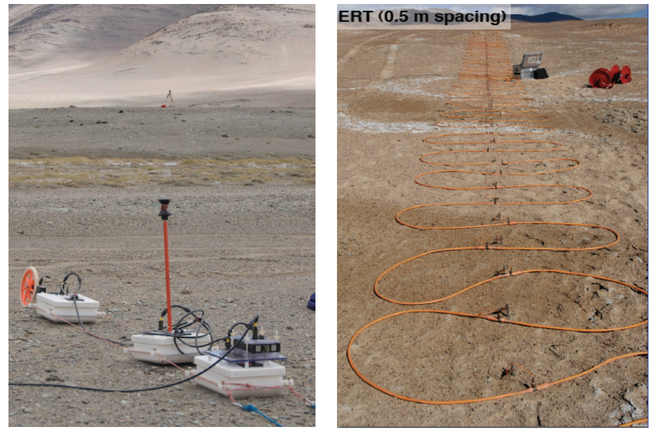

Figure 2. Some of the geophysical methods used in permafrost investigation in this project. The left is ground penetrating radar, and the right is electrical resistivity tomography.

Two joint teams from the Institute of Environmental Physics, University of Heidelberg, Germany, and the Cold and Arid Regions Environmental and Engineering Research Institute, Chinese Academy of Sciences conducted field investigations on the degradation of permafrost on the QTP and its environmental impacts in the source regions of the Three Rivers, in the east from August to October in 2006, and in the Tianshuihai Lake region in the Western Kunlun Mountains in August to September 2007. Three long-term monitoring stations were established in Zuimatan, Qumahe, and Chumaerhe along the access road from Yushu, along National Highway 214 (Xi'ning to Yushu section) to Budongquan along National Highway 109 (Golmud to Lhasa section) in 2006; a long-term monitoring station was established in Tianshuihai (Fig. 1). These stations are the very first in these regions.

Methods

Conventional exploratory methods such as hand-dug pits, water and soil sampling, in situ measurements of soil moistures and temperatures, and surface surveys were augmented with new geophysical investigation methods (Fig. 2), such as electrical resistivity tomography (ERT), new multi-channel ground penetrating radar (GPR), electromagnetic survey (EMS), and DC-resistivity (Arcone et al. 1998, Jared et al. 2003, Pettersson & Nobes 2003, Sass 2000, Schwamborn et al. 2000, Yu & Cheng 2003). They were applied for investigating the structures of the active layer, permafrost, cryogenic phenomena and vegetative differentiations, distribution of ground water tables and soil moistures, migration of salts, the physical properties of permafrost in the vicinity of the permafrost table, and the thickness of permafrost.

Results and Discussion

1) Based on investigations in the source regions of Three Rivers, three sites with representative landscapes were instrumented for soil and weather data as shown in Figure 1.

The landscape at the Chumaerhe Station is characteristic of barren land with sparse vegetation, but rich in ground water. The Qumahe Observation Plot is more densely vegetated and is covered by about 20 cm of peat layer. The Zuimatan Observation Site is sparsely vegetated, with saline soils and groundwater. The three sites were chosen along a gradient of the permafrost; with Chumaerhe in the continuous permafrost region, Qumahe in the patchy permafrost region and Zuimatan at the edge of the patchy permafrost region. In addition to measurements of wind direction and speed, air temperature, precipitation, and net radiation, there are profiles of temperature sensors and of CS616 and TDR100 soil moisture sensors down to the ice table at depths between 1.3 m and 2.8 m. The interval of the temperature sensors is 10 cm to 20 cm, and that of the moisture sensors is 20 cm to 40 cm. Furthermore, there are borehole temperature sensors from 3 m to 15 m with intervals between 0.5 m and 1.0 m (Table 1).

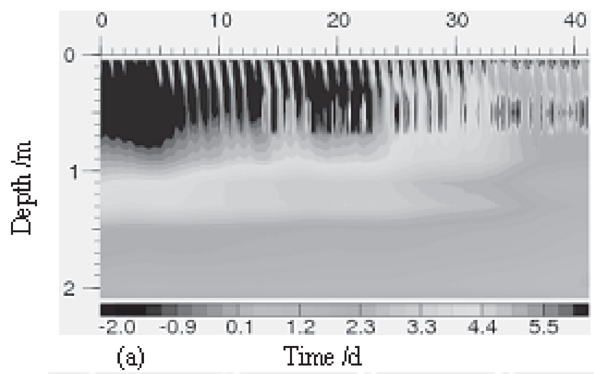
2) In Three Rivers source region and Tianshuihai Lake area, water and soil samples at different depths were collected in the active layer of various surface landscapes for studying the cryogenic phenomena and migration of salts.

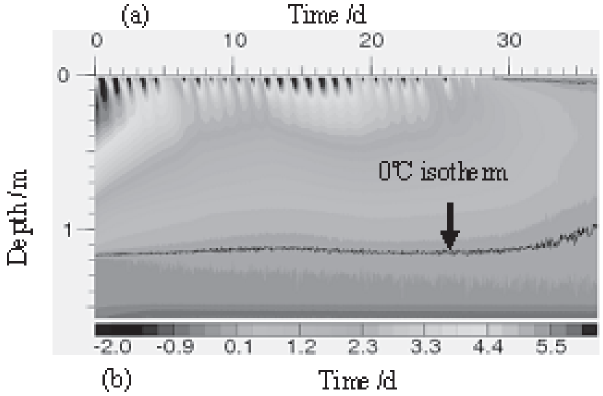
Early data on ground temperatures at three stations in the east from early September to mid-October 2006 were read (Fig. 3). As indicated from the change in ground temperature, geomorphic units and surface landscapes have important influences on ground temperatures. The highest ground temperature is at the Chumaerhe Station, and the lowest is at the Qumahe Station. The temperature was always positive in this period, while the other two started freezing from the bottom. This shows that more vegetation in Qumahe tends to shade solar radiation onto the ground surface in summer, which helps in protection of permafrost by reducing surface heating (Fig. 3b). However, the freeze-up of ground is significantly later at the Zuimatan Station (Fig. 3a).

The Tianshuihai Lake region is the center of low air temperatures in China, and it could be the last region of permafrost degradation on the QTP in future (e.g. Li & Chang 1999). Continued research in this region is important

Table 1. The positions and observations of the comprehensive observation stations.

Stations	Chumaerhe (No.1)	Qumahe (No.2)	Zuimatan (No.3)	Tianshuihai
Characters	Discontinuous vegetation, shallow organic soil	Continuous vegetation, thick organic soil	Slight saline soil at surface, salty ground water	Slight saline soil at surface, no vegetation
Permafrost table	2.45	1.25	2.65	1.6
Ground water table	1.51	—	2.05	1.4
Latitude	93°57′E	94°47′E	99°08′E	79°32′ E
Altitude	35°11′N	34°54′N	35°22′N	35°24′N
Elevation	4443m	4447m	4187m	4840m
Observations	Net radiation, precipitation, air temperature at depth 2 m, atmospheric pressure wind speed, wind direction ground temperature, soil moisture.			





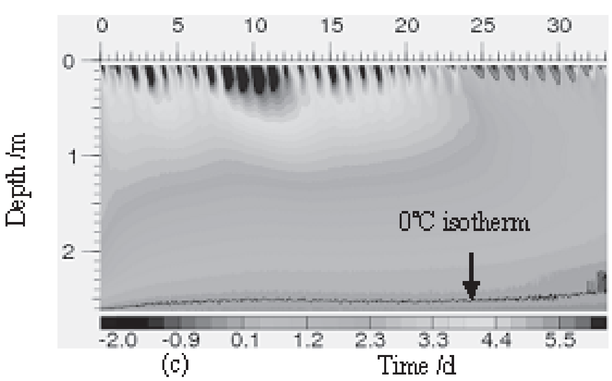


Figure 3. The ground temperature for the three weather stations are from Sept-Oct 2006. a. Chumaerhe station; b. Qumahe station; c. Zuimatan station.

for better understanding of existing permafrost conditions on the QTP as a whole and of its developing trends.

3) In the continuous permafrost region of Tianshuihai Lake area (79°26′E, 35°45′N, 4952 m to 79°59′E, 34°53′N, 5055 m) in Xingjiang Uygur Autonomous Region, although there is little precipitation, plenty ofsuprapermafrost water exists at the opened areas in alluvial-fluvial plains, and the ground water table is only about 1.0 to 1.2 m. Most of the surface is sparsely vegetated or completely barren; the coverage is generally less than 5% even on the gentle slopes. The ground ice was probably formed in the relict permafrost during the Late Quaternary, and the drainage patterns and mass and salt migration control the distribution of vegetation and permafrost. During the last 40 years, vegetation has changed significantly. For example, there was thick vegetation, and wild animals (like bronco) were at Tielongtan (79°40′E, 35°03′N, 4958 m) in the 1960s and 1970s, but it is barren land now (Li et al. 1998).

4) The geology and permafrost along the Xinjiang-Tibet Highway (K513~K650) significantly differ from those in the interior and on the eastern QTP.

Along the 80-km-long segment of the highway on the Tielongtan fluvial plain, the active layer is gravelly and with high ice content, sometimes even consisting of ice layers with soil inclusions on the gentle mountain slopes. Along the 30-km-long Gyttja section in the Tianshuihai Lake area, the soil consists of clayey sands with gravels or sandy clay. Dirty ice layers with volumetric ice content greater than 90% at depths of 1.0–1.4 m, are common.

5) At the Tianshuihai Lake region, permafrost is saline. The salinity of soils is low at the alluvial-proluvial fans; it is high on the gently sloped mountains, and even water at the low ground is salty. However, cryopegs were not detected during the investigation in the Tianshuihai area, whereas they are common on the northern QTP.

6) Extensive and various relict cryostructures, such as sand wedges and involutions, formed by soil movement during the freeze-thaw cycles were found in both research regions, and they have important influences on vegetation (Fig. 4) (Jin et al. 2007). There are many other periglacial phenomena, such as pingos and unsorted circles, and others, on the Tianshuihai Lake terraces and recently dried lakebeds (Fig. 5).

7) GPR exploration results show that landscape, vegetation distribution, and soil moisture content can significantly influence the permafrost table and ground -ice content. The coverage of small sand dunes, vegetation, and soil moisture conditions in or near ground surface are favorable for permafrost development and protection, while roads and tracks, as well as other human activities can lead to permafrost degradation (Fig. 6).

8) Geophysical methods, such as eletromagnetic survey

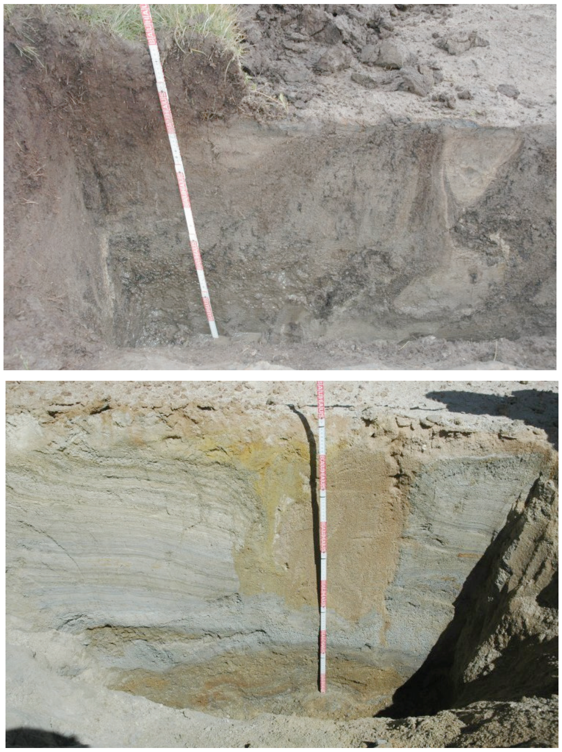

Figure 4. The upper picture is the involution found in river sources region, and the lower picture is the sand wedges found on the second Tianshuihai Lake terrace.

Figure 5. The landscape of cryogenic phenomena in Tianshuihai regions, the upper photo is pingo, the lower photo is unsorted circles.

(EMS), can better reveal the thickness of permafrost, especially for permafrost thicker than 50 m.

The EMS investigation results show that the thickness of permafrost is about 100 m in the Tianshuihai Lake area. Mean annual ground temperatures measured at depths from 15 m to 20 m in boreholes are about -2°C to -4°C. Considering the ground temperature gradient, the survey data with EMS should have good consistency with the average ground temperature.

9) The latest geophysical techniques have proven indispensable and effective tools for field permafrost research, particularly for revealing subsurface soil structures, moisture conditions, and other properties of permafrost, using various geophysical methods or their combinations.

Detailed information on the processes in the active layer and on the spatio-temporal changes of the permafrost table, such as soil strata and moisture contents, depth of the permafrost or ground water table, and distribution of ground ice can be obtained using GPR (better with multi-channel GPR) and ERT. To reveal the permafrost table and base, ERT is better for shallow permafrost, but EMS is better for thick permafrost. Soil moisture and salinity have strong influences on applicability and results of geophysical methods. In general, the quality of GPR survey data from areas with high soil moisture and salinity are usually poor and difficult (if not impossible) to interpret; ERT, EMS and DC-resistivity can provide viable alternatives under this circumstance. In dry areas, the situation is reversed.

The data and samples from field investigation and

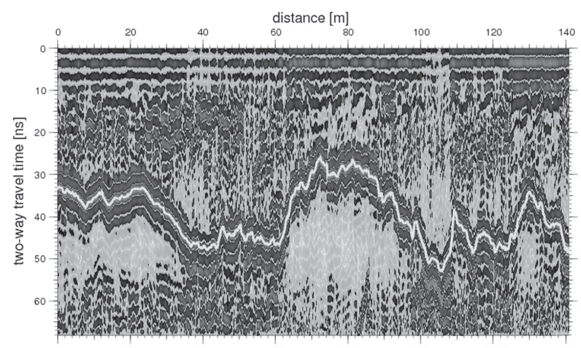

Figure 6. The investigation result of GPR in Tianshuihai.

monitoring are being studied. In the future, plans with emphasis on study of the western Kunlun Mountains will be executed. Further plans call for a north to south transect study through the permafrost province of the Tanggula Mountains and for construction of a third biodiversity transect in China, for the very important study of permafrost and cold-region ecology and biodiversity.

Severity of Climate Conditions in the Russian Federation

S. I. Zabolotnik
Melnikov Permafrost Institute, SB RAS, Yakutsk, Russia

Abstract

This paper evaluates the severity of permafrost and climate conditions and the distribution of permafrost in the Russian Federation. It presents a permafrost and climate severity map of the Russian Federation, drawn on the basis of long-term air temperature records from over 3000 weather stations. The map delineates 6 environmental-climatic zones at a 1250°C·day interval. The mapping shows that the most extreme conditions occur north of 60°N latitude in Yakutia, where the so-called Cold Pole of the Northern Hemisphere is located, and in the adjacent parts of Krasnoyarsk Krai and Magadan Oblast. The permafrost of these regions has the lowest temperatures and largest measured thicknesses. Harsh conditions exist in the remainder of these provinces, in Chukotka, northern West Siberia, and the adjacent Arctic islands. The least cold areas are located in the southwestern part of European Russia where only seasonal freezing of soils is observed and no permafrost exists.

Keywords: air freezing index; climatic conditions; permafrost.

Introduction

The Russian Federation extends across the whole of northern Asia and much of north-eastern Europe. Because of its northern location, Russia has a cold climate and widespread permafrost which underlies about 65% of the country (Shepelev & Shatz 2005). Permafrost is a natural integral indicator of environmental and climatic conditions. The frozen ground greatly influences human life and activities. For example, the existence of ground ice poses many engineering problems for the construction and maintenance of buildings and facilities; the great thicknesses of permafrost, reaching 1000–1500 m in Yakutia, make water supplies difficult to obtain; the development of cryogenic processes require additional measures and costs for agricultural developments. In view of these harsh conditions, there is a continuing need for comprehensive appraisal of the natural environment in which humans live and work. Such assessment requires an aggregate indicator that would be able to measure both the permafrost conditions and the extremity of the environment.

At the first stage, the indicator selected was the degree of climate severity since permafrost is a product of climate, and its formation, distribution, temperature, and thickness largely depend on the intensity and duration of winter cold. It is defined as the sum of negative (below 0ºC) air temperatures during the year (air freezing index), which was used as a basic mapping criteria. Then, the climate severity index was correlated with the distribution and type of frozen ground within the identified zones.

The climate severity zonation of Russia has been an issue for a long time. The problem remains unsolved and is still much debated.

The first subdivision of Russia into the regions of the Far North and territories equated to it was undertaken in 1932 in order to stimulate industrial development of the northern and remote eastern regions by providing incentive payments. The list of Far North areas included the Kola Peninsula, Murmansk Okrug, Yakut Autonomous Republic, Kamchatka Oblast, as well as the Okhotsk, Koryak, and Chukotka Okrugs of the Far East Krai.

This list has been continuously revised by adding more areas. At present, 28 federal units are categorized as the regions of the Far North and equivalent areas and 41 units use regional coefficients. In 2002, the additional burden on federal and local budgets for the cost of "non-northern" territories reached 65 billion rubles (Zhukov 2005). The regions where employees are entitled to northern allowances (0% to 80% increase to wages depending on the length of employment) or regional coefficients (fixed regional rates of extra wage payment) now comprise more than 88% of the total area of the Russian Federation.

Huge financial expenditures for extra wage payments in the federal units, which do not incorporate areas with the far northern and equivalent regions status, generated a need to improve the labour compensation system and to introduce changes into the current legislation. The State Duma Committee for North and Far East Affairs resolved to revise existing criteria and to develop a science-based system for assessing living conditions. For this purpose, an interdepartmental working group was established including representatives from regional governments and parliaments, as well as those from relevant research institutions, including the Melnikov Permafrost Institute at Yakutsk.

State of the Problem

Some work on this topic was done in 1998, when the Federal Ministry of Economy and Trade together with the Institute of Geography Russian Academy of Sciences (RAS), and the Institute of Economic Problems, RAS Kola Scientific Centre devised a methodology for environmental and climatic zonation of Russia. Much consideration in this document was given to zonation criteria.

Earlier, the Institute of Geography proposed "a new version of the method that takes into account both zonal and azonal factors affecting the selection of indicators and criteria of extremity of environmental and social conditions

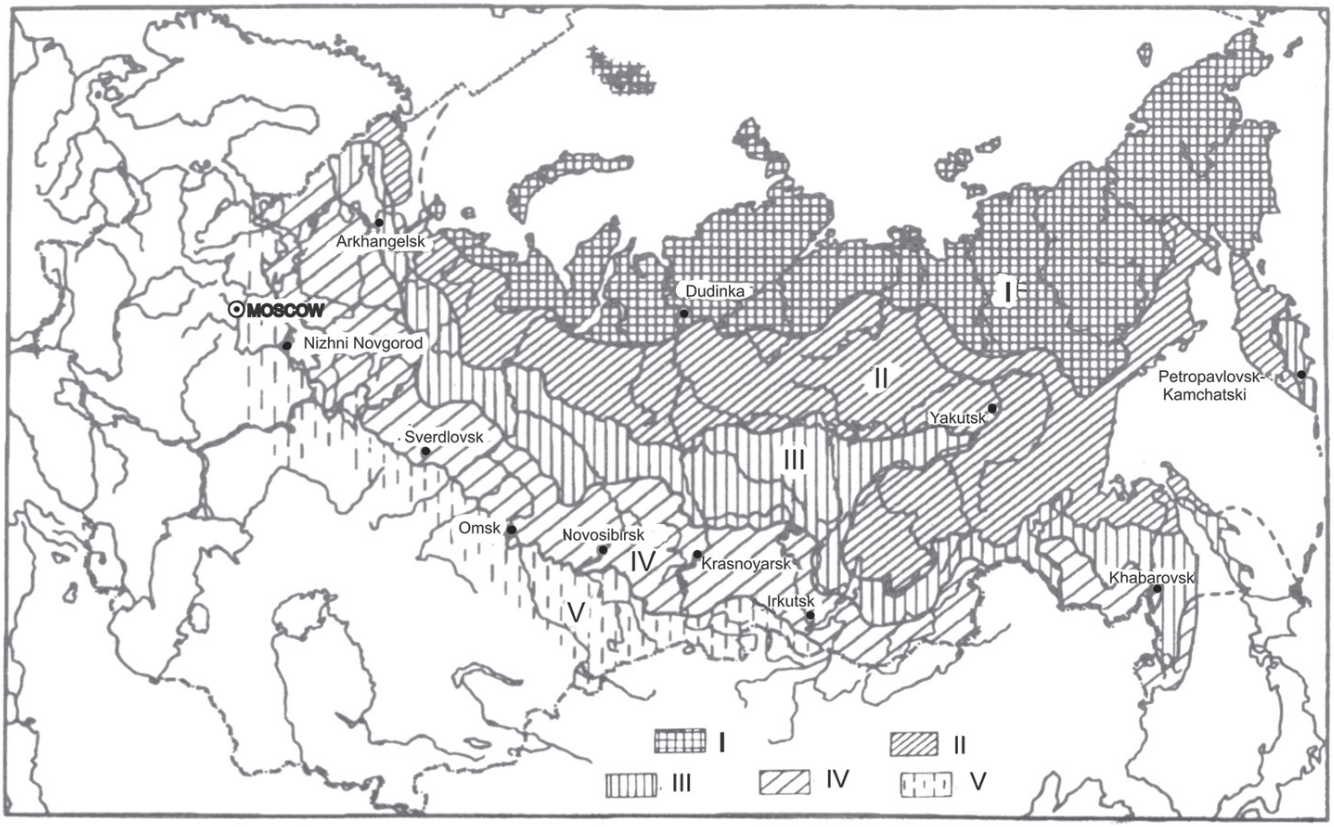

Figure 1. Zonation of environmental and climatic conditions affecting human life with consideration of azonal factors, Northern and Eastern Russia (after Zolotokrylin et al. 1992). I – absolutely unfavorable; II – extremely unfavorable; III – unfavorable; IV – relatively unfavorable; V – favorable.

of life" (Zolotokrylin et al. 1992). The new scheme was applied for zoning and mapping the Russian North and East (Fig. 1). Four unfavorable zones were distinguished in this map, based on a large number of indicators. However, analysis of the final product gives rise to many questions. For example, why are the populated centers with very different environmental conditions which show a range of 11°C in mean annual air temperature, *t* (*USSR Climate References* 1964–1967) placed into the same extremely unfavorable zone (zone II)? This zone includes Murmansk (t = +0.3°C), Salekhard (t = -6.4°C), Turukhansk (t = -7.0°C), Yakutsk (t = -10.3°C), Magadan (t = -4.7°C) and Palana in Kamchatka (t = -2.8°C). Similar examples can be found for other zones. The difference in living conditions among these populated centers is obvious and needs no comment.

The understanding that "the map was inadequate in reflecting the azonal factors that affect human life, such as strong winds, high humidity, frequent fogs in coastal areas, paludification, and others" (Krenke et al. 2001) caused a need for further work. The author analyzed seven bioclimatic indices, applied clothing insulation and seasonal freeze and thaw depths as azonal factors, and adjusted the zone boundaries in relation to geobotanical and permafrost physiographical boundaries. As a result, a new map of unfavorable zones was produced (Krenke et al. 2001). This map also has shortcomings. For one, the northernmost absolutely unfavorable zone (I) was significantly extended to the south to include the Okhotsk coastal areas with Ayan (t = –2.7°C to -3.3°C) and all the localities listed above except the coldest one, Yakutsk. All these localities were within the extremely unfavorable zone (II) of the earlier map (see Fig. 1).

The usefulness and necessity of the multiple-factor taking into account different environmental parameters is beyond question. However, these two maps seem to have over-estimated the role of secondary parameters, leading to such results. In order to avoid misjudgments in future, it is necessary to re-examine and re-define the significance of each comparison factor.

A few such attempts were made by Gavrilova et al. (2003, 2004). Building on the earlier works, they proposed "the number of days below 5°C" as "an additional criteria of nordicity." The results obtained were reflected in two maps: "Climate and Economic Subdivision of the North" (Gavrilova et al. 2003) and "Zonation of the Russian North" (Gavrilova et al. 2004). These maps, however, take no account of such important factors as the length of a period of extreme cold temperature (e.g., below -40°C). As a result, the later map (Gavrilova et al. 2004) places the northern part of the Kola Peninsula with the ice-free port of Murmansk where winters are as mild as in Moscow (long-term mean winter temperature, t_{win} is -6.8°C to -7.0°C at both localities (*USSR* Vol. 2 1965, *USSR* Vol. 8 1964) into the absolute unfavorable (Arctic) zone (1). Palana in Kamchatka,

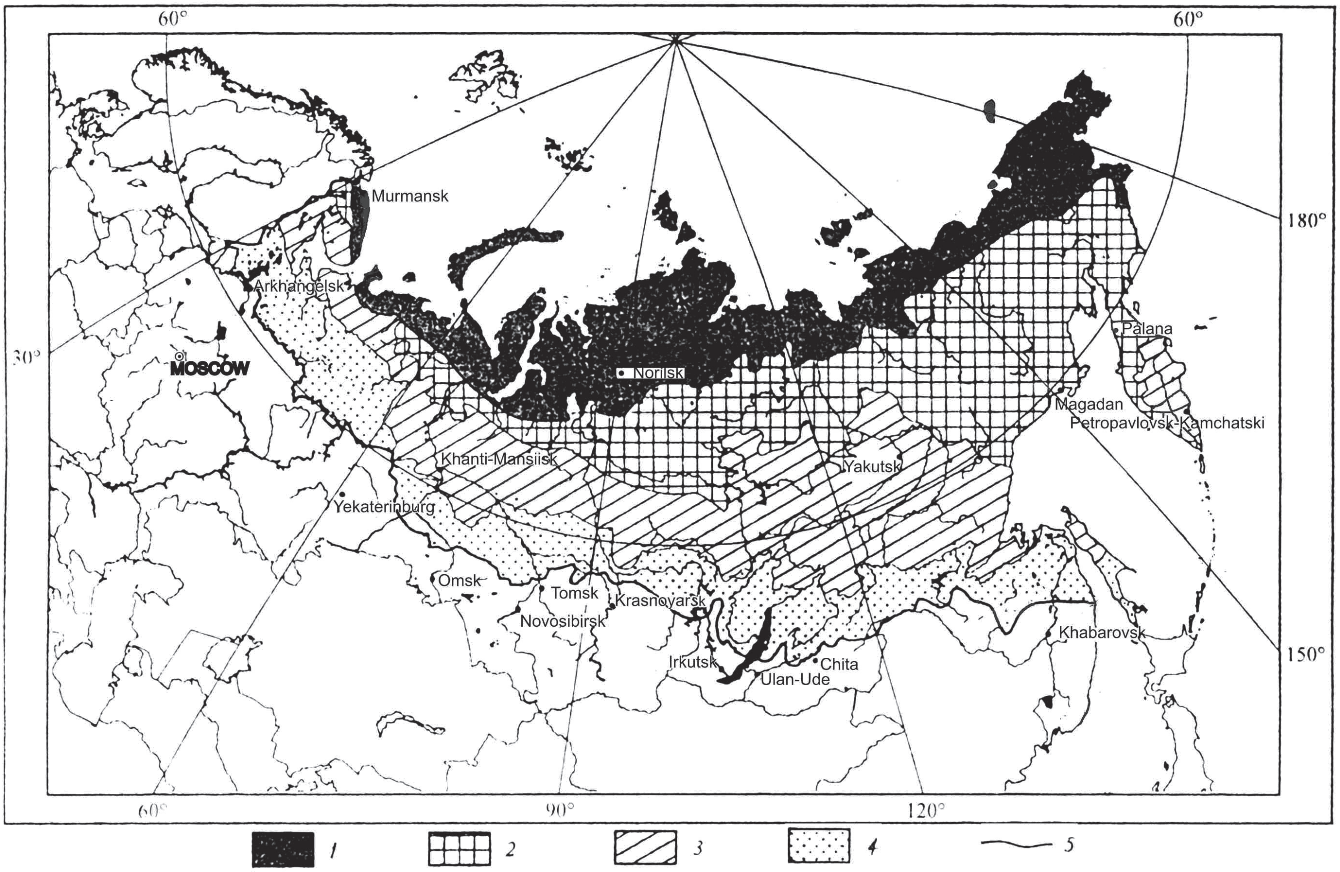

Figure 2. Zonation of the Russian North (after Gavrilova et al. 2004). 1 – Far North– absolutely unfavorable (arctic) zone, 2 – Far North equivalent – extremely unfavorable (subarctic) zone, 3 – North – unfavorable zone, 4 - North equivalent - relatively unfavorable zone, 5 – limit of the North.

and Magadan, where t_{win} is -10.4°C (*USSR* Vol. 27 1966) and -14.2°C (*USSR* Vol. 33 1966) respectively, are in the extreme unfavorable (Subarctic) zone (2), while northerner and much colder Yakutsk where t_{win} = -26.5°C (*USSR* Vol. 24 1966) is in the most southern of the three enumerated zones – unfavorable zone 3 (Fig. 2).

It is obvious that shortcomings in the zonation schemes result from the fact that all investigators try to incorporate a large number of different (often incomparable) environmental parameters into a single scheme, and such attempts are not always successful. Besides, it is time to abandon efforts to regionalize the North only, because, conditions for life in the Altai and Sayan Mountains in southern Russia, for example, are much worse than in Chukotka. The present author shares M.A. Zhukov's view that "zonation should be made not for the North …, but for the whole country based on the main significant unfavorable factors … And unfavorable conditions should be taken into account where conditions are unfavorable, not where it is the North, South, West, or East" (Zhukov 2005).

Attempts to regionalize the entire territory of Russia have been made before, based, among others, on the air freezing index. The Working Group's report contains a map (author not given), which delineates the areas with the air freezing indices (Στ) of 0°C·days to -4000°C·days (five zones) and below -4000°C·days (one zone). The latter zone includes all regions where the freezing index varies from -4000°C to -7700°C·days; i.e., the range of variation is nearly the same as in the first five zones combined. Resultantly, the same climatic zone includes Oymyakon (the air freezing index is -7300°C days to -7670°C·days), Yakutsk (Στ = -5550°C days to -5575°C·days), and Anadyr (Στ = -3570°C days to -4200°C·days) (*USSR* Vol. 24 1966, *USSR* Vol. 33 1966), which is totally incorrect.

Results

The particular climatic qualities of a territory are the most important factors affecting human activities and quality of life. Their effects are not at all uniform. In relatively favorable regions, including much of European Russia and the southern parts of West Siberia and the Far East, the climate variation is not so great as to exert a strong effect on the human organism. But in the continental areas of East Siberia, Yakutia, and the adjacent northwestern part of Magadan Oblast, the climate harshness increases so greatly, that all indicators showing the possibility of long outdoor activity and residence change radically.

To demonstrate this, published air temperature data from all Russian weather stations were analyzed (*USSR Climate*

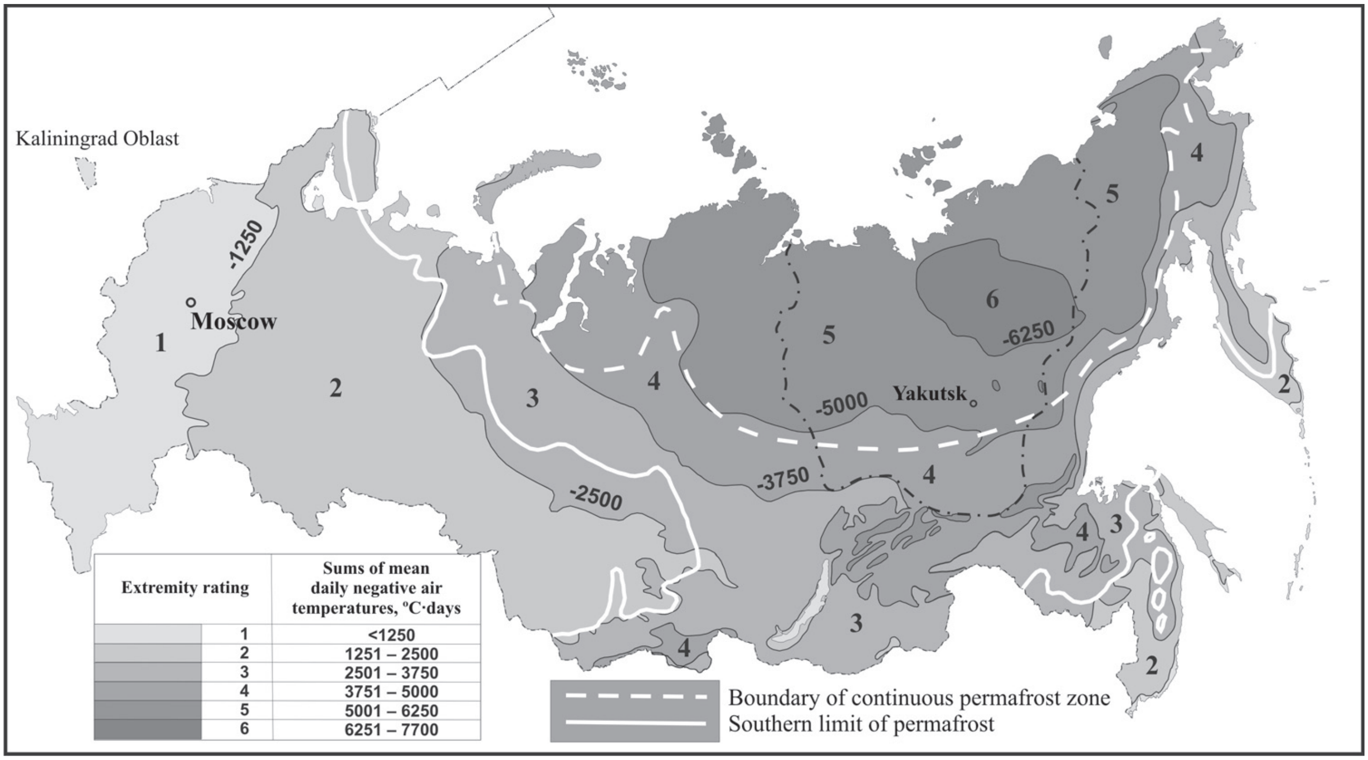

Figure 3. The permafrost and climate severity map of the Russian Federation. Dot-and-dash line – boundary of the Republic of Sakha (Yakutia).

References 1964–1967). For each weather station the average air freezing index for the whole period of record (τ), which in many cases exceeded 100 years, was calculated. The air freezing indices (Στ) for more than 3000 stations were drawn on a base map, and interpolated and extrapolated accounting for topography. This work resulted in "The Permafrost and Climate Severity Map of the Russian Federation" at a scale of 1:5,000,000. This map is presented, in a reduced form, in Figure 3. The map provides a climatic severity rating and identifies six zones, as in the earlier mapping schemes, but with equal air index intervals.

It is shown that absolutely extreme conditions (score 6) occur in the northeastern mountainous part of Yakutia and in the adjacent part of Magadan Oblast where Στ varies from -6251°C·days to -7669°C·days (Fig. 3). This zone is smallest in size and occupies only 3% of the country. At the same time, it is the coldest zone where the coldest places of the Northern Hemisphere, Verkhoyansk and Oymyakon, are located. The mean annual air temperature at these populated centers is -15.7°C to -17.0°C, and the minimum temperatures are -68°C to -70°C (*USSR* Vol. 24 1966). The mean winter air temperatures (for the persistent period of freezing temperatures) vary from -24.5°C to -32.5°C in the zone.

Extreme conditions (score 5, Στ = -5001°C·days to -6250 °C·days) are characteristic of the arctic archipelagos of Severnaya Zemlya and the New Siberian Islands, the vast areas of East Siberia, Yakutia, Magadan Oblast, and Chukotka Autonomous Okrug, as well as the high mountainous areas of northern Buryatia, Chita Oblast, Amur Oblast, and Khabarovsk Krai. Winters are very cold in these regions, with average temperatures varying from -17.0°C to -27.5°C. This zone covers extensive areas in northeastern Russia, comprising 22.4% of the area of the country.

The regions with severe conditions (score 4, Στ = -3751°C·days to -5000°C·days) are Franz Josef Land, islands in the Kara Sea, northern West Siberia, central East Siberia, southern Yakutia, the mountainous parts of Tuva and Altai, the northern parts of Buryatia, Irkutsk, Chita and Amur Oblasts, and Khabarovsk Krai, as well as parts of Magadan and Kamchatka Oblasts, Chukotka Autonomous Okrug, and Wrangel Island. This zone fringes the previous zone semi-circularly, intruding to the mountains of Trans-Baikal and Pre-Amur, and comprises about 18.2% of the area of Russia. Winters are still cold in this zone, with mean temperatures ranging from -13.5°C to -24.0°C.

The zone of unfavorable conditions (score 3, Στ = -2501°C days to -3750°C days borders all the above zones in the west, south, and east (Fig. 3). It covers about 22.5% of the area of the country and includes the Novaya Zemlya and Vaigach Islands, the eastern part of Nenets Autonomous Okrug, the northern Urals, northwestern and southern areas of West Siberia, and parts of Krasnoyarsk, Khabarovsk and Primorsky Krais, Magadan and Kamchataka Oblasts, and Chukotka. Winters are still long, especially in the Arctic islands, but now not so cold. The mean winter temperatures vary from -10.5°C to -20.5°C.

Temperate conditions (score 2, Στ = -1251°C·days to -2500 °C·days) are characteristic of much of the North-western and Privolzhsky Federal Districts, the southern part of the Urals Federal District and southwestern part of the Siberian Federal District. To the east, such conditions are found along the southern edge of Lake Baikal and in a small part of southern Chita Oblast. In the Far East, the temperate zone includes Khabarovsk Krai, most of Primorsky Krai, Sakhalin, and Kamchatka, and narrow coastal areas of Magadan Oblast and Anadyr Bay in Chukotka. This zone is largest in size (approximately 25% of the area of the country), and winters are relatively mild. The mean winter air temperatures vary from -6.5°C to -16.5°C.

The zone of relatively favorable living conditions (score 1, Στt above -1250°C·days) in the proposed map includes only those areas where the mean air temperatures for the cold season (t<0°C) are above -8.5°C. This zone occupies the Kola Peninsula coast in the Barents Sea, the northern part of the Onega Peninsula, the southwestern coasts of Onega Bay in the White Sea, Kaliningrad Oblast, the Central Federal District, southwestern Privolzhsky District, and Southern Federal District in the European part of Russia. Virtually all of Siberia, the Far East, and Chukotka have more severe conditions. Relatively favorable conditions are found here only along the sea coasts in Primorsky Krai, in southern parts of Sakhalin, along southeastern coasts and the southernmost part of Kamchatka, and on the Kuril and Komandorskie Islands. The relatively favorable zone lies mostly in the west of the country (Fig. 3), and its total area comprises about 9% of the Russian Federation.

In addition to climate severity analysis, the character of permafrost distribution within the identified zones was evaluated by the present author together with V.V. Kunitsky, M.M. Shatz and V.V. Shepelev (Shepelev et al. 2007).

The evaluation shows continuous permafrost in the areas with absolutely extreme or extreme conditions where Στt is -5001°C·days to -7669°C·days (zones 5 and 6 on Fig. 3).

In zone 4 with severe conditions (Στt of -3751°C·days to -5000°C·days), either continuous (mainly in the northern parts) or discontinuous permafrost and permafrost islands occurs. It should be noted that, except the Barents Sea islands, "the continuous permafrost zone lies entirely within the Asian part of Russia" (Shepelev & Shatz 2005).

In the areas with unfavorable conditions (see Figure 3, zone 3) where Στt ranges from -2501°C·days to -3750°C·days, permafrost islands mostly occur.

In zone 2 with temperate conditions (Στt of -1251°C·days to -2500°C·days), permafrost is of limited occurrence and exists as islands or isolated patches in the European North and in the Sayan foothills in the southeast of the country. The zone is generally free of permafrost, as is zone 1 with relatively favorable conditions (Στt > -1250°C·days) where only seasonal freezing of soils is observed, and permafrost never exists (Fig. 3).

For the purpose of illustration, permafrost zone boundaries from Baranov's (1977) Geocryological Map of the USSR were overlain on the present map. Although Baranov's map was published 30 years ago, it remains one of the best frozen-ground maps for Russia and former Soviet Union republics. More recent maps only add details for individual areas or refinements to the limits of seasonal and perennial frost which can not be reflected on this small-scale map.

Comparison shows that the presented map radically differs from all the earlier maps. The major distinction is that this map shows, for the identified zones, both the real extreme conditions with the coldest and thickest permafrost and the areas with milder and relatively favorable conditions where permafrost occurs as isolated patches or is absent. For example, Yakutia has always, now and 100 years ago, been the coldest region in Russia with the largest measured depth of permafrost (up to 1500 m). But the earlier classifications placed only the northern part of Yakutia in the absolutely and extremely unfavorable zones. Moreover, these zones included the Kola Peninsula coasts washed by the warm Gulf Stream (Figs. 1, 2) with the open sea near Murmansk where permafrost never forms, and the continental areas of the peninsula where only patches of frozen ground less than 50 m in thickness are encountered (*Geocryology of USSR* 1988).

As for the problem of defining the Far North and equivalent areas and the territories with regional coefficients, their total area is within a reasonable range. The geographic location of the Russian Federation is such that most of the country has difficult climatic conditions. The regionalization presented in this paper shows that the regions with extreme, severe, and unfavorable conditions, where the air freezing index ranges from -2500°C·days to -7700°C·days, occupy little more than 66% of the country. If the zone of temperate living conditions is added, the total area will reach 91%.

Conclusions

The present work is not yet sufficient to provide a basis for establishing regional coefficients in the entire Russian Federation. For this purpose, it is necessary to investigate in greater detail the effect of many other natural factors. In particular, more detailed consideration should be given to the geocryological situation in the regions and to their impact on human life and activities. Nevertheless, the proposed map can help compare temperature conditions with permafrost and other environmental factors, as well as value at the validity of previous elaborations.

Abstract

This paper presents recent observations of active layer changes at three CALM (Circumpolar Active Layer Monitoring) tundra sites in northeastern Russia (Chukotka region). Results show that regional changes of climate became evident after 2000. In the Anadyr area (CALM sites R9 and R11) air temperatures in June–September significantly increased from 7.4°C (1901–2000) to 9.3°C (2001–2007), with corresponding increase in accumulated thawing degree days (DDT). At the Lavrentiya site (R27), DDT in 2001–2007 rose by 217°C as compared to 1929–2000. After 2000, all sites demonstrate significantly greater end-of-season grid-averaged thaw depths in response to the increase of incoming warmth. Annual values of edaphic factors display significant positive trend (0.03 y^{-1}) at R9 (P = .026) and no trends at R11 and R27. This demonstrates a different response of the active layer in local ecosystems to warming. Analysis shown that microhabitats with shallower thaw depths are more sensitive to warming.

Keywords: active layer; monitoring; Northeast Russia; permafrost; tundra.

Introduction

The CALM (Circumpolar Active Layer Monitoring) network includes three sites in the northeastern part of the Russian Federation (Chukotka peninsula). All sites are located near the Russian coast of the Bering Strait in the continuous permafrost zone (Fig. 1). The Cape Rogozhny site (R9) was established in 1994 on the northern coast of Onemen Bay (64°49′N 176°50′E) off the Bering Sea, and is the closest to the coast of the Chukotka CALM sites. Site R11 (Mount Dionisiya, 64°34′N 177°12′E), operating since 1996, is 25 km to the south of Anadyr city and about 11 km from the nearest seacoast. The direct distance between these two sites is 33 km. Both sites are dominated by cotton grass tussocks on Gleyi-Histic Cryosols. Site R27 was initiated in 2000 in the vicinity of Lavrentiya settlement (65°36′N 171°03′W), 3 km from the coast of the Bering Strait. The direct distance between the Lavrentiya site and the above-mentioned sites in the Anadyr area is 560 km. Within the landscape of the Lavrentiya site, wet sedge-*Salix* mosses tundra on Gleyi-Histic Cryosols are dominant. More detailed site descriptions are available in our earlier papers (Zamolodchikov et al. 2004).

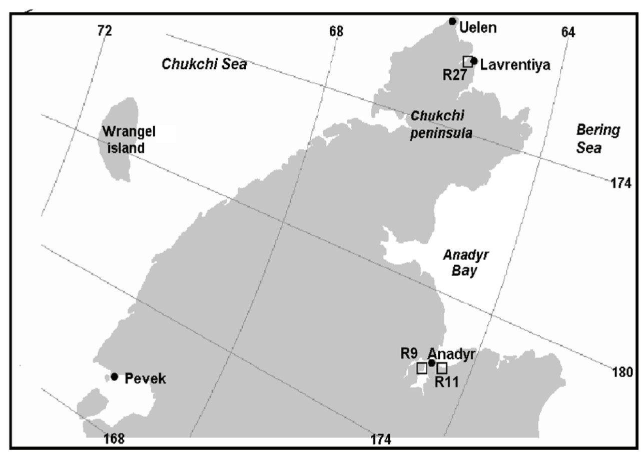

Figure 1. CALM sites in Northeast Russia: R9–Cape Rogozhny; R11–Mount Dionisiya; R27–Lavrentiya.

Methods

The standard sampling design recommended under the CALM program (Brown et al. 2000) was applied, with minor modifications, at all northeastern CALM sites. Permanent 100x100 m grids were established, with 10 m intervals between grid nodes marked with stakes (121 per grid). Thaw depth was measured at each grid node using a steel rod. Grids at the Cape Rogozhny and Mt. Dionisiya sites had one measurement replication per node, with four replications per node at the Lavrentiya grid. The active-layer was measured once each year at the end of the warm season at the Cape Rogozhny and Mt. Dionisiya sites, whereas the Lavrentiya grid was monitored throughout thaw season, with a maximum of four complete replications over the season.

An additional set of parameters was monitored at the three sites in order to estimate the influence of different natural controls over the temporal and spatial variability of the active layer. At the Cape Rogozhny site, we inventoried the surface characteristics of microhabitats such as tundra, vehicle tracks, and frost boils. At Mt. Dionisiya, the relative areas occupied by tundra vegetation, water tracks, and frost boils was determined accompanied by grid leveling. The most comprehensive set of additional parameters was collected on the Lavrentiya grid including a topographic survey, qualitative characteristics of microhabitats, measurements of volumetric soil moisture, projective cover of vegetation, moss cover, and organic layer thickness.

The Cape Rogozhny and Mt. Dionisiya grids are presently equipped with temperature data loggers measuring air and soil temperatures to a depth of 1 m. The Lavrentiya grid is equipped with a 21X Campbell data logger, recording a wide spectrum of meteorological characteristics. Unfortunately, these data loggers were not initiated at the very beginning of site occupation. It is therefore not surprising that in further analyses we used climate data from the nearest long-term government weather stations. The nearest to sites R9 and R11 is the weather station at Anadyr city (the direct distance from this weather station to the sites is 25 and 30 km, respectively), and for the Lavrentiya site (R27) it is the weather station in the native settlement of Uelen (direct distance of 85 km). Previously it was shown that air temperatures at the sites are well correlated with the temperature data from the nearest weather stations (Zamolodchikov et al. 2004).

In addition to observations made according to the CALM protocol (Nelson et al. 1996), several other geocryological and ecological surveys were conducted at the sites. Detailed descriptions of cryolithological structure and cryogenic processes were compiled for Cape Rogozhny site (Kotov et al. 1998, Kotov 2001). Mt. Dionisiya was one of the official sites of the International Tundra Experiment (ITEX; Arft et al. 1999), a program designed to examine variability in arctic and alpine plant species response to increased temperatures. The Lavrentiya site is the location of intensive year-round investigations of CO_2, water vapor fluxes, and energy balance using the eddy-covariance technique (Zamolodchikov et al. 2003).

Results

Regional climate changes become evident after the year 2000 (Fig. 2). Near the sites R9 and R11, the Anadyr weather station recorded a mean annual air temperature of -7.6°C in the 1901–2000 period and -6.3°C in 2001–2006, which is significantly warmer (P < .05). Warm season (June–September) mean air temperature increased from 7.4°C in 1901–2000 to 9.3°C in 2001–2007. The corresponding increase in accumulated thawing degree days (DDT) was 214°C at Anadyr region (R9, R11). The same tendencies could be found in data taken from other long-term weather stations in the region. For example, in the Lavrentiya area (R27), mean DDT values in 2001–2007 increased by 217°C compared to the 1929–2000 period.

After the year 2000, all three sites demonstrate a clear trend of increased of end-of-season grid-averaged thaw

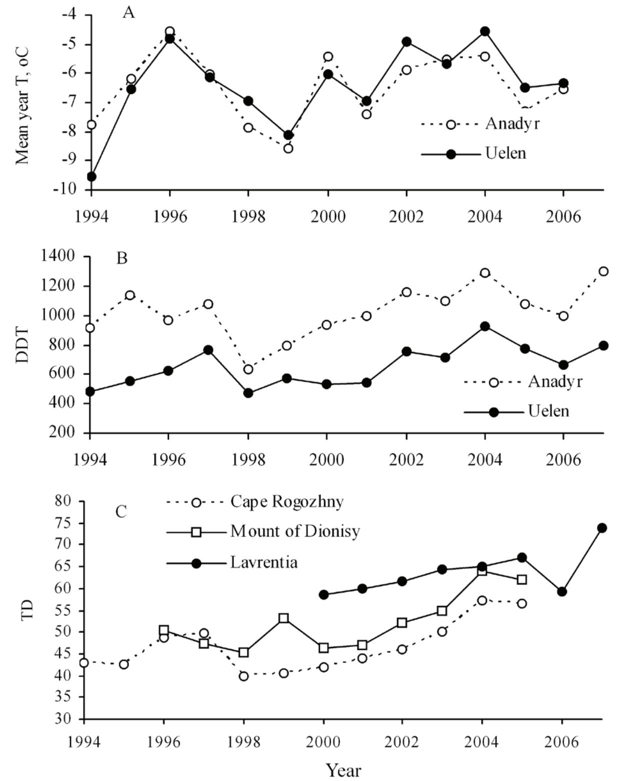

Figure 2. Mean air temperature dynamics (A) and accumulated thawing degree-days (B) at Anadyr and Uelen weather stations, and mean end-of-season depth of thaw (C) at the CALM sites in East Chukotka (Russia). Missing thaw depth data points in Anadyr sites in 2006–2007 (C) are due to logistical problems.

depths. Thus, in 2000, thaw depths were 42 cm at R9, 46 cm at R11 and 59 cm at R27. Five years later, thaw depth increased by 15 cm (35%) and 16 cm (34%) at Anadyr sites R9 and R11, respectively. Thaw depth increased by 15 cm (21%) at Lavrentiya site R27 by 2007.

The specificity of thawing processes at different sites can be characterized by the so-called edaphic factor (E), estimated as a rate, or coefficient of proportionality, between thaw depth and the square root of DDT (Nelson & Outcalt 1987). This approach was very effective in application to different sites at circumpolar Arctic sites (Hinkel & Nelson 2003; Mazhitova et al. 2004; Zamolodchikov et al. 2004, and many others). For the period of observation, mean edaphic factors were estimated as 1.49 at the R9 site, 1.70 at R11, and 2.43 at R23. It was found that the values of E display positive interannual trends (0.02–0.03 y^{-1}) at tussock tundra sites R9 (P = 0.026) and R11 (P = 0.25), though not significant in the latter case, and have no significant trend (P = 0.56) at site R27 (sedge-Salix moss tundra).

The R9 grid exhibits rather low spatial variability in active-layer thickness. The average annual coefficient of spatial variation (CV) is only 0.11. The R11 and R27 sites demonstrate more expressed spatial variability within the grid, with CV coefficients of 0.20 and 0.21, respectively. This is about twice the value observed on the R9 grid.

The interannual node variability (INV, %) reflects the level of interannual changes of spatial thaw depth distributions (Hinkel & Nelson 2003). R11 and R27 grids have similar INV estimates (21 and 19%, respectively). The R9 site demonstrates the greatest interannual node variability (29%). We note that CALM grids in East Chukotka have significantly greater INV values, as compared to East European tundra sites (Mazhitova et al. 2004).

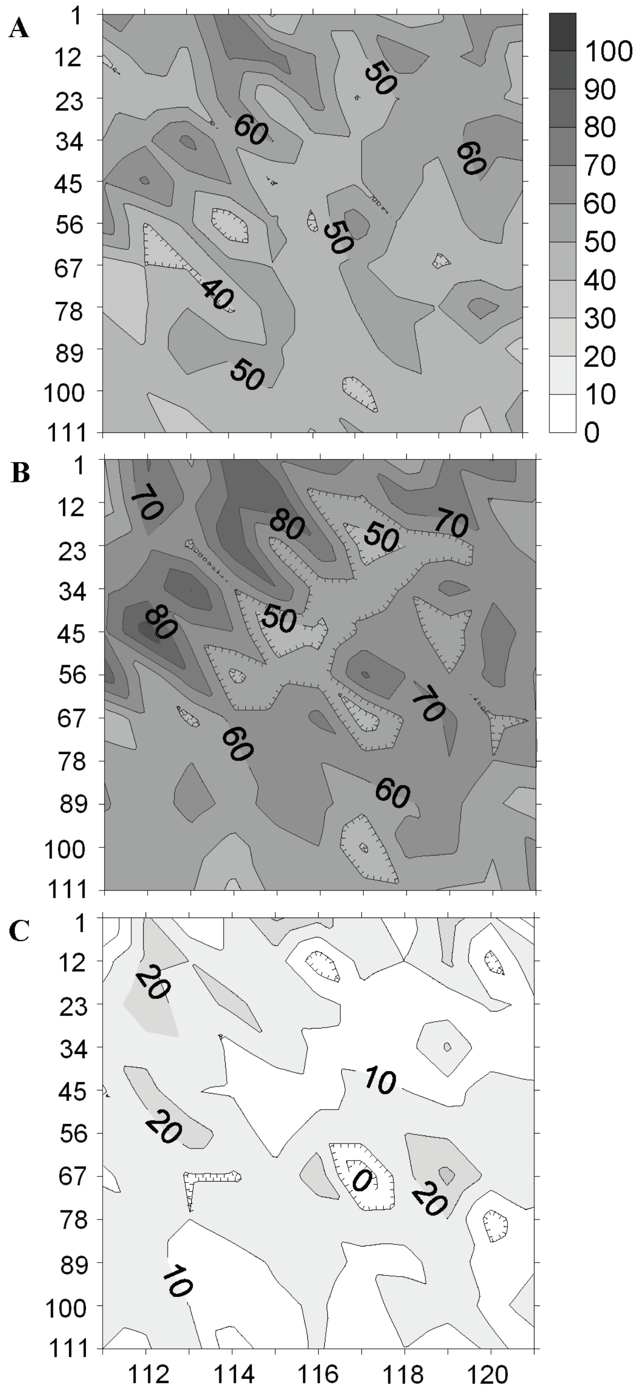

Figure 3.Thaw depth patterns and increments (cm) at the Mt. Dionisiya grid (R11). Parameters are mapped over the grid area using triangulation with linear interpolation algorithm; grid node numbers are shown on left and bottom margin. A: thaw depth, August 21, 1996; B: thaw depth, September 14, 2005; C: increments of thaw depth between 1996 and 2005.

Nonuniform rates of thawing in different habitats is one possible factor of interannual spatial variability. Spatial distributions of interannual thaw depth increments (Figs. 3C, 4C) are essentially different from those of thaw depth (Figs 3A, 3B, 4A, 4B). To put it another way, maximum thaw depth at a given location within the plot does not necessarily result in the maximum incremental increase in thaw under warming conditions.

The question arises as to whether different grid nodes demonstrate different rates of thawing. To answer this question, grid nodes were grouped and ranked by thaw depths measured in the first year of observation for each grid. The first group included the 40 nodes (33%) with the shallowest thaw depth, the second group had 41 nodes with intermediate thaw depths, and the third group incorporated the 40 nodes with the deepest thaw. Table 1 shows the average thaw depths by groups at the beginning and the end of the observation periods on different grids.

The results show that at all CALM grids, the maximum incremental increase were observed at nodes with the shallowest initial thaw depth. Hence, microhabitats with shallow thaw depths are more sensitive to warming. This is also evident from the negative coefficients of correlation between incremental thaw increase and initial thaw depths values. The correlations were highly significant for grids R9 (R = -0.47, P < 0.01) and R27 (R = -0.30, P < 0.01), but not significant for R11 (R = -0.11, P = 0.21).

Discussion

We have shown a well-defined general tendency for increasing thaw depth at all East Chukotka tundra CALM sites within the last 10–15 years of observations. This is due to a significant rise in mean annual temperature and accumulated thawing degree days. The recent tendency of increased summer temperatures are observed in most regions of the Russian Arctic (Pavlov & Malkova 2005).

The anomalous year of 2006 demonstrates a

Table 1. Incremental change in thaw depth by node groups at CALM grids in northeastern Russia.; see text for explanation.

Grid, periods of observations	Grid nodes grouped by thaw depth at first year	Average thaw depth, cm		Thaw depth increment, cm
		first year	last year	
R9, 1994–2005	low	38	54	16
	medium	43	56	13
	high	48	59	11
R11, 1996–2005	low	40	53	13
	medium	49	61	11
	high	62	72	11
R27, 2000–2007	low	46	64	19
	medium	58	73	15
	high	72	86	14

disproportionately low thaw depth at the Lavrentiya site (Fig. 2C) if compared to the Uelen weather station temperature data only (Fig. 2A, B). The explanation is due to the influence of local weather conditions. The Gulf of Lavrentiya, adjacent to the experimental site, is part of the Bering Strait. Throughout most of the summer season of 2006, the Gulf was completely blocked with ice due to prevailing winds from the Arctic Ocean. This resulted in a well-expressed local cooling effect. This was not the case in other regions of the Chukotka peninsula, as is apparent from the corresponding values of mean annual temperatures at the Uelen and Anadyr weather stations (Fig. 2A).

In the following year (2007), the average thaw depth at the Lavrentiya site returned to the overall general tendency. In doing so, the deepest active layer measurement for all years of observation and at all sites was recorded (Fig. 2C). In 2007, the Anadyr weather station recorded the greatest annual sum of thawing degree days for the entire period of 108 years of observation since 1899, which exceeded 1300°C. This DDT sum matches the normal range characteristic of the northern geographical zone of boreal forest (north taiga).

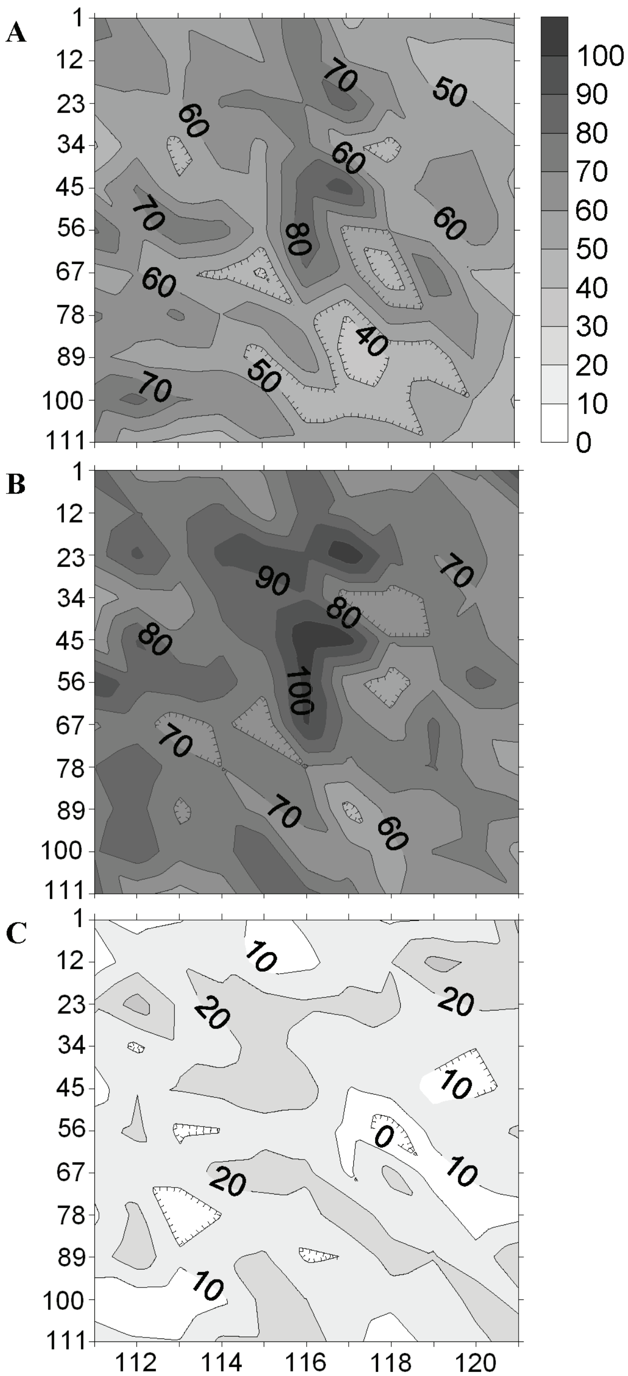

Figure 4. Thaw depth spatial patterns and increments (cm) at the Lavrentiya grid (R27). Parameters are mapped over the grid area using triangulation with linear interpolation algorithm; grid node numbers shown at left and bottom margins. A: thaw depth, September 29, 2000; B: thaw depth, September 25, 2007; C: increments of thaw depth between 2000 and 2007.

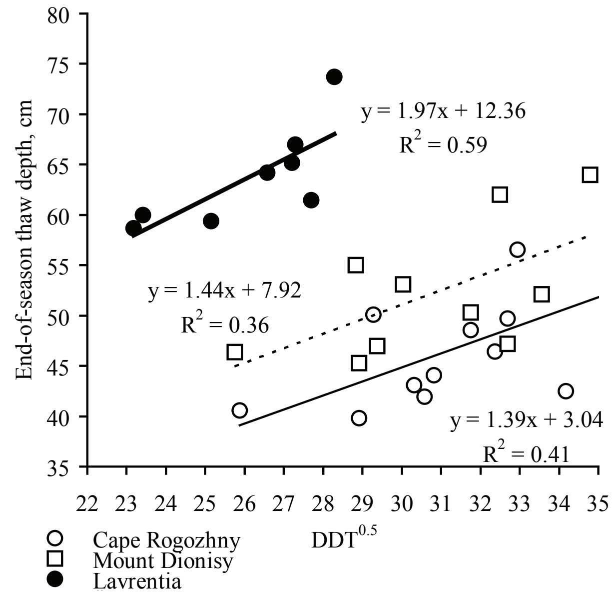

Figure 5. End-of-season thaw depth (cm) vs. accumulated thawing degree days ($DDT^{0.5}$) at East Chukotka CALM sites (Russia).

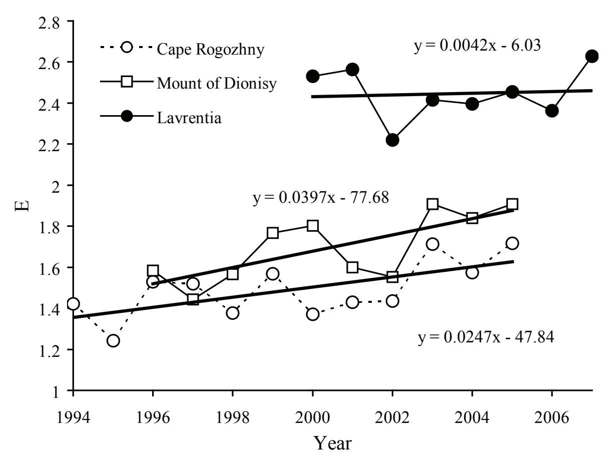

Figure 6. Interannual changes of calculated edaphic factors (E) at East Chukotka sites (Russia). Missing data points in curves for the Anadyr sites (trend lines below) are due to logistical problems in 2006–2007.

The average thawing-degree-days sums during the periods of observations at both Anadyr experimental sites are almost 1.5 times greater than at the Lavrentiya site (Fig. 5). The latter site is located much further north and is a substantially colder climate (Fig. 2B). Despite this fact, the average interannual thaw depth at the Lavrentiya site is significantly greater than at the two sites in the Anadyr region. According to our data, we believe that the difference is mostly due to the greater storage of aboveground phytomass, including more developed moss and lichen mats, bodies of *Eriophorum* tussocks, dwarf-shrub and shrub layers, and litter reserves in tussock tundras. All these factors result in better insulation.

Nevertheless, in spite of overall long-term trend of thaw depth increase, different local ecosystems could demonstrate site-specific reactions. The so-called edaphic factor *E* (the rate of active layer thickness to incoming warmth) is supposed to be an estimate of the response rate of a permafrost layer in a given ecosystem to external warming. Factor *E,* as a general property of a given soil and vegetation complex, defines a slope of a direct proportion between the rate of soil thawing and the accumulated sum of incoming warmth depending on soil structure and its other important characteristics (Brown et al. 2000). Hence, this factor is bound to demonstrate a relatively constant value in a given ecosystem. However, as is shown in Figure 6, it is not true in all cases.

In the wet sedge-Salix mosses coastal ecosystem of the Lavrentiya site, the rate of soil thawing during the entire period of observations remains constant (Fig. 6). At least one of two tussock tundra sites in the Anadyr area (Cape Rogozhny, R9) demonstrates a highly significant linear trend for this rate to increase ($P = .026$). The positive nature of this tendency suggests that, in contrast to other two ecosystems, continuous warming more affects the latter ecosystem, which possibly fails this growing pressure and degrades, or begins to change adaptively.

The spatially more heterogeneous Lavrentiya and Mount Dionisiya sites possibly remain more stable and relatively tolerant to recent warming. Such a well-expressed reaction of the Cape Rogozhny ecosystems may be also due to more intense local anthropogenic stress (pressure of all-terrain vehicles in the past), as compared to the other sites.

As was shown, the greater the depth of seasonal thaw at a given microhabitat, the less the anticipated impact of warming. This means that a given micro- and meso-habitat structure of ecosystem (i.e., the degree of its spatial heterogeneity) can seriously impact the average rate of thawing within the landscape. Under extended rise of temperature, this could offset the warming effect in permafrost ecosystems.

To estimate the stability and significance of the trends and patterns found, it is highly desirable to continue monitoring using the CALM design.

Acknowledgments

We devote this paper to the memory of Dr. Anatoly Kotov, our friend and colleague. The study was supported by NSF grants OPP-9732051 and OPP-0352958. Thanks are also due to O.D. Tregubov, Yu.A. Vertebsky (Anadyr), G.M. Zelensky (Lavrentiya), and A.I. Ivaschenko (Moscow State University) for logistical support and assistance in the field.

Abstract

This paper describes the results from several data logger systems that were installed along the above-ground portion of the Trans Alaska Pipeline System (TAPS) which transverses Interior Alaska and discontinuous permafrost terrain. These data logger systems record air, ground surface, and subsurface ground temperatures using thermistor strings. From these freezing and thawing data, n-factors are calculated and are presented for a few sites. Several of the instrumentation sites also included installing a pressure transducer in the heat pipe within the thermal vertical support members (VSM). These heat pipes are used to cool the ground around VSM during winter and can be used as thermometers to sense the temperature at the base of thermal VSM. The heat pipe pressure-derived temperature measurements correlate well with subsurface thermistor data. Reading heat pipe pressures has been adopted as a strategy for determining permafrost temperatures along the TAPS in the discontinuous permafrost region.

Keywords: data loggers; heat pipes; *n*-factors; permafrost; pipeline; temperatures.

Introduction

Design of the Trans Alaska Pipeline System (TAPS) began in 1970, and construction of the access road, pipeline, marine terminal, and pump stations started in 1974. The pipeline went into operation in 1977. The 800 mile (1270 km) pipeline has its origin at Prudhoe Bay on the North Slope of Alaska and its terminus at the ice-free port of Valdez. About one half on the pipeline is built above ground where it crosses non-thaw stable permafrost. North of the Brooks Range, where the climate is the coldest, the permafrost is continuous. South of the Brooks Range, where the climate is warmer, the permafrost is discontinuous across most of Alaska's Interior. Along the southern portion of Interior Alaska, in the Copper River Basin, discontinuous permafrost transitions to sporadic permafrost and to seasonal frost before reaching Valdez. Thermal issues relating to permafrost design of the TAPS were presented by Jahns (1983).

The above-ground pipeline is supported by bents formed by two to four piles, a cross-beam with a sliding shoe riding on the cross beam and attached to the pipe. The piles on each end of the crossbeam are called vertical support members or VSM. Bents are generally spaced approximately 60 ft (18.3 m) apart.

In the non-thaw stable discontinuous permafrost zone, each VSM has two heat pipes installed which are called thermal VSM. These heat pipes are one-way heat transfer devices that extract thermal energy from the ground during the winter when the air temperatures are less than the ground temperatures. During the summer, the heat pipes become inactive.

Much of the field testing of thermal VSM that occurred during the design phase of the pipeline was conducted in the early 1970s when the climate conditions were somewhat colder than present, with a large portion of this testing occurring near Fairbanks, Alaska. Figure 1 shows freezing and thawing indices for the last 55 years for Fairbanks. Based on a linear least squares best fit trend line through these data, the average freezing index has decreased about 11%, and the average thawing index has increased about 8% over the last 35 years. Because a safety factor of two was applied to conservative thermal design criteria, the constructed above-ground pipeline system continues to perform well, despite warming trends. This is evidenced by the very small number of VSM which have undergone measurable settlement or heave.

Throughout the operating life of the pipeline, more than 80 sites along the TAPS rout have monitored subsurface soil temperatures. However, air temperatures at these sites were not monitored. As a proactive measure to evaluate the above-ground pipeline support system under current climate conditions, Alyeska Pipeline Service Company (APSC) initiated an additional ground and air temperature monitoring program in 2003. This program consists of the installation of data loggers and temperature measuring sensors at over 40 sites along the pipeline, from fairly continuous permafrost regions just south of the Brooks Range to sporadic permafrost regions near the Little Tonsina River north of Big Thompson Pass. Each data logger site monitors air temperature, ground surface temperature, and sub-surface ground temperatures. Several of the data loggers also monitor the pressure inside the heat pipes (thermosyphons) installed in the thermal VSM.

Data from these sites have been analyzed in terms of air

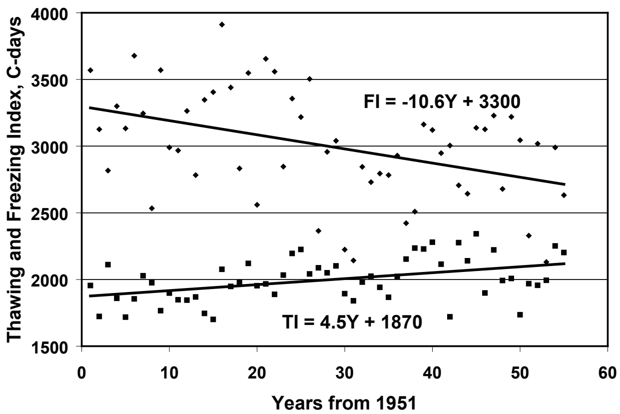

Figure 1. Freezing and thawing index data and trends for Fairbanks, Alaska beginning in 1951.

Figure 2. Installation of photovoltaic panel, battery box, data logger enclosure on VSM and thermistor string enclosure.

and surface freezing and thawing degree days and indices. From these data, freezing and thawing n-factors have been calculated and are presented for three of the data logger sites near Fairbanks. These n-factors are commonly used by engineers to predict depths of freeze or thaw. Many of these sites are undisturbed during the winter months, i.e., there is no snow removal. Surfaces are typically graveled, with either sparse grasses and/or brush growing, but growth is controlled by mowing from time to time (see Fig. 2).

Because the working fluid inside the heat pipes is in the two phase region, the heat pipes can be used as thermometers. The measured pressure inside a heat pipe can be converted to temperature of the liquid pool at its base. Thermistor strings have also been installed adjacent to several vertical support members that have pressure transducers installed. During the summer season when the heat pipes are non-operational and soil temperatures surrounding the VSM have come to equilibrium, the temperatures measured by these two methods are almost equal. During the winter months, the base of heat pipe temperatures are colder than the soil temperatures adjacent to the vertical support member, as expected when the heat pipes are operational. Graphs are presented showing air temperature, base of heat pipe temperature, and soil temperature surrounding the VSM.

Instrumentation System

Power for each of the instrumentation systems consists of a nominal 20 watt solar voltaic panel connected through a charge controller to a sealed 12-volt, 100 amp-hour lead acid battery. The data logger system is a Campbell Scientific CR10X data logger coupled to an AM/16/32 multiplexer housed in a fiberglass all weather enclosure. Air temperatures are measured with a thermistor housed in a Campbell Scientific six gill radiation shield. Ground surface temperatures and ground temperatures at depth are measured using thermistors. Ground surface temperature thermistor strings use two-pair direct burial telephone cable which has a polyethylene jacket providing mechanical protection over the range of temperatures experienced under arctic conditions. Air and vertical ground thermistor strings are single pair or multi-pair, respectively, Halar coated conductors, with a Halar outer jacket. The thermistors are 16,320 ohms at 0°C, +/- 0.1C°, YSI P/N 44034. KPSI pressure transducers with a range of 0 to 600 psia (0 to 4.1 MPa), or programmable Honeywell PPT pressure transducers with a range of 0 to 1,000 psia (0 to 6.9 MPa) were used to measure heat pipe pressures. Because the nominal output-range of the pressure transducers are 0 to 5 volts, a Campbell Scientific VDIV2.1 voltage divider is used to reduce the input voltage to match the CR10X's 0 to 2.5 volt input range. The photovoltaic panel, polyethylene battery box, and all-weather enclosure are mounted to Unistrut. The Unistrut supporting the photovoltaic panel and enclosure are banded to the VSM, and the battery box is banded to the cross-beam as shown in Figure 2.

Data were retrieved from the data logger by swapping SM4 storage modules, or downloaded using Campbell Scientific's PConnect software with a Palm handheld or by directly connecting to a laptop computer through the data logger's serial port.

N-Factor Results

N-factors are empirically determined and used to estimate ground surface temperatures based on air temperatures. These factors are used in the modified Berggren method for depth of freeze and thaw calculations. Geotechnical finite element thermal modeling programs typically use n-factors to arrive at an annual surface temperature variation. To determine an *n*-factor, the air and surface temperatures are measured at a chosen site. The freezing and thawing degree days are calculated based on the following relationships:

$TDD = T_{AVE} - 0^0 C$ if $T_{AVE} < 0^OC$ and
$FDD = 0^0 C - T_{AVE}$ if $T_{AVE} > 0^OC$

From these data, air and surface freezing and thawing indices are calculated on a seasonal basis, using the cumulative method. Then the ratio of the surface and air freezing indices and surface and air thawing indices are calculated from measured and recorded temperatures to arrive at the site-specific *n*-factor. The equations stating these relationships are:

$$n_F = \frac{Surface \cdot Freezing \cdot Index}{Air \cdot Freezing \cdot Index}$$ and

$$n_T = \frac{Surface \cdot Thawing \cdot Index}{Air \cdot Thawing \cdot Index}$$

A compilation of measured n-factors has been published by (Lunardini 1978). However, there have been very few *n*-factors published for surfaces other than paved and gravel roads, and airport runways and taxiways.

Air and surface temperature data have been collected at most of the sites for the last four years. Three of the instrumented sites are along a section of above-ground pipeline between Chena Hot Springs Road and Nordale Road, northeast of Fairbanks. This section of above-ground pipeline is usually referred to as the Love Road site.

The Love Road site is typical for a low-lying, non-thaw stable permafrost area in Interior Alaska. It is a marshy lowland flood plain area, underlain by ice-rich silt with more than 95% typically passing a no. 200 sieve (Pearson 1977). The natural vegetation around the gravel pad area consists of tussocks, mosses, tamarack, black spruce, and willows and other brushy plants, as well as various varieties of grasses. This area represented a "worst case scenario" in terms of thermal stability design in a warmer permafrost horizon. During construction, the natural ground was covered with a gravel work pad to allow installation of VSM supports and the pipeline. The work pads have been maintained over the years by application of additional gravel surfacing. The northern end of this section of pipeline was the first above-ground pipeline constructed, with the work pad placed in March of 1974 and 14 VSM in early October of 1974 (Pearson 1977). It is also the area where initial field testing of several pre-construction heat pipes was performed. Twelve of the VSM became part of the pipeline, with production heat pipes installed in these VSM in March of 1975 (Pearson 1977). Table 1 identifies the three instrumented sites as A, B, and D, with their corresponding pipeline mileposts. Soil temperature data for the VSM at Site A, at elevations below the surface of the gravel pad, were recorded from 1974 through 1976 (Pearson 1977).

Air temperature and ground surface temperature curves are shown in Figure 3 for Site A. The n-factors for the three sites A, B, and D, along this section of pipeline are presented in Table 2, beginning with winter 2003–4 through summer 2007.

Thermistor strings at the Love Road Sites A and C were installed to a depth of 18 m and within 0.8 m of the VSM on the drive lane side of the work pad. An additional thermistor string, Site B, was installed to a depth of 18 m at the mid-point between bent C and the bent station immediately north (upstream). Whiplash curves are shown in Figures 4 and 5 for the thermistor strings installed at Sites B and C.

Comparing Figures 4 and 5 shows the ground cooling effect provided by the heat pipes in the thermal VSM. It is also noted, that the top of the permafrost next to the thermal VSM is about 2 m below the ground surface after 30 years of pipeline operation. Midway between bents, the top of the permafrost has receded to about 4 m below the ground surface nearly 30 years after pile placement. Design phase calculations predicted 3.3 m of seasonal thaw after 20 years of operation (Jahns et al. 1978) and from 4 m to 6 m of thaw after 20 to 30 years of operation, (Jahns 1983).

The top of the permafrost was at a depth of about 2 m

Table 1. Site location in miles from Prudhoe Bay and comments about location.

Site	Mile Post	Comments
A	456.130	VSM/Bent Station at preconstruction test site
B	456.183	Thermistor string 18 m north of Site C
C	456.189	VSM/Bent Station adjacent to preconstruction test site
D	458.178	VSM/Bent Station at transition to below ground

Table 2. Year and *n*-factors for Sites A, C, and D.

Year and N-Factor		Site A	Site C	Site D
2003–4	N_F	.22	.17	N.A.
2004	N_T	1.08	1.07	1.12
2004–5	N_F	.21	.18	.25
2005	N_T	1.04	1.08	1.09
2005–6	N_F	N.A.	0.35	0.48
2006	N_T	1.02	1.10	1.09
2006–7	N_F	.0.34	0.32	0.49
2007	N_T	1.04	1.07	1.09

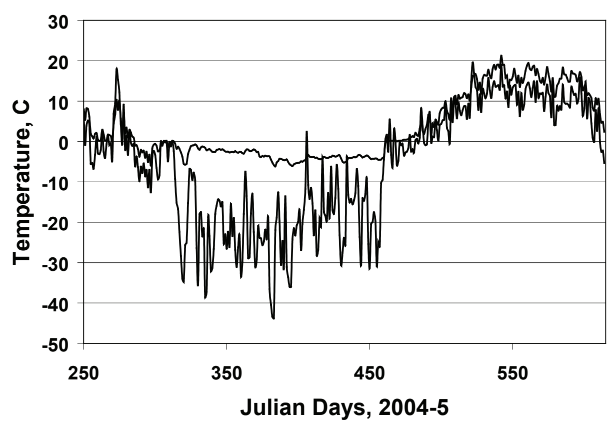

Figure 3. Air (highly variable curve) and ground surface temperatures for instrumentation Site A near Fairbanks. The soil surface temperature measured 6 m from VSM.

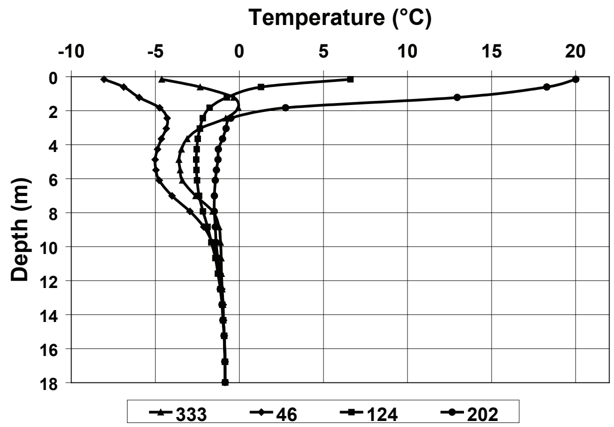

Figure 4. Site C whiplash curves for Julian days 46, 124, 202, and 333 within 1 m of thermal VSM in 2004.

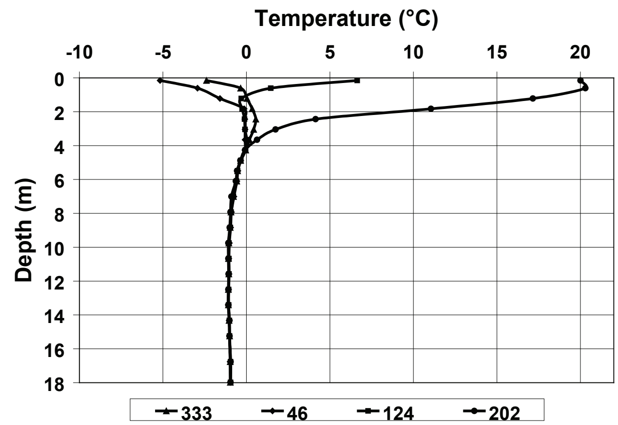

Figure 5. Site B whiplash curves for Julian days 46, 124, 202, and 333 midway between bent stations in 2004.

in October of 1976 (Pearson 1977). In 2004, the top of the permafrost had receded to about 4 m midway between bents as shown by the whiplash curves in Figure 5. The temperature at a depth of 8 m beneath the work pad was about -0.5°C in October of 1976. Figure 5 indicates about the same temperature at a depth of 8 m in 2004.

End of summer temperatures at 8 m depth in October 1976 adjacent to the VSM at Site A were about -2.2°C. The warm side trumpet curve shown in Figure 6 in 2003–2004 shows similar recorded temperatures at the 8 m depth.

Figure 6 shows the cold side and warm side trumpet curves for Site A. It is observed the ground temperatures at depth are about 1°C colder at this site than Site B referenced in Figure 4 which is about 92 m away. There is a remote gate valve close to Site A, which is supported by four thermal VSM which provide greater combined ground cooling in the immediate area. It is worth noting, that installing free-standing heat pipes next to existing thermal VSM is a way to mitigate potential climate warming effects and have been successfully employed at a few locations on the TAPS.

Heat Pipes as Thermometers

The 124,300 heat pipes installed in the VSMs of TAPS were manufactured by the McDonnell Douglas Corporation. The heat pipes are 2-inch (51 mm) OD steel pipe below the top of the VSM and 3-inch OD pipe above the top of the VSM. Inside diameter is a uniform 1.5-inches (38 mm). Heat pipes with a 4-foot (1.22 m) long extruded aluminum fin were made in lengths of 28 ft (8.5 m) to 37 ft (11.3 m) in 3-foot (0.9 m) increments. Heat pipes with a 6-foot (1.83 m) long extruded aluminum fin were manufactured in lengths from 42 ft (12.8 m) to 75 ft (22.9 m) in 3-foot (0.9 m) increments. These heat pipes were originally charged with anhydrous ammonia.

In 1983, (Johnson 1983), six years following completion of TAPS, it was reported that many of the heat pipes were experiencing an accumulation of non condensable gas inside the units. The gas was determined to by hydrogen. During operation, the hydrogen is swept by the ammonia vapor

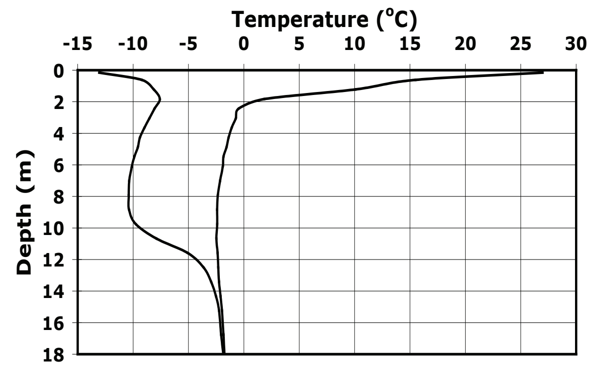

Figure 6. Site A cold and warm side trumpet curves for the period of 2003 to 2005 at 1 m from the thermal VSM.

to the top of the heat pipe. The ammonia then condenses, leaving the hydrogen behind, partially blocking the top finned section from condensing additional ammonia. Using infrared camera technology, the amount of blockage or "cold topping" is determined. In the 1980s through the 1990s, getter pins were installed in the top of the heat pipes to absorb the hydrogen. The getter pins contained a metal halide, zirconium dimanganese. When the getter pins became saturated with hydrogen, non-condensable gas blockage would return. In 2001, Sorensen et al. (2003), developed a program of bleeding-off the ammonia and non-condensable gas and recharging with carbon dioxide. This process required the installation of a valve at the top of the heat pipe.

The pressure transducers were attached to valves installed above the finned section of the heat pipes. A thread-o-let was welded on the side of the steel pipe above the fins, and a hole drilled through the heat pipe wall to within 1/8 inch of breaking through. A hot tapping tool was then attached to the thread-o-let, and the final drilling was completed through the wall of the heat pipe. The ammonia was bled off, and the heat pipe was evacuated and purged with nitrogen before the final charge of carbon dioxide was performed.

Because the working fluid in the heat pipe is in the two phase region, pressure and temperature are not independent

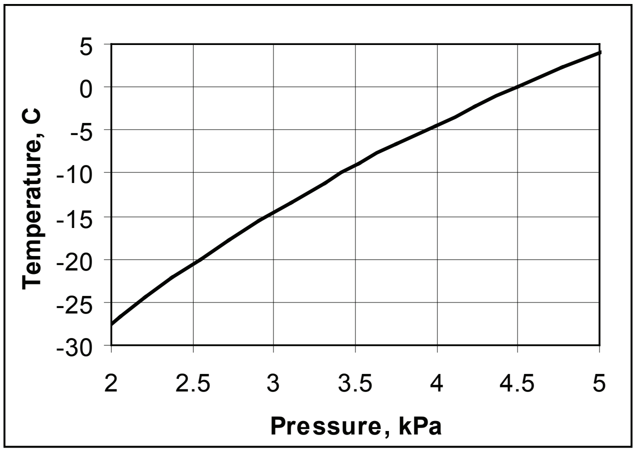

Figure 7. Saturation temperature–pressure relationship for carbon dioxide.

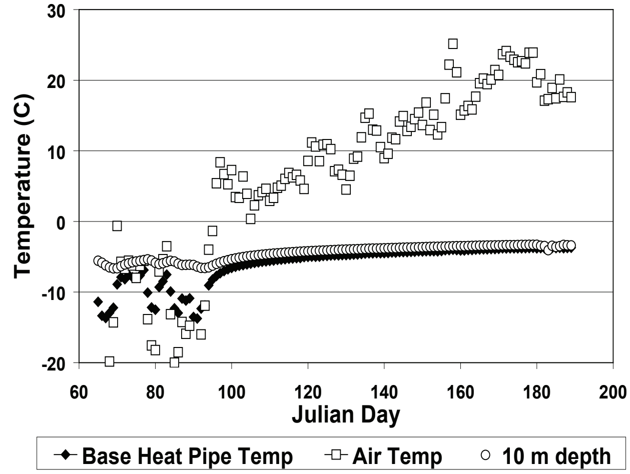

Figure 8. Comparison of air, base of heat pipe, and ground temperature near base of VSM.

properties for a single component fluid. Therefore, by measuring the pressure inside the heat pipe, the temperature is readily determined by referencing the thermodynamic tables of the specific working fluid. At those instrumented sites where the temperature at the base of the VSM was desired, a hot taping operation was performed to bleed-off the ammonia, and then the heat pipe was recharged with carbon dioxide. The saturation temperature–saturation pressure relationship for carbon dioxide is shown in Figure 7. The pressure indicated by the pressure transducer was corrected for the hydrostatic head of vapor in the heat pipe to arrive at the pressure at the liquid pool vapor interface at the base of the heat pipe. Then, using a chart as shown in Figure 7, the temperature at the base of the heat pipe was established.

When the air temperature is colder than the ground temperature surrounding the VSM, the heat pipe operates and removes heat from the ground. When the air temperature is warmer than the ground temperature surrounding the VSM, the heat pipe ceases to reject heat.

Figure 8 shows air temperature, base of heat pipe temperature, and the ground temperature as measured by a thermistor at the same elevation as the base of the heat pipe. This thermal VSM is at the northern end of the Love Road site. Temperatures of air, base of heat pipe, and ground at the 10 m depth are plotted in the Figure for Julian days 65 through 195. During the winter, it is seen that when the air temperature is coldest, the base of heat pipe temperature is warmer, and the temperature of the surrounding ground the warmest. It is noted that there are a few days during the winter period that the outdoor air temperature exceeded the ground temperature and the heat pipe would become inoperative. When the heat pipe ceases to function in the spring of the year, the base of heat pipe temperature and the surrounding ground temperature trend to equilibrium. It is observed that the temperature measured by the thermistor and the temperature calculated from measuring the heat pipe pressure (refer to Fig. 7) are almost exactly the same.

By measuring the pressure in the heat pipe during or after maintenance is performed, the temperature of the permafrost at the bottom of the VSM can be determined. Measurements in late summer using this method have revealed that most VSM base temperatures remain below freezing, even in cases of severe cold topping. In many cases, where temperatures are initially near or slightly above freezing during maintenance, re-freezing tends to occur within one to two years, even in sporadic permafrost areas. In addition, the method assists in providing a relatively dense map of late summer subsurface temperatures along the TAPS right-of-way that would be difficult to achieve by any other method.

Conclusions and Discussion

The Campbell Scientific data loggers and multiplexers have proven to be very reliable. A few intermittent problems that occurred initially with respect to data logging among the 40 sites included flooding of one data logger due to stream icing/overflow, broken thermistor lead wires at two sites due to frost heave and settlement, and low battery voltage in valleys where the sun does not shine on the photovoltaic panels for several months during mid-winter at two locations. Because batteries are mounted on the crossbeams of the bents, they are exposed to ambient temperatures. Their capacities are decreased with decreasing temperature, and their charging efficiency is also decreased at low temperatures Many researchers bury batteries beneath the snow to avoid exposure to low ambient temperatures. However, in this case, mounting the batteries on the crossbeams provided greater security and allowed better access for periodic maintenance. All of these challenges were addressed early in the project to ensure effective monitoring.

The thawing *n*-factors are lower than typical thawing n-factors for gravel surfaces (Lunardini 1978). Early morning and late evening shading by trees and brush along the sides of the right-of way, daily shading of the ground from the shadow cast by the pipeline, and ground shading by vegetation are all causes for the lower thawing *n*-factors.

The freezing *n*-factors show more variation from year to year. The amount and timing of the snow cover has the major effect on the freezing n-factors. Early and deep snow covers yield lower freezing n-factors.

The trumpet and whiplash curves presented for sites A, B, and C show no significant changes in temperature from the data presented by Pearson (1977). The heat pipes installed in the VSM have been effective in maintaining reduced permafrost temperatures around the VSM. The drive lane for this section of pipeline serves as a summer and winter recreational trail. Wintertime activities include dog mushing, Nordic skiing, and snowmobiling, which tend to compact the snow. Additionally, APSC plows this section of drive lane from time to time in the winter for access to the two remote gate valves along this section. The effects of compacting and/or removing snow enhance cooling of the ground as the thermal resistance of the snow is reduced.

Using the heat pipes as thermometers is a very effective method of determining the late summer base of heat pipe temperatures. This tends to be a more cost effective method of obtaining these temperatures in comparison to the installation of thermistor strings.

The dynamics of heat pipe cooling in thermal VSM as a function of time and air temperature is better understood. Thanks to the early work by others at the Fairbanks sites during design of the pipeline, a good comparison of long-term thermal data is possible. By evaluating thermal conditions at several sites in a region, *n*-values have been determined for use in trending and predictive maintenance of thermal VSM.

Acknowledgments

Study of Western Taymyr Permafrost in the Framework of the IPY Education Program

Alexandra M. Zemskova
Lomonosov Moscow State University, Faculty of Geography, Dept. of Cryolithology and Glaciology, Moscow, Russia

Abstract

A 10-day course on Permafrost and Periglacial Geomorphology of Western Siberia and Western Taymyr (PPG), as part of the framework of the IPY education program, was jointly developed by faculty of the Geography Department of Moscow State University and researchers from the Earth Cryosphere Institute. The course was held at the end of July and beginning of August 2007 aboard the *Fedor Naianov* vessel, which sailed on Yenisey River from the town of Dudinka to the port of Dikson on the Arctic coast. The course attracted six Russian upper-level undergraduate and graduate students from Moscow State and St. Petersburg State Universities. The main topics of the course were (1) landscape-specific permafrost conditions and characteristics of the lower Yenisey River region, (2) ground ice and cryolithology, (3) Quaternary history of Western Taymyr, and (4) field methods of geomorphologic investigations. The course consisted of extensive field excursions at nine stops along the Yenisey and a lecture series and laboratory work aboard the ship.

Keywords: ground ice; IPY education program; landscapes; permafrost; Quaternary deposits; Western Taymyr.

Introduction

The expedition was organized under the supervision of two doctors of science: Irina D. Streletskaya (Lomonosov Moscow State University, Faculty of Geography, Dept. of Cryolithology and Glaciology, Moscow, Russia) and Aleksander A. Vasiliev (The Earth Cryosphere Institute SB RAS, Tyumen, Russia).

The young participants of the expedition were Alexandra M. Zemskova, Mikhail N. Ivanov, Ivan V. Kopytov, Sergey A. Simonov (Lomonosov Moscow State University, Faculty of Geography, Dept. of Cryolithology and Glaciology, Moscow, Russia), Maria A. Medvedeva, and Alexandra G. Cherkasheva (St Petersburg State University, Faculty of Geography, St. Petersburg, Russia) (Fig. 1).

Students participated in applied geocryology, geomorphology, biology, and Quaternary research. This included the study of the spatial distribution of major landscapes, vegetation, and soil along the prime climatic gradient from Dudinka to Dikson; the study of geological cryogenic structures of Pleistocene sediments; collection of characteristic vegetation, soil, and sediment samples; and collection of ground ice samples for isotopic analysis. Contemporary cryogenic processes of the Western Taymyr coastal zone were studied, including coastal dynamics, ice wedges, thermokarst, etc.

Figure 1. Our research group: Maria A. Medvedeva, Aleksander A. Vasiliev, Alexandra M. Zemskova, Alexandra G. Cherkasheva, Ivan V. Kopytov, Irina D. Streletskaya, Sergey A. Simonov, Mikhail N. Ivanov.

Study Area

The study area was along the Yenisey River from Dudinka to Dikson Island. The eastern coast of the Yenisey Gulf from Sopochnaya Karga Cape to Dikson Island is the northwest periphery of the Taymyr Peninsula. Geographical characteristics of the region are influenced by the high latitude and the cold Kara Sea currents (Fig. 2).

Despite a general increasing trend of summer precipitation from north to south, the difference is not large: Ust'-Port, 137 mm; Igarka, 213 mm. The radiation balance in the warm period varies by latitude: Dikson Island, 891.7 MW; Turuhansk, 1218.3 MW.

The radiation balance during the cold period at Dikson Island is equal to 380.9 MW and in Turuhansk, 255.3 MW. The difference in the degree-hour sum for the cold period in the north and in the south is not more than 25%. The precipitation variance from north to south is large: Gol'chiha, 107 mm, and Igarka, 294 mm. The reason for this contrast is in the barrier for the western air masses, such as Putorana Plato. The Yenisey River valley is the territory of increased snow accumulation. Changes in topography effect the development of cryogenic processes.

The northern portion of the described region has relief with stepped construction. We can observe continuity of

Figure 2. The map with the route of research: 1 - Dudinka, 2 – Sopkarga, 3 – Vorontsovo, 4 – Budenovsk, 5 – Dixon, 6 – Krest'yanka, 7 – Narzoi, 8 – Zverevsk, 9 – Innokentevskoe.

relief levels from interfluve to river valley. Formation of these levels is connected with the presence of Pleistocene sea basins, lake reservoirs, and rivers. According to the main exogenic processes, which form contemporary relief, it is possible to substract three types of relief in this area: Pleistocene marine terraces; Pleistocene-Holocene, lake-limnetic accumulative depressions; and alluvial terraces.

The continuity of landscape zones with its own complex of cryogenic processes goes from the south to the north. The southern zone of low-bush tundra stretches from the latitude of Dudinka to Karaul. The northern zone of moss-lichen tundra extends close to 72°N latitude. Finally the arctic zone extends northward to the town of Dikson. (Tumel' 1988, Popov & Tumel' 1989).

Our research was in the northern part of this region. This polar region of the permafrost distribution consists of a tundra zone that stretches for 450 km from Dudinka latitude to the coast of the Kara Sea. Permafrost is continuous here. The permafrost thickness is greatest at the mouth of the Yenisey River: from 10 m to 600 m. Minimal thickness is observed at the low inundable levels where contemporary permafrost is forming. The annual average air temperature spectrum is wide: from 0°C to -9°C or -10°C. To the north from Ust'-Port the average air temperature is -7°C to -9°C.

Quaternary history of Western Taymyr

Mesozoic aqueous rocks crop out only to the North from Kuznecovskiy Cape. To the south Pleistocene sediments have practically solid sedimentary cover above the bedrock. The intensive erosion of bedrock came before the Quaternary period, therefore the overdeepening of the Yenisey valley was 380 m lower than contemporary sea level. The thickness of Pleistocene sediments increases regularly from 100 to 200–400 m from south to the north. Quaternary deposits are as follows: alluvial, marine, glacial-marine, fluvio-glacial, glaciolacustrine, and deluvial- soliflual Pleistocene-Holocene sands, loams, and clays (Troickiy 1966).

Methods

Seven scientific-educational field trips have been undertaken by the participants of the expedition. We were doing observations, collecting samples of frozen ground and ice for different analyses, and making some field measurements (e.g., evaluation of the moisture content of frozen samples). For study of the contemporary permafrost state, ground ice specifics, and paleogeographical reconstructions a complex of field and laboratory methods has been used: geomorphological, cryolithological, geobotanical, landscape, geological, paleontological, radiocarbon, isotopic,

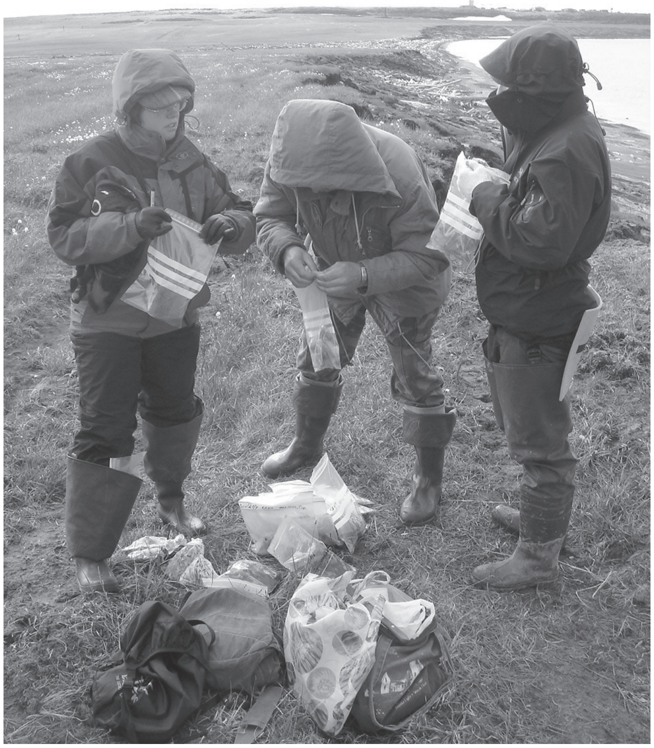

Figure 3. Packing samples of ice from the ice wedges.

optically stimulated luminescence (OSL), geochemical, pellet-mineralogical analysis by the Surkov method, and sporo-pollen analysis. For these purposes, samples of frozen ground, snow, and ice were collected from coastal exposures (Fig. 3).

Geothermal survey methods were used in two wells equipped with loggers to monitor the temperature regime of the Western Taymyr accumulative land forms (alluvial spits). The boreholes are situated at the flat coast of the Sopochnaya Karga lagoon.

During the expedition students acquired fieldwork skills (describing boreholes and transverse sections, defining ice fraction, and collecting and registering of samples) and field and cameral treatment of collected materials (evaluation of solid natural moisture content, herborization, and sorting of samples).

Field Observations

During the expedition, Pleistocene-Holocene deposits in the coastal exposure of the east bank of the Yenisey River and Yenisey Bay were studied. The two types of frozen rocks showed epigenic type (freezing after the rock forming) and syngenetic type (freezing synchronously with sediment formation). The Samarovskaya (MIS (marine isotopic stage) 10) moraine deposits of middle Pleistocene, Sanchugovskie (MIS 8-6) marine and Kazancevskie (MIS 5) (Late Pleistocene) glacial-marine, marine and coastal-

Figure 4. Ice complex (coastal area of Sopochnaya Karga polar station).

Figure 5. Collecting the samples of ice from the "ice complex."

marine deposits of Late Pleistocene refer to the epicryogenic type. As usual, the Middle-Pleistocenic deposits are characterized by comparatively low ice content: up to 20% in volume and massive or nonregular cryogenic structure. The Late Pleistocene Kazancevskie deposits have greater ice content—up to 50%—and tabular massive ground ice with visible thickness more than 10 m were found (Figs. 4, 5).

Late Pleistocene-Holocene deposits of ice complex and Holocene deposits of contemporary deluvium and accumulative marine and fluvial formations refer to the syncryogenic type of permafrost. Ice complex deposits are characterized by high ice content—up to 80% in volume—and lenticular-stratified cryostructure (Karpov 1986). They contain polygonal ice wedges 4 m wide in the upper part of the section and up to 12 m high (Fig. 6).

Contemporary cryogenic processes of the Western Taymyr coastal zone were also studied. They are the following: coastal dynamics, ice wedges, thermokarst, etc. It is possible to see that for the last several decades the permafrost gas degraded in the explored region. Two wells were equipped with loggers for temperature regime monitoring of Western

Figure 6. Ice wedges near the Dikson.

Taymyr accumulative land forms (alluvial spits). The boreholes are situated at the flat coast of the Sopochnaya Karga lagoon.

Conclusions

Natural conditions at the Yenisei delta and at the Yeniseyskiy Bay coastal area from Sopochnaya Karga polar station to Dikson were studied.

Research methods in arctic landscapes, plant formation and soil covering, transverse sections of permafrost thicknesses have been taught in real, natural settings. Areal differentiation and variability of dominant landscapes, plant formations, soil cover in relation to the nature climatic zone at the Dudinka–Dixon transect have been studied. Geology aspects and cryolithological specifics of Middle-Late Pleistocene and Holocene deposits of Western Taymyr were studied too.

The samples of snow and ice from ice wedges and ice complex for study of isotopic composition of ground ice have been selected. Samples for optically stimulated luminescence (OSL) analysis of sand deposits have been selected with the purpose to determine absolute age of Middle-Late Pleistocene deposits.

Solids and ice samples were collected for laboratory study of their properties. We get new data for different parameters such as grain texture, mineralization of soils, spore-pollen compound and OSL, and radiocarbon age. Isotopic sampling was done almost for the first time ever at this part of Taymyr Peninsula.

Detailed data about flora specifics and their ratios in the different natural and climatic zonality—from forest tundra to arctic tundra—were collected.

Unique deposits of ice complex, inclosing repeated-wedge ice of great thickness, have been defined. It is established that the ice complex of Western Taymyr is represented by Late Pleistocene-Holocene sabulous deposits, the youngest deposits in the transverse section.

We plan to continue our observations on loggers. This will help to get new data about offshore permafrost on the lowland accumulative forms of relief (beach, bay bar); the speed and dynamic of permafrost formation; and how permafrost follows annual air temperature; that is, its reaction on climate changes.

Our research helps to improve the methods of field investigation and the use of new technologies and methods in the field. Results of these analyses would apply as a foundation for master and Ph.D. student work.

This expedition is a first step in international research group organization to do research work in this region.

But of course, some things need to be improved. If our group were able to use more portable technical equipment (e.g., modern GPS, salinity meter – to compare water in the Yenisey River and Yenisey Bay and ground, different soil and meteorological portable equipment, etc.) it could have made information, that we got more accurate and our trip would have been even more informative and productive. This would be useful because the region of our investigations is unique and poorly studied.

Acknowledgments

Research has been sponsored by ConocoPhillips Russia, Inc., and by the Oceanology Institute in Saint Petersburg. Special thanks to Elena Zemskova, to the management of the Great Arctic Reserve, to Mrs. A. F. Lubnina and Mr. G. I. Lubnin for lectures and for historical and ecological tour arrangements in the town of Dikson. I also express thanks to the reviewers of this paper for their comments and editorial changes.

Abstract

The Circumpolar Active Layer Monitoring (CALM) site was established in the Taymir Peninsula to compensate for some deficiencies in the CALM observational network in Russia. The regular active layer measurements were initiated in 2005 followed by detailed characterization of landscapes and surface conditions. Periodic frost heave and thaw subsidence measurements by optical leveling were initiated in 2007. A short three-year period of observations allowed for only preliminary conclusions. The grid-average ALT for the study period is 87 cm. The thickness of the active layer varies from 45-50 cm to 125-150 cm, depending on landscape-specific conditions. The maximum thickness of the active layer is observed at landscapes represented by sparsely-vegetated patterned ground and dry hillocks. The minimum ALT was found in the polygonized peatlands. In the near future we intend to extend the observational program to include air and ground temperature monitoring. The establishment of complementary sites in underrepresented landscapes is currently under consideration.

Keywords: active layer thickness; CALM; Taimyr Peninsula.

Introduction

The active layer is the most dynamic and sensitive part of the climate-permafrost system. Knowledge of spatial and temporal characteristics of the active layer and factors affecting its long-term behavior and spatial pattern is required for assessing and predicting environmental conditions and socio-economic development of permafrost regions. Active layer investigations have a long history in Russia (Shiklomanov 2005) and include both empirical (Garagulya 1985, Kudryavstsev 1979) and modeling studies (Feldman 1977, Anisimov et al. 2002, Malevsky-Malevich et al. 2006).

Beginning in the 1990s systematic, standardized active layer and shallow permafrost observations were initiated under the international Circumpolar Active Layer Monitoring (CALM) program (Brown et al. 2000, Nelson et al. 2004). The series of 41 CALM sites that constitute the Russian portion of the network extends from the European tundra of the Pechora and Vorkuta regions to Chukotka and Kamchatka (Shiklomanov et al. 2008). However, the area adjacent to the Taimyr Peninsula, which constitutes a vast portion of Russian permafrost regions, is largely underrepresented by CALM. Two sites established in the Taymur region in the early 1990s were discontinued due to logistical circumstances (Fig. 1). To compensate for this CALM network deficiency, in 2005 a new Talnah site was established on the Taimyr Peninsula, in the Norilsk Industrial Region. This report provides a detailed description of the Talnah CALM site, observational methodology, and initial results obtained over the 2005-2007 period.

Study Area

The Talnakh grid (R32 according to CALM classification) is located (69°26′01″N, 88°28′03″E) in the northern part of Eastern Siberia on the Taimyr Peninsula (Fig. 1) at the Noril-Rybnin interfluve, about 2.5 km southeast of the settlement of Talnakh (Norilsk Industrial Region). Kharaelakh Ridge of the Putorana Mountains lays 1.5 km north of the site. The site is situated on a fluvial terrace, characterized by loamy soils and underlain by low-temperature, continuous permafrost (Sheveleva & Khomichvskaya 1967, Ershov 1991). The climate of the region is temperate continental with prolonged, snowy winters and short, cool summers (Tushinskiy & Davydova 1976). On average, the period with negative mean daily air temperatures extends 245 days. Mean annual air temperature is –9.8°C. Mean air temperature of the coldest month (January) is -27.6°C, of the warmest month (July), +13.4°C. Average annual wind speed is 6.3 m/s and the annual sum of precipitation is 340 mm/yr. The climatologically average maximum snow-cover thickness is 80 cm.

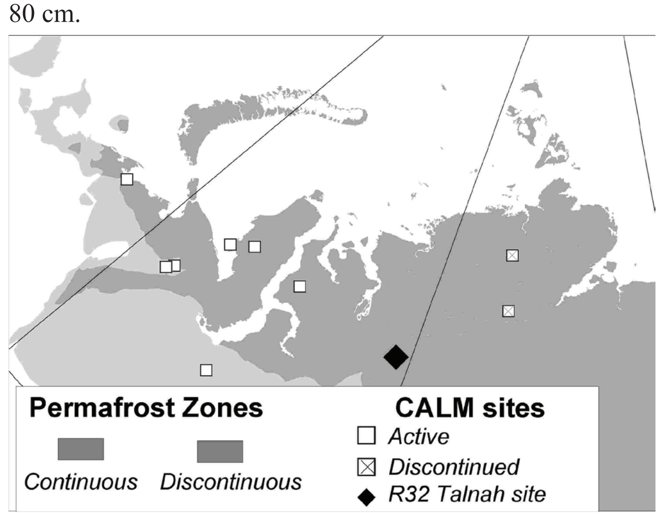

Figure 1. Distribution of permafrost zones (Brown et al. 1997) and location of CALM sites in Russian European North, West Siberia and Taimyr Region.

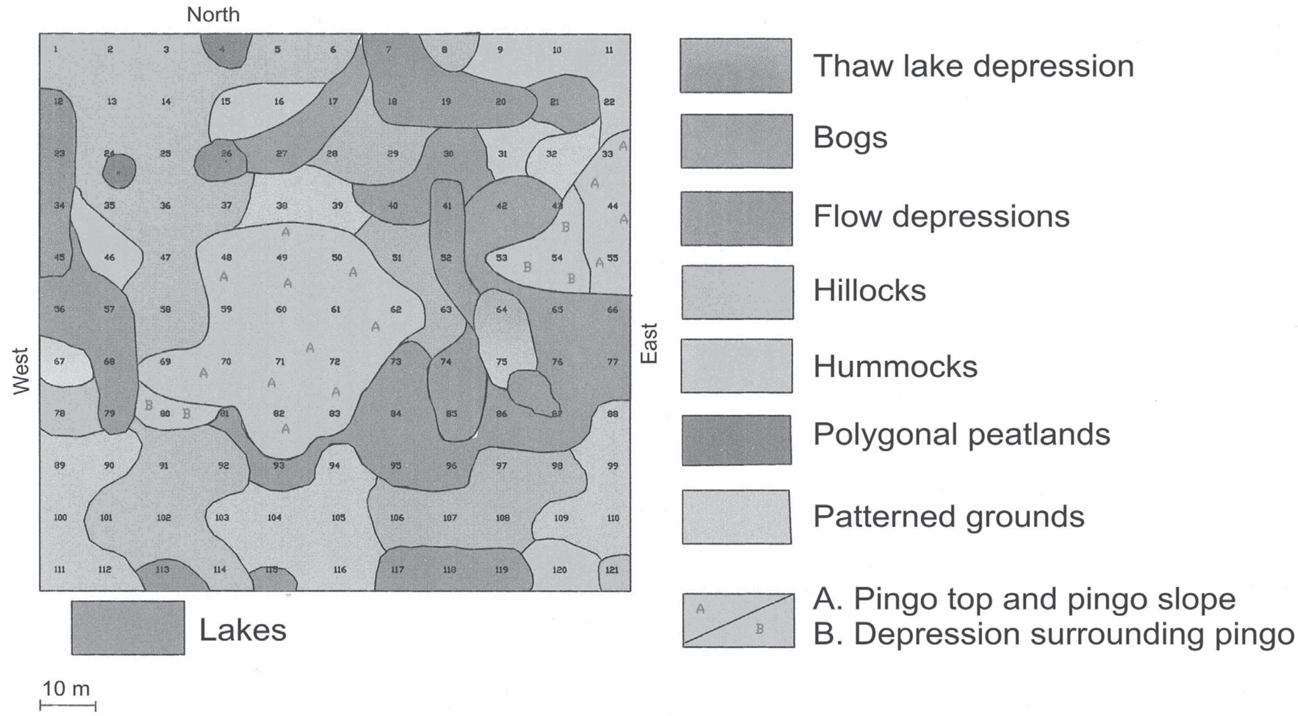

Figure 2. Results of landscape classification within the R32 Talnakh 1-ha CALM site.

Sediments primarily consist of loam with small intrusions of pebbles and overlain by a thin peat layer. The grid is situated on subhorizontal surface with elevation decreasing in a southeast direction. A small frost mound (pingo) 30 m in diameter and 1.5 m high occupies a portion of the site. The frost mound is surrounded by flow depressions and polygonized peatlands. The size of the polygons varies from 6 to 8 m across. Hummocks up to 20 cm in height and hillocks up to 60-70 cm in height are widely present. Typical tundra vegetation occupies the site and consists of shrubs, dwarf-shrub and sedges. Mosses and lichens are largely absent from the site. The environmental and geocryologic conditions of the site closely correspond to those of the southwestern part of the Taimyr Peninsula.

Methodology

A regular 100 x 100 m (1 ha) grid was established at the site in the summer of 2005 according to recommendations provided by CALM protocol (Brown 2000).

The establishment of the grid was followed by detailed characterization of landscapes and surface conditions. Nine main landscape categories, characteristic of the south-western part of the Taimyr Peninsula are contained within the grid (Fig. 2).

Periodic annual active layer measurements were initiated in 2005 at grid nodes separated by 10 m, yielding an array of 11 x 11 nodes across the grid (Fig. 2). The measurements are performed by mechanical probing using a graduated metal rod. As a rule, each point is probed twice. However, if the difference between two measurements is significant, additional observations are taken at close proximity to the sampling point. An average value is calculated for each sampling point, yielding a total of 121 data values for the grid per probing date.

During the 2007 field season the optical leveling of grid nodes was initiated following CALM-approved procedure described in detail at the CALM website (http://www.udel.edu/Geography/calm/research/MazhitovaMethod.pdf).

Records of major climatic parameters are available from the Russian meteorological station, Alykel Airport, located 50 km west of the grid. In the near future we intend to instrument the Talnah site for continuous air and ground temperature monitoring.

Results and Discussion

The Digital Elevation Model (DEM) of the site for the year 2007 is shown in Figure 3. DEM indicates a slight increase in elevation in the northwest direction. The optical leveling will be continued annually and will be used to evaluate changes in the position of the ground surface associated with frost heave and thaw subsidence.

To analyze the spatial distribution of the active layer thickness, grid-node values of ALT were interpolated using krigging technique to produce annual maps of ALT. Annual ALT maps for the 2005-2007 period and map of three-year averages are shown in Figure 4. The summary statistics for three years of available ALT measurements are presented in Table 1.

The maximum three-year grid average ALT is 87.3 cm, with the minimum 50 cm and the maximum 126.5 cm; standard deviation is relatively small and does not exceed 15 cm (Fig. 4).

Constructed annual maps of ALT show high spatial variability of this parameter, despite the fact that the variation of the summer climatic signal expressed as Degree-Days of Thawing on a moment of measurements did not exceed 10% and on average was around 980°C·days.

To evaluate landscape-specific contributions to overall active layer pattern, the ALT values, as measured at each particular landscape presented in Figure 2, were analyzed. The landscape-specific statistical distributions of ALT values, obtained over a three-year period and representing both temporal and spatial ALT variability, are shown in Figure 5.

The highest degree of variability was encountered at patterned ground features represented by frost mounds. It

Unit	I	II	III	IV	V	VI	VII	VIII	IX
ALT	82	74	80	81	90	92	95	114	87

can be attributed to sparse vegetation cover and thin organic layer characteristic of these landscapes. Dense vegetation and thick organic layer significantly mitigate the influence of variability in climatic forcing resulting in less temporally and spatially heterogeneous active layer. This effect is illustrated by small ALT variations, observed at densely- vegetated, polygonized peatlands and thaw lake depressions. These landforms are also characterized by thick accumulations of peat. The high degree of active layer variability observed at hillocks and hummocks can be largely attributed to significant differences in ALT values obtained from the tops of hummocks and from interhummock depressions. The high spatial heterogeneity of the active layer in a tussocky and hummocky landscape was observed in Alaska and reported by Nelson et al. (1999). Flow depressions, surrounding frost mounds, are characterized by a high degree of variability around mean, but a relatively small range of values. This can be explained by the relatively small sample of points representing this landscape unit.

The landscape-specific three-year means of ALT are presented in Table 2. The highest value of 114 cm was observed at flow depressions, which are subject to convectional heat transfer by running water. The thinnest ALT (74 cm) is characteristic of polygonized peatlands with dense vegetation cover and thick organic layer.

Conclusions

The Talnah CALM site was established in the Taymir Peninsula to compensate for some deficiencies in the CALM observational network in Russia. Regular active layer measurements were initiated in 2005. A short, three-year period of observations allowed for only preliminary conclusions. The grid-average ALT for the study period is 87 cm. The thickness of the active layer varies from 45–50 cm to 125–150 cm, depending on landscape-specific conditions. The maximum thickness of the active layer is observed at landscapes represented by sparsely-vegetated patterned ground and dry hillocks. The minimum ALT was found in the polygonized peatlands. Periodic heave and subsidence measurements by optical leveling were initiated in 2007. In the near future we intend to extend the observational program at the Talnah site to include air and ground temperature monitoring. The establishment of complementary sites, characteristic of regional landscapes underrepresented by the Talnah site, is currently under consideration.

Acknowledgments

This study was conducted as part of the research and educational plan of the Department of Geography at Moscow State University. We are also grateful to the U.S. National Science Foundation for their partial financial support through an OPP-0352957 grant, administered by the University of Delaware.

Experimental Study on Mechanisms of Subgrade Deformation in Permafrost Regions Along the Qinghai-Tibetan Railway

Jianming Zhang

Bo Zheng
China Academy of Railway Science, Beijing, China

Abstract

Field observations at the Beiluhe test site along the Qinghai-Tibetan Railway indicate that, even though the permafrost table under the embankment has moved up since the railway was built, the embankment still has suffered quite a lot of settlement, and the settlement has been mainly due to deformation of the warm and ice-rich frozen soils under the original permafrost table. In order to understand the mechanism of the subgrade deformation in permafrost regions, pressure meter tests were conducted under the embankment, and compression tests were carried out in the laboratory. Based on the test results, the settlement in the embankment at the Beiluhe test site was estimated taking into consideration the compression of the warm and ice-rich permafrost. Over the next 50 years, the estimated settlement in the embankment is about 40 cm, even though the permafrost under the embankment will not thaw at all.

Keywords: embankment settlement; permafrost regions; Qinghai-Tibetan Railway; warm and ice-rich frozen soils.

Introduction

In permafrost regions, the construction of a roadway embankment changes not only the thermal regime of the permafrost under the embankment but the stress state in the subsoil as well. With the adjustment of both temperature and stress in the subsoil, the stability of the embankment will inevitably be modified, and settlement of the embankment takes place. According to experience gained from the Qinghai-Tibetan Highway, the settlement of a roadway embankment in permafrost regions is generally composed of three parts: (1) compression of the fill, which depends on the material of the embankment and the density of the fill; (2) consolidation of the active layer, which is controlled by the soil type and its water content; (3) thaw settlement of the permafrost, which is related to the thickness of the embankment and the ice content in the permafrost. Of the three kinds of deformations, the thaw settlement of permafrost under the embankment is the most significant for the stability of the roadway embankment (Wu et al. 1988, Wu & Liu 1989, Yu & Yan 1986).

During the construction of the Qinghai-Tibetan Railway in 2001, many measures were taken to protect the permafrost in the subsoil. Among them the most common practice was to build an embankment thick enough to prevent the permafrost from thawing. However, field observations from 2002 to 2005 at Beiluhe test site along the railway indicated that, even though the permafrost table under the embankment has moved up since the railway was built, the embankment has still suffered quite a lot of settlement, and the settlement has been mainly due to deformation of the ice-rich frozen soils under the original permafrost table. In order to understand the mechanism of this kind of deformation and to estimate the settlement of the railway embankment in the future, pressure meter tests were conducted under the embankment in the summer of 2005, and compression tests on ice-rich frozen soils under a stepped temperature rise were carried out in the laboratory in 2006. In this paper, we present the field observation data, the test results, and then an estimate of the settlement of the railway embankment in the coming 50 years.

Field Observation

Test section

Since 2002, after the embankment was built, six test sections have been set up at Beiluhe test site along the railway to monitor the ground temperature under the embankment and the layered settlement of the subgrade. The layout of the test sections is shown in Figure 1, and the permafrost conditions at each section are given in Table 1.

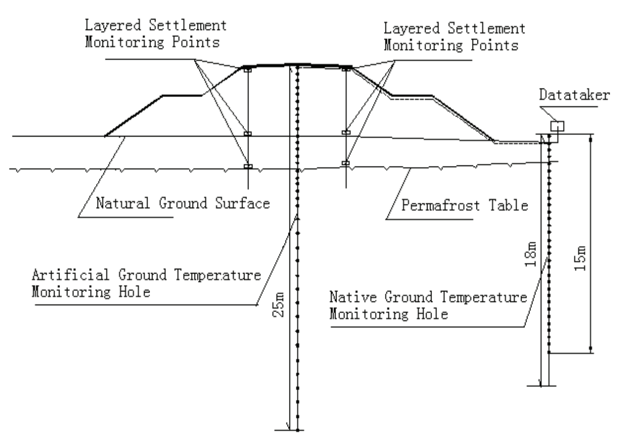

Figure 1. Component layout at the test section.

Table 1. Permafrost conditions at each test section.

Test section (km+m)	Embankment thickness (m)	Permafrost table in natural ground (m)	Mean annual ground temperature (℃)	Thickness of ice-rich frozen soils (m)
DK1136+520	2.9	2.2	-0.74	4.4
DK1136+540	4.5	2.0	-0.78	3.5
DK1136+580	5.0	1.9	-1.01	5.6
DK1136+755	3.0	2.0	-0.46	2.0
DK1136+775	4.2	2.0	-0.45	3.0
DK1136+800	5.4	2.3	-0.46	4.5

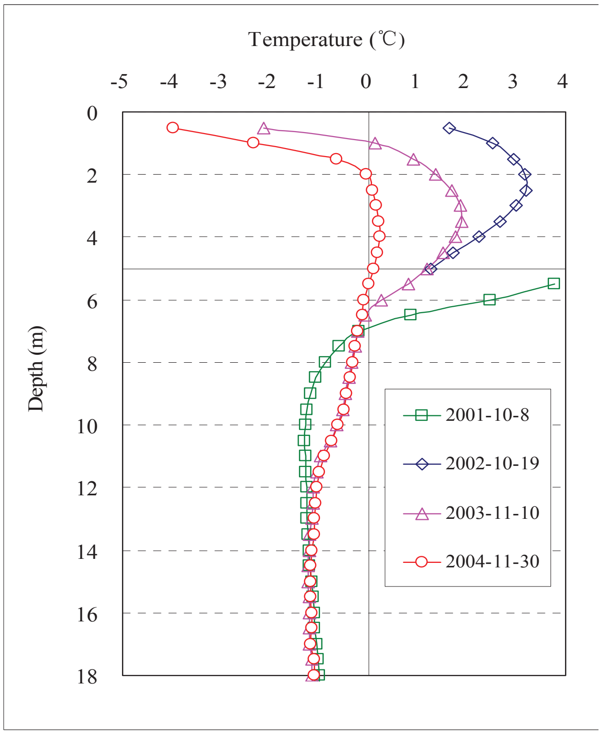

Figure 2. Ground temperature profiles in the embankment.

Ground temperature

Figure 2 shows the typical ground temperature profiles at the centerline of the embankment at DK1136+580 during 2001 to 2004 in the seasons of max. thawing depth. It can be seen that, though the permafrost table under the embankment has moved up gradually since the embankment was built, the ground temperature under the original permafrost table also rose remarkably at the same time. The ground temperature rise will certainly cause changes in mechanical properties of the permafrost, resulting in settlement of the embankment.

Embankment settlement

Figure 3 presents layered settlement processes of the embankment at DK1136+580 from 2002 to 2005. Taking a close look at the processes, we can see that the difference in settlement between the roadway surface and the natural ground surface, which is the compression of the fill, is rather small. The difference between the ground surface and the original permafrost table, which is the consolidation of the active layer, is also small. However, the settlement at the

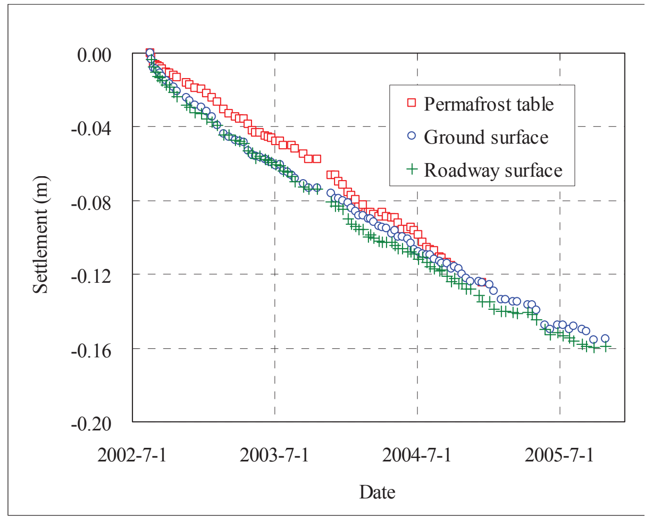

Figure 3. Layered settlement processes of the embankment.

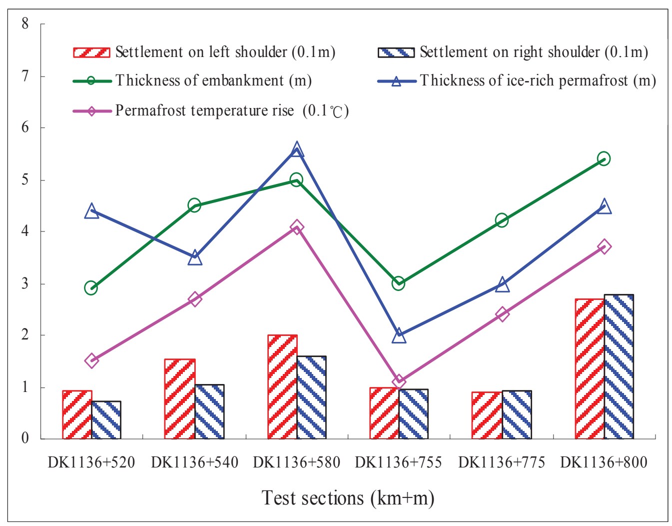

Figure 4. Embankment settlement and permafrost conditions in the subgrade.

original permafrost table is much larger. It is clear that the total settlement of the roadway embankment is largely due to the deformation of the warm and ice-rich frozen soils under the original permafrost table.

Discussion

Figure 4 shows the total settlement values at each of the six test sections and the possible factors which have an effect on the settlement, such as the thickness of embankment and

Table 2. Soil conditions of the pressure meter tests.

Test position	Under embankment				Natural ground	
Depth (m)	1.4	2.1	3.6	4.0	3.6	4.7
Soil type	Silty clay					
Temp. (℃)	-0.25	-0.31	-0.50	-0.69	-0.85	-0.89
Moisture (%)	20.8	101	36	63.9	37.3	24.5
Density (g/cm^3)	2.27	1.39	2.09	1.66	2.07	2.12

the thickness of ice-rich permafrost in the subgrade, as well as the temperature rise of the ice-rich permafrost due to the construction of the embankment. In this figure, it can be seen that the settlement values relate well with the factors at most of the test sections. At the sections with thicker embankment, thicker ice-rich permafrost, and more temperature rise, the settlement of embankment is greater.

Pressure Meter Test

Test condition

In order to investigate the variation of mechanical properties of the permafrost in the subgrade, pressure meter tests were carried out under the railway embankment as well as in the adjacent natural ground in September 2005. The device used in the tests was a TEXAM pressure meter made by ROCTEST with a metallic probe of 58mm in diameter. The tests were performed in the strain controlled mode, and the test conditions are given in Table 2. In the table, it is obvious that, at the same depth below the original ground surface, the soil temperatures under the embankment are always higher than those in the natural ground.

Test result

Figure 5 and Figure 6 show the pressure meter test results of shear modulus and max. pressure, respectively, at different depths under the embankment and in the natural ground. It is evident that both the shear modulus and the max. pressure in the subgrade are lower than those in the natural ground. This means the mechanical properties of the permafrost in the subgrade have been changed considerably since the railway embankment was constructed. It also confirms that the settlement of the embankment was mainly due to the deformation of the ice-rich frozen soils under the original permafrost table caused by temperature rise in the subgrade.

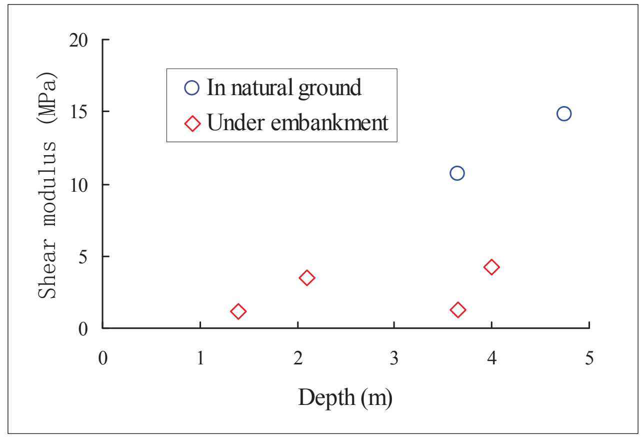

Figure 5. Comparison of shear modulus between under embankment and in natural ground

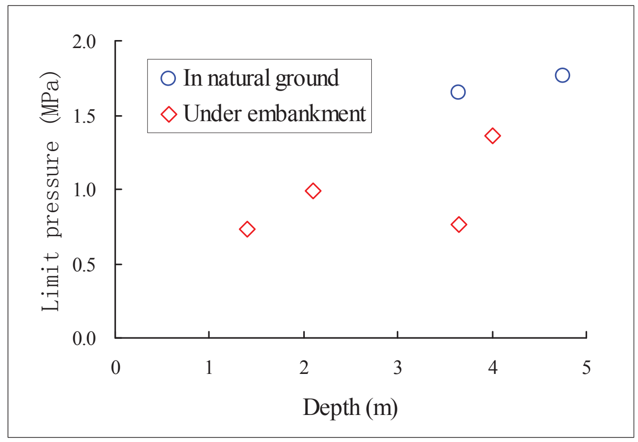

Figure 6. Comparison of max. pressure between under embankment and in natural ground

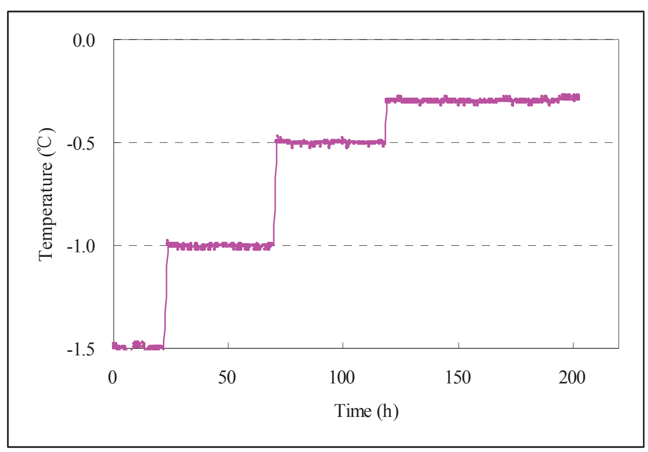

Figure 7. Temperature process in the compression test.

Compression Test

Test condition

In order to determine the compressibility of the ice-rich frozen soils caused by temperature rise, compression tests were carried out in the laboratory. The soil samples of silty clay from the test sections were prepared with water contents of 40% and 80%, respectively, and the water contents were kept constant during the tests. The tests were performed in an oedometer with a diameter of 61.8mm and a height of 40mm. In order to understand the influence of temperature on the compressibility of frozen soil, the load was kept constant in each test, and the temperature was controlled in a stepped rise mode as shown in Figure 7.

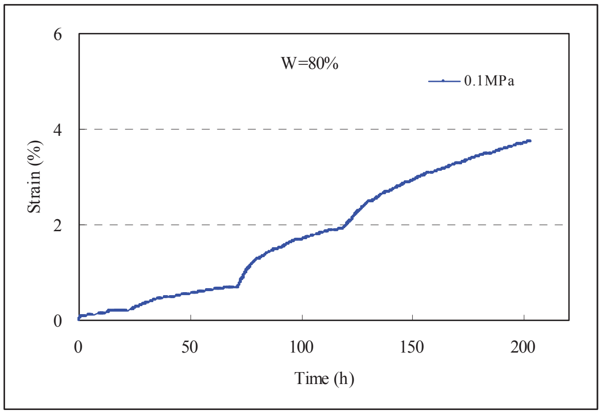

Figure 8. Deformation process in the compression test.

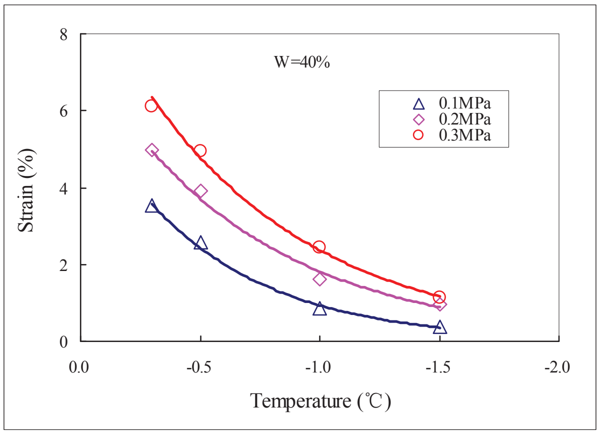

Figure 9. Total compressibility vs. temperature step.

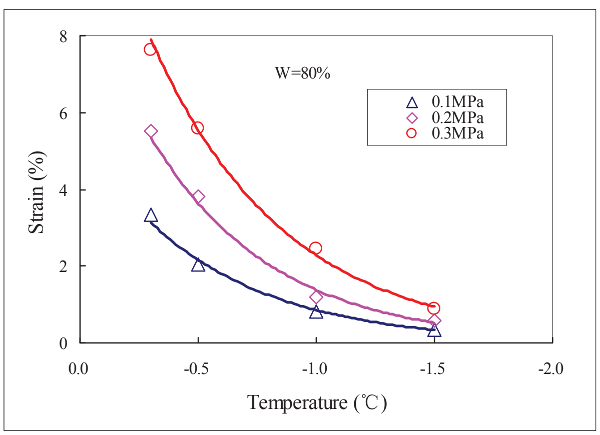

Figure 10. Total compressibility vs. temperature step.

Test result

Figure 8 shows the deformation process of the frozen soil with water content of 80% and under pressure of 0.1MPa, corresponding to the temperature steps shown in Figure 7. It is apparent that, even under such low stresses, the frozen ice-rich, silty clay can produce quite a lot of deformation during the temperature rise process, especially when close to 0°C. Figure 9 and Figure 10 present the test results of compressibility under different temperature steps and different pressures. It should be noted that the compressibility is more sensitive to pressure when temperature approaches 0°C.

Settlement Estimation

Calculation model

Based on the test results and concepts mentioned above, we can estimate the settlement of the railway subgrade in permafrost regions. According to experience obtained from both the Qinghai-Tibetan Highway and the Qinghai-Tibetan Railway, the settlement of the subgrade must include both the thaw settlement and the compression of the permafrost under the embankment, and it should be calculated as:

$$S = S_1 + S_2 + S_3 = \sum_{i=1}^{n} A_i \cdot h_i + \sum_{i=1}^{n} \alpha_i \cdot P_i \cdot h_i + \sum_{j=1}^{m} \Delta\alpha_j^{\Sigma} \cdot P_j \cdot h_j$$

where S is the total settlement of the subgrade, S_1 is the thaw settlement of the permafrost, S_2 is the consolidation of the permafrost after thawing, and S_3 is the compression of the warm and ice-rich permafrost. In detail, A is the thaw-strain parameter of permafrost, h is the thickness of soil strata assumed in the calculation, α is the compression coefficient of thawed soil, P is the pressure applied on the soil strata, and $\Delta\alpha^{\Sigma}$ is the variation of the compression coefficient of frozen soil caused by temperature change.

According to the geological conditions at Beiluhe test site, the permafrost profile adopted in the calculation is shown in Figure 11. The compressible layer is the ice-rich frozen soil under the embankment from 2 to 8 m below the natural ground surface. The mechanical parameters of the ice-rich frozen soil in the subgrade are: A=0.084, α=0.45MPa. The variation of a^S with temperature is shown in Figure 12, and h is taken as 0.25 m referring to the calculation of the ground temperature profiles over the next 50 years.

Ground temperature prediction

Before the settlement of the subgrade is estimated, it is necessary to predict the ground temperature profiles under the embankment. According to the numerical model to calculate heat transfer in frozen ground (Zhang et al. 2006), the ground temperature profiles in the centerline of the embankment over the next 50 years in the seasons of max. thawing depth are shown in Figure 13. In this figure, it is clear that the ground temperature in the subgrade will increase with the service life of the railway embankment.

Calculation result

Based on the subgrade deformation model and the ground temperature profiles, the settlement of the subgrade in future can be calculated. Figure 14 presents the estimate of the subgrade settlement processes for different embankment thickness. It can be seen that the settlement increases with increase in embankment thickness, and it will be about 40 cm by the end of the next 50 years even though the permafrost under the embankment does not thaw at all.

Conclusions

The results of both pressure meter tests and compression tests confirm that the warm and ice-rich permafrost in the railway subgrade can produce quite a lot of deformation

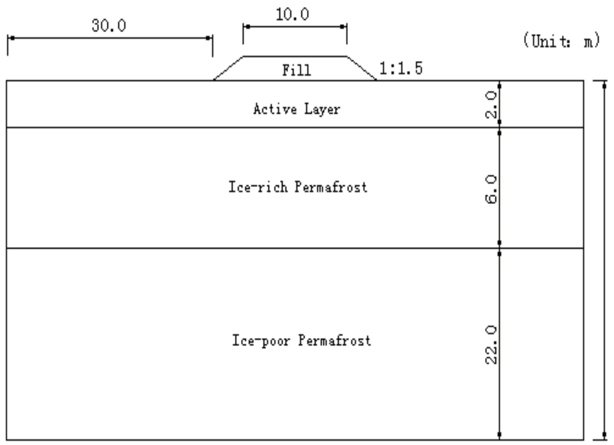

Figure 11. Permafrost profile under the embankment.

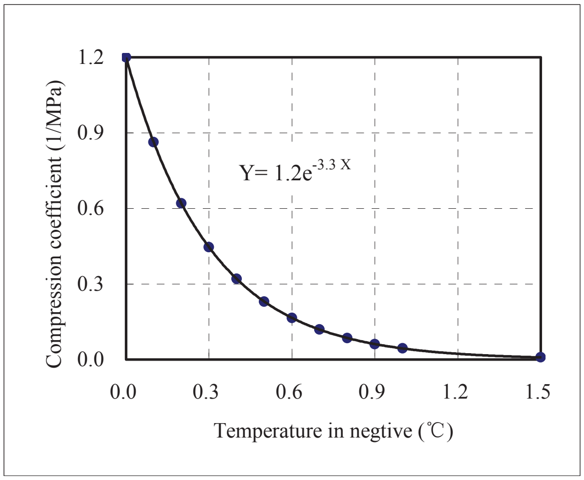

Figure 12. Relationship between compression coefficient of frozen soil and temperature.

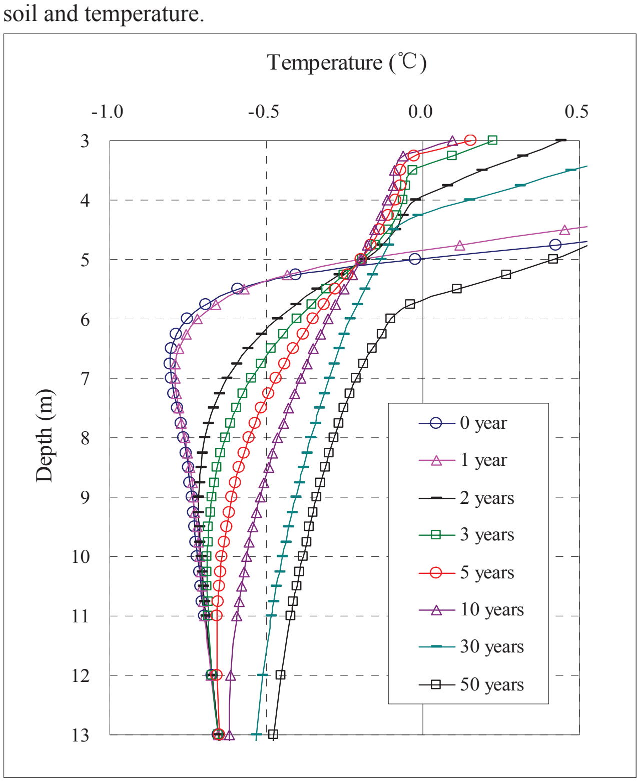

Figure 13. Prediction of the ground temperature under embankment (embankment thickness: 3 m, MAGT: -0.5°C).

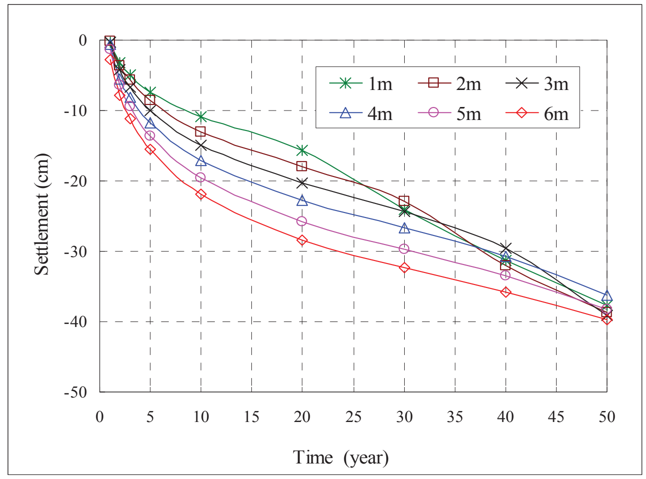

Figure 14. Estimate of the subgrade settlement process (embankment thickness: 1~6m, MAGT: -0.5°C).

due to the temperature rise in the subgrade, even though the permafrost table under the embankment moves up after the railway is built. The estimate of the subgrade settlement indicates that the settlement increases with the increase in embankment thickness and ground temperature. Therefore, if this kind of deformation is to be controlled, active cooling measures must be taken to lower the ground temperature in the subgrade. The traditional method of increasing the embankment thickness is ineffective and even worse for the stability of the railway subgrade in the warm and ice-rich permafrost regions.

Abstract

The Qinghai-Tibet Highway is a significant engineering structure built in the permafrost regions of China. When the highway was initially constructed in the 1950s and permafrost was encountered, the road embankment was just paved with the nearby materials. Since the 1970s, the highway has been rebuilt or repaired on a large scale three times, mainly to treat problems caused by the permafrost. Along with continuous repairing activities, research work was carried out three times, focusing on embankment stability and permafrost status. In the first research work before 1979, the main factor considered in the embankment height designing was the buried depth of the local permafrost table. In the second research work during 1979–1985, when it was paved with asphalt, the embankment height was increased and a permafrost-protecting principle was adopted. In the third research work after 1985, roadbed problems along the whole length were investigated. The investigation showed that 152 km of the highway were damaged by settlement. To avoid future thaw settlement, comprehensive remedy methods were applied to actively protect the permafrost and, subsequently, the roadway.

Keywords: designing principle; embankment height; permafrost; roadbed; Qinghai-Tibet Highway.

Introduction

The total length of the Qinghai-Tibet Highway (QTH) is 1937 km from Xi'ning of the Qinghai province to Lhasa of the Tibet Autonomous Region. The length of the section from Golmud to Lhasa, which is a second-class highway, is 1150 km. The highway is very important, as more than 85% of materials and more than 95% of passengers to Tibet were transported this way since 1954. The highway crosses a permafrost area with a length of more than 630 km from Xidatan Valley to Andou County (Fig. 1), where the average elevation is over 4500 m a.s.l.

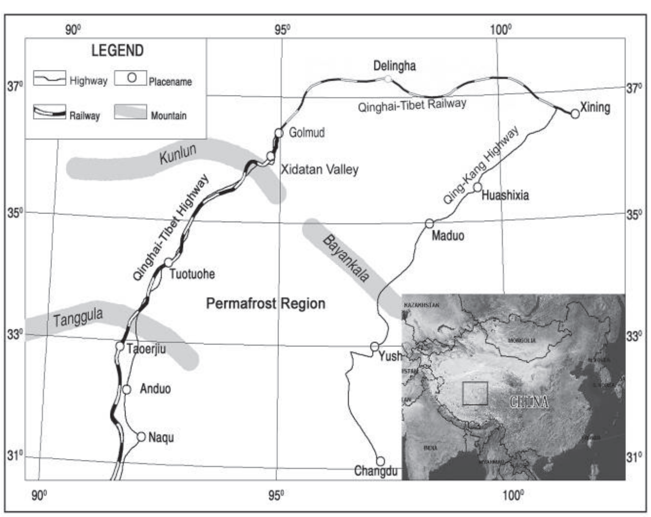

Figure 1. The location of the QTH and permafrost distribution in the Qinghai-Tibet Plateau.

The QTH was initially constructed in the 1950s, and then about 20 years later, an asphalt layer was paved on the surface. Since the 1990s, the highway has been rebuilt or repaired greatly three times, and research work has been carried out which focuses on the embankment design principle and height. Though some problems of the QTH have not been thoroughly solved so far, the average driving speed can be 60 to 100 km/h now. Such a speed is the highest value in the servicing history of the highway.

Embankment Height Designing of the QTH Before 1979

The QTH research group drafted an Asphalt Layer Construction Manual of the QTH in Permafrost Regions in October 1978. In the report, it was pointed out that there were more than 100 km of ice-saturated and massive-ice permafrost along the highway. As the underlying permafrost was not effectively treated during roadbed construction, some problems, including thaw slumping, roadbed deformation, and frost boiling, occurred when the road was opened to service. The problems were eliminated after repair and remedy over 20 years. However, it was pointed out that the heat balance would be destroyed again if the asphalt layer were paved. Also, new diseases would occur if the permafrost were not protected effectively. It was also pointed out that a filling-but-not-cutting principle should be followed in roadbed construction in permafrost regions, except in icy soil, ice-poor soil, and seasonally frozen ground sections. Embankments in ice-poor and icy soil regions may be designed without any special structure. The frozen ground should be properly protected in sections of ice-rich permafrost. Necessary measures were suggested to protect the underlying frozen ground in ice-saturated permafrost regions, and to strictly protect massive-ice permafrost regions. These prescripts indicated that the design principle during this period was to protect the permafrost in roadbed construction.

The results of the field experiments along the highway showed that the sandy surface lowered the permafrost table with a value of 15–25cm. The relation between embankment height (H) and the depth of permafrost table (h) was

$$h = 0.95H - 0.15 \tag{1}$$

However, the permafrost table lowered 25–30 cm under the black asphalt surface. Considering the different thermodynamic conditions of asphalt and gravel surface, suggestions on the embankment height were given as listed in Table 1, based on monitored results (QTH Research Group 1978).

According to Table 1, the maximum embankment height of QTH was less than 1.5 m. Based on the principle of protecting permafrost and suggestions on the embankment height, an embankment design scheme between Wudaoliang (mileage of K3007) and the Tanggula Mountain (mileage of K3350) was recommended. At the same time, it was confirmed that a black asphalt surface can be paved on the embankment in permafrost regions.

Embankment Height Designing of the QTH from 1979 to 1985

Since 1979, black road surface was mainly paved in permafrost regions where geological conditions were poor and frozen damage easily occurred. In order to ensure the quality of the project, the embankment height was suggested to be increased to protect the underlying frozen ground, based on engineering practice and observation. Some methods were proposed such as: (1) a principle of protecting frozen ground should be followed in permafrost regions; (2) embankment height should be increased to counteract the influence of black road surface, and two lateral sides should be protected too; (3) necessary embankment height should be determined,, keeping the permafrost table stable or a little lowered in regions where the frozen ground has low ice-content (lower than the ice-content in ice-rich soil), instead of keeping the roadbed totally frozen. To practice these methods, the permafrost along the way was classified into 4 classes. Two sets of embankment height value were suggested in 1980 and 1981 (QTH Research Group 1978, 1981). The values were listed in Tables 2 and 3.

Comparing the values listed in Tables 2 and 3, the embankment height was higher in 1980 and 1981 than that in 1978 and 1980. At same time, the embankment height values suggested in 1981 were higher up to 1.0 m than those in 1980. The embankment height values suggested in 1980 were based on considerations of frozen soil types and embankment soils. The values suggested in 1981 were based on considerations of frozen soil types, permafrost table, and topography. Therefore, the values of 1981 were increased in accord with protecting frozen soil and status of the QTH.

The repair design in this period was changed according to the suggested height values in 1980. Then part of the embankment was repaired considering investment capacity and building time.

Along with progress of research work on the QTH, some other suggestions were proposed, such as the filling soils could be cut from the nearby ground as it was lack of sand and stone materials along the highway, but it was strictly

Table 1. Suggested embankment height in different permafrost regions (unit: m).

Permafrost	Embankment soil		
	Silty clay and clay	Sand and sandy soil	Gravel soil
Ice-rich soil	0.5- 0.8	0.5 - 0.8	0.5 - 0.8
Ice-saturated soil	0.8 - 1.0	0.8 - 1.1	0.8 - 1.2
Massive ground-ice	1.0 - 1.2	1.1 - 1.3	1.2 - 1.4

Table 2. The suggested minimum embankment height for protecting the underlying permafrost in 1980 (unit: m)

Permafrost	Embankment soil		
	Silty clay and clay	Sand and sandy soil	Gravel soil
Ice-rich soil	0.8- 1.0	0.9 - 1.1	1.0 - 1.2
Ice-saturated soil	0.9 - 1.2	1.0 - 1.3	1.2 - 1.5
Massive ground-ice	1.1 - 1.4	1.2 - 1.5	1.3 - 1.7

Table 3. The suggested minimum embankment height for protecting the underlying permafrost in 1981 (unit: m).

Permafrost	Depth of the natural permafrost table /m	Critical height H_0 /m	Design height /m	Topography
Icy soil	>2.5	1.0	（0.6~0.7）H_0	Valley zone
Ice-rich soil	2.0- 2.5	1.0 - 1.3	H_0	High plateau regions
Ice-saturated soil	1.6 - 2.0	1.3 - 1.6	(1.1 - 1.2) H_0	High plateau and river terrace
Massive ground-ice	>1.2~≤1.8	1.4 - 1.8	(1.2 - 1.3) H_0	Mountain regions
Massive ground-ice	≤1.2	>1.8 - 2.0	(1.2 - 1.3) H_0	Frozen peat soil island

restricted to excavating filling materials within 10 m away from the road slope toe. According to different engineering geological conditions, permafrost along the highway was classified into five types: ice-poor soil, icy soil, ice-rich soil, ice-saturated soil, and massive ground-ice. In determining an embankment height designing formula suggested in this period, deformation compressed by seasonal thawing layer and traffic loads were also considered. The calculating method was given as the formula below, and the relevant parameters were listed in Table 4, 5, and 6 (Yu & Wu 1986).

$$H_d = mH_c + S \tag{2}$$

where H_d is the designed embankment height and H_c is the critical minimal height; m is corrected comprehensive coefficient. It is determined by frozen soil type, the permafrost table, and water-containing status of seasonal thawing layers, and its values are suggested in Table 4. The value is suggested to adopt the higher one when the buried depth of the permafrost table is shallow and the ground-ice is rich; contrarily, it is suggested to adopt the lower one.

S is the compressed deformation value of the seasonal thawing layers and is determined with the formula below.

In the maximum thawing season:

$$s = \sum_{1}^{n} a_{0i}\delta_{0i} \tag{3}$$

During the freezing period:

$$s = \sum_{1}^{N} A_{0i}h_i + \sum_{1}^{N} a_{0i}\delta_{0i}h_i \tag{4}$$

where N is the number of seasonal thawing layers above the embankment bottom; h_i is the thickness of the i layer; δ_{0i} is the average total stress of i layer, which equals to average appending stress and weight stress; A_{0i} and a_{0i} is thawing subsidence coefficient and frost-heave coefficient of i layer correspondingly. The values of A_{0i} and a_{0i} were listed in Table 5 and 6.

The embankment design principle and embankment height suggested in 1985 were reasonable at that time; however, it was not widely applied as asphalt-paving work was finished in 1985. It was only used in the embankment repair in a section from the Kulun Mountains (mileage of K2898) to Wudaoliang (mileage of K3007) in 1986.

Embankment Height Designing of the QTH after the 1990s

The QTH crosses 630 km of permafrost region, of which 83.6% is continuous permafrost and 16.4% is island permafrost. Engineering geology conditions of frozen soil along the highway are complex and variable, as they are controlled by many factors. On one hand, the air temperature in the Qinghai-Tibet Plateau gradually increased from 1962 to 1999 with a value of 0.02–0.03ºC/a during wintertime. The value changed to 0.01–0.02ºC/a during summertime

(Wei et al. 2003). On the other hand, the permafrost was in degradation, influenced by global warming (Wu et al. 2000, 2003). Especially as the black road surface absorbed radiation energy, the situation of the underlying frozen ground was worsening and resulted in new problems. According to statistical data in 1990, the total length of damaged section caused by thawing deformation was 152 km, which was 24% of the total length in the permafrost region. Aiming at solving the problems, the Ministry of Communication approved the First Repair Project Plan to repair the 339 km section of the QTH with serious problems. The designed embankment height in the project still followed the principle of protecting permafrost. It was designed following the principle that the settlement caused by lowering of the permafrost table should be less than the maximum displacement of the road surface in servicing life of the asphalt pavement. The embankment height was increased 30 cm based on formula (2), considering global warming influences on permafrost, so to avoid new damages. During the repair, the neighboring environment was required to be recovered. The suggested embankment height values were listed in Table 7 during the time.

In the first repair project, a longitudinal crack with a width of 15–20 cm and a length of 300 m appeared in the embankment of a section from mileage K3403 to K3409, north to Anduo in winter, 1993. Longitudinal cracks with a width of 15–25 cm and a length of 500 m also appeared in sections of K2932–K2935 and K2947–K2951 in winter, 1995. The total length of the highway damaged by longitudinal cracking was up to 14 km according to an investigation in April 1997. It was found that more than 80% of longitudinal

Frozen soil type	Icy soil	Ice-rich soil	Ice-saturated soil	Massive ground-ice
Embankment height	1.5	1.8	2.2	2.6

Figure 2. Longitudinal cracks and settlement developed in the embankment of the QTH.

Figure 3. Crack damage of the concrete surface layer.

cracks along with settlement appeared in the sun-facing side of the embankment (Fig. 2). The embankments once seriously damaged on Kunlun Mountains Pass, Kekexili Mountains, Fenghuoshan and Tanggulashan Mountains Pass had less damage this time, while the embankments in Chuma'erhe Plateau, Beiluhe Basin, Wuli, Kaixinling to Tongtianhe and north of Anduo regions suffered more longitudinal cracking and subsidence deformation. Sections of these regions possessed more than 95% of the total length damaged by longitudinal crack. Based on analysis of ground temperature data of the QTH for many years, it was found that when the mean annual ground temperature (MAGT) was lower than -1.5ºC, the longitudinal cracking and embankment deformation were minor, while when the MAGT was higher than -1.5ºC, such problems were serious. This indicated that MAGT has a close relationship to the embankment problems. As the longitudinal crack problems were very serious, paving with a concrete surface layer was tested to see if it was able

Table 8. Height values of embankment with asphalt surface suggested in 1995 (unit: m).

Designing principle	Protecting frozen ground (low temperature district)			Controlling thawing rate(high temperature district)		
Frozen soil type	Icy soil	Ice-rich soil	Ice-saturated soil	Icy soil	Ice-rich soil	Ice-saturated soil
Embankment height	1.6 - 2.0	1.8 - 2.6	2.4 - 3.2	1.8 - 2.4	2.2 - 3.2	2.6 - 3.4

to resist crack damage. The tested results showed that such a surface could not solve the problem when the roadbed was not stable enough. The concrete layer was damaged seriously, too (Fig. 3). Therefore, the surface damages were mainly caused by deformation of the embankment.

The first repair project of the QTH was finished in 1995, and survey and design work for the second repair project was soon followed. In order to use index of ground temperature to evaluate the roadbed stability, researchers suggested -1.5ºC as the dividing value for classifying high-temperature permafrost (warm permafrost) and low-temperature permafrost (cold permafrost), considering the ground thermal regime along the highway. As the different temperature districts were divided, a new principle was proposed, as (Zhang 1996) protecting the frozen ground, controlling the thawing rate, and comprehensive treatment. In low-temperature permafrost regions, embankment designing should follow the principle of protecting the frozen ground. In high-temperature regions, it should follow the principle of controlling thawing rate. Comprehensive treatments can be used to avoid roadbed problems in poor geological condition sections. According to the principle, the minimal embankment height is given in Table 8. It was also suggested that on the basis of considering frozen soil type, geomorphology, and water conditions along the two sides, an additional embankment on the slopes be constructed 0.8–1.5 m in height and 2–3 m in width.

Maintaining and Repairing Project from 2002 to 2004

Construction of the Qinghai-Tibet Railway (QTR) started in 2001. This project was regarded as one of the four major projects in West China. The railway construction depended very much on the QTH to transport workers, materials, prefab concrete structures, machines, etc. This greatly increased traffic load on the highway. Though the highway was a second-class way, it was hard to support too much, as its main part was in permafrost regions. To ensure the railway construction, 12.2 billion Yuan were invested to carry out a large-scale repair project of the QTH from 2002 to 2004. According to research and statistics in 2001, embankments of the QTH with serious subsiding deformations and longitudinal cracks were mainly in warm and ice-rich permafrost regions. The total length of such sections was 60 km. The sections had never been reconstructed or repaired, and the embankment

Figure 4. Thermosyphone installed along the QTH to treat thawing settlement.

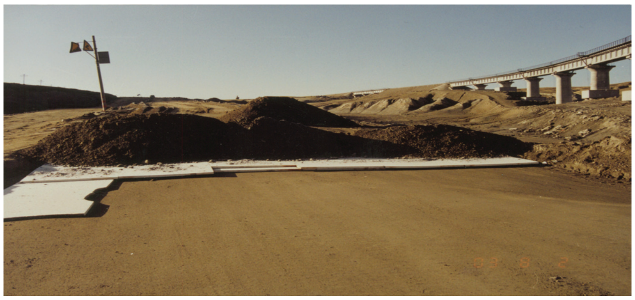

Figure 5. Insulation layer installed along the QTH to keep the underlying permafrost.

was somewhat high. High embankment might cause new problems, which mainly resulted from disturbance of the surrounding environment. The designing principles in this period included: (1) recovering the damaged permafrost environment of both sides of the road; (2) using artificial ground-freezing methods (such as thermosyphone, Fig. 4) and increasing heat resistance (such as using EPS, XPS material, Fig. 5) to treat the subsiding and cracking problems; (3) properly adjusting the roadbed according to actuality of embankment and bearing capacity of surface layer; (4) strengthening drainage structure. The route-change section was designed according to the recommended values for asphalt surface roads in 1995. Focusing on treating roadbed problems in warm and ice-rich permafrost regions, some field experimental research work was carried out at same time. The work included study on the genesis and mechanism of roadbed settlement and longitudinal cracks, and new construction methods for highways in permafrost regions and their engineering effects. The new methods included thermosyphone embankments, crushed-stone embankments, duct-ventilated embankments, and also thermal-insulated embankments. Some testing sites were constructed along the highway during the time. Among the testing sites, some of them were installed to study the reasonable embankment height along both the QTH and the Qinghai-Tibet Railway (QTR). In the Beiluhe region, several testing embankments with different height were studied (Cheng et al. 2004). The tested results showed that the minimum embankment height has a close relationship to the surface conditions of the roadway and the local mean annual air temperatures. The minimum embankment height needed to be increased when the mean annual air temperature was higher. There was no minimum embankment height effective unless the local

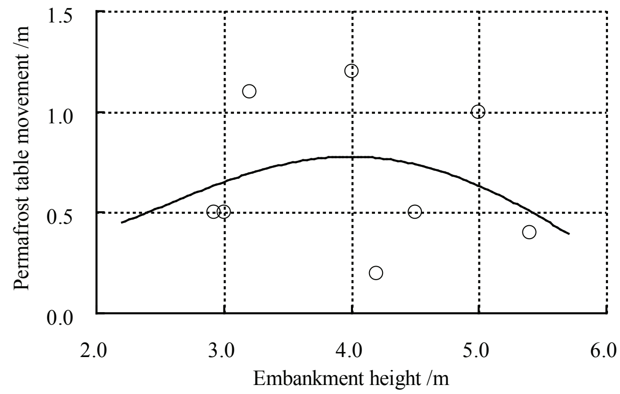

Figure 6. Relation of permafrost table movement with embankment height (Cheng et al. 2004).

mean annual air temperature was lower than a critical value (-3.8°C). That means no matter how high the embankment was, the permafrost table under the roadway would fall.

The tested results of relationship between the permafrost table movement and embankment height is drawn in Figure 6. The figure indicates that when the embankment rose to a certain range the permafrost table would drop but not rise. Therefore, the range of the applied height was a function of properties of the fill materials, the surface conditions, and the mean annual air temperatures.

Now after years of study, a comprehensive design principle for determining embankment height and protecting roadbed stability in permafrost regions is proposed. It suggests that in low-temperature regions, the permafrost is recommended to be protected. Some methods such as increasing the height, installing an insulation layer, or installing the side berm, can be applied. The height values may be referred to the data listed in Table 8. In high-temperature regions, the critical height values are not the controlling index of embankment design. Some methods, including crushed stone embankment, thermosyphone associatex with insulation layer embankment, duct-ventilated embankment, and land bridge, can be adopted. Certainly a minimal height of embankment to install the structures mentioned above is necessary.

Conclusions

(1) The Qinghai-Tibet Highway was constructed in the 1950s. Permafrost was not considered at that time, and roadbed problems were rooted thereby. After that, large-scale repair was carried out three times to maintain the roadbed stability. The embankment height was an important research content during the past, and it was suggested differently during different time.

(2) The suggested embankment height before 1979 was mainly based on considering the depth of the permafrost table, along with kinds of frozen ground and soil fill materials.

(3) The suggested embankment height value was increased from 1979 to 1985, as a permafrost-protecting principle, and the critical minimal height was proposed.

(4) The influences of global warming and ground temperature on roadbed stability were considered after the 1990s. District division of permafrost according to the ground temperature was applied, and different designing principles were proposed after that.

(5) In the last maintenance and repair projects of the highway from 2002 to 2004, the permafrost environment, new construction methods, and drainage systems were considered. The permafrost-protecting principle was confirmed. To realize the principle, some of the new methods were tested, and their effectiveness was evaluated. Now the Qinghai-Tibet Highway is in its best servicing status in history.

Modeling Long-Term Dynamics of Snow and Their Impacts on Permafrost in Canada

Yu Zhang and Wenjun Chen

Daniel W. Riseborough
Geological Survey of Canada, Natural Resources Canada, Ottawa, Canada

Abstract

Seasonal snow, controlled mainly by temperature and precipitation, has a significant impact on ground temperature; therefore, it is essential to integrate snow dynamics for assessing the impacts of climate change on permafrost. In this study, we simulated snow dynamics in a permafrost model over the years 1850–2100 in Canada at a spatial resolution of 0.5° latitude/longitude. We validated the results by comparing them with snow measurements at climate stations. This long-term spatial modeling shows that snow depth would be thinner in eastern and northern Canada, and the duration of snow cover would be shorter almost everywhere in Canada by the end of the 21st century, causing a 1°C–2°C warming of annual mean ground temperature compared to changes in the annual mean air temperature. That means the concurrent change in snow condition would reduce the amount of permafrost degradation in response to climate warming.

Keywords: climate change; ground temperature; model; permafrost; snow dynamics.

Introduction

Annual mean ground temperature near the surface at high latitudes is usually several degrees warmer than the annual mean air temperature due to the insulating effects of snow (Zhang 2005, Zhang et al. 2005, Goodrich 1982). Changes in air temperature and precipitation would directly alter snow dynamics through changes in snowfall, snow density, and snowmelt. Therefore, it is essential to integrate snow dynamics in assessing the impacts of climate change on ground temperature and permafrost.

Some of the permafrost modeling studies used measured snow-depth or snow-water equivalent (SWE) as input. However, field, satellite, and climate station data are usually limited in temporal and spatial coverage, especially for observations of snow density, which is critical for quantifying the insulating properties of snow. Therefore, modeling the dynamics of snow is essential for assessing the impacts of climate change on permafrost and for other applications, such as estimating the feedbacks of snow on climate system, assessing avalanche risks, quantifying flooding and other hydrological processes, and modeling ecosystems and soil biogeochemistry.

Snow models can be categorized based on the purpose for which the models are developed. Models for snow avalanche risks consider the details of the mechanical features of snowpack and their changes (e.g., Bartelt & Lehning 2002); models for the impacts of snow on hydrology and flooding pay more attention to the spatial distribution of the total SWE and the rate of snowmelt; models for the impacts of snow on ground temperature and permafrost are concerned primarily with the thermal effects of the snow, while snow models for climate systems consider the thermal and hydrological effects of snow and the effects on surface energy processes, especially albedo. Tempo-spatial scales also vary significantly depending on the models' purposes.

Although it is recognized that snow cover has significant effects on ground temperature and permafrost, few permafrost models integrate snow dynamics. The major challenges include the following: (1) The model should have the capacity to simulate the dynamics of snow depth and snow density, since both are important for the thermal effects of snow on the ground. (2) The response of permafrost to climate change could take centuries; therefore, long-term climate data are needed to drive the models. (3) Detailed climate station data usually have limited spatial coverage. Monthly data are usually the only available historical climate datasets with long-term and spatial coverage.

Recently, we developed a process-based model—NEST, a model for northern ecosystem soil temperature—to quantify the impacts of climate change on permafrost, including the concurrent changes of snow (Zhang et al. 2003). Monthly climate data were down-scaled to run the model over the years 1850-–2100 in Canada at a spatial resolution of 0.5° latitude/ longitude (Chen et al. 2003, Zhang et al. 2006). In this paper, we describe the procedures and validation of the snow sub-model, and then analyze the simulated long-term patterns of snow dynamics in Canada and the effects on ground temperature and permafrost. The simulated distribution and changes in soil temperature and permafrost conditions have been presented in other papers (Chen et al. 2003, Zhang et al. 2005, 2006, 2008a, b).

Methods and Data

The NEST model

The NEST model was developed to simulate the transient response of ground thermal regime to climate change. It explicitly considered the effects of different ground

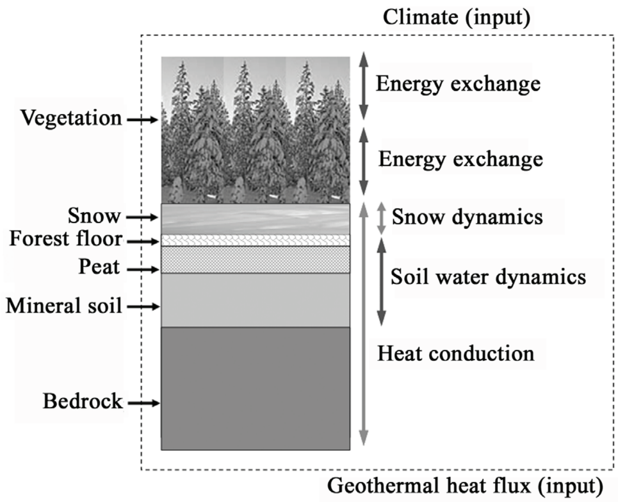

Figure 1. The components and processes considered in the NEST model (Zhang et al. 2003, 2008a)

conditions, including vegetation, snow, forest floor or moss layers, peat layers, mineral soils, and bedrock (Fig. 1). The dynamics of the ground temperature were simulated by solving the one-dimensional heat conduction equation. The upper boundary conditions (the ground surface or snow surface when snow is present) were determined based on the energy balance, and the lower boundary conditions (at a depth of 120 m) were defined based on the geothermal heat flux. The ground profile was divided into 63 layers with the thickness of the layers increased gradually from 0.1 m for top layers to 4.8 m close to the lower boundary. Soil water dynamics, including phase change, were simulated, and their effects on energy balance and on soil thermal properties were considered as well. A detailed description of the model and its validation were provided by Zhang et al. (2003).

The snow sub-model

The dynamics of snow were integrated in the NEST model. The thickness of the snow was determined based on snow density and the amount of snow (in SWE) on the ground, calculated as the cumulative difference between snowfall and snowmelt. Daily snowfall was determined by precipitation and air temperature (discussed below), and the density of fresh snow was estimated using air temperature. Snowmelt was determined based on the available energy calculated from the energy balance on the surface. The snowpack was divided into layers of about 0.1 m in thickness. The profile of snow density and its change with time were simulated considering compaction and destructive metamorphism, following Kongoli & Bland (2000). The equations and the calculation procedures were described by Zhang et al. (2003). Since the spatial resolution of this study (0.5° latitude/longitude) was much coarser than the fetch scale of blowing snow, wind effects on snow redistribution were not considered in this study.

Precipitation was designated as rainfall or snowfall based on air temperature. Measurements from climate stations in Canada show that snowfall occurs over a range of air temperatures around 0°C, and the range differs from place to place. Rather than defining a constant critical air temperature, we used a probability distribution function, similar to the approach of Riseborough and Smith (1993), to designate precipitation as rainfall or snowfall

$$P_s = 1 - 1/\{1 + \exp[-k(T_a - T_0)]\} \quad (1)$$

where P_s is the probability of precipitation as snowfall in a day. T_a is daily mean air temperature (°C), k is a parameter determining the slope of the frequency changing with air temperature around 0°C, and T_0 is the temperature at which rainfall and snowfall are equally likely. We selected 37 climate stations across the whole Canada landmass and determined the parameters k and T_0 for each station using historical daily measurements of temperature and the fractions of rainfall and snowfalls. Except for one station on the west coast, k was closely correlated with mean annual vapor pressure (V in mb), and T_0 was correlated with the total precipitation from October to December (P in mm)

$$k = -0.0517V + 0.7605 \qquad (r=0.78, n=36) \quad (2)$$

$$T_0 = -0.0135P + 2.2928 \qquad (r=0.74, n=36) \quad (3)$$

V and P were calculated as long-term averages. The above statistical relationships are probably related to the regional climate conditions and weather systems (e.g., wet and mild southeast Canada frequently has rainfalls when air temperature is below 0°C, while the Prairies, Yukon, and high Arctic frequently have snowfalls when air temperature is above 0°C. T_0 is also related to annual total precipitation ($r = 0.66$, $n = 36$) but not as significant as for the precipitation from October to December). Equations 2 and 3 were used for each grid except for the west coast region, where k and T_0 were assigned according to the station data (k = 0.8, T_0 = 0.7). For each day with precipitation, a random number from 0 to 1 was generated. If this number was smaller than P_s calculated based on the daily air temperature, the precipitation was assigned as snowfall, otherwise the precipitation was assigned as rainfall (We did not consider the cases with mixed rainfall or snowfall in a day, since such cases are relatively few).

Data

Inputs to the model include information about vegetation (land cover types, leaf area index), ground conditions (thickness of organic layers, texture of the mineral soils, soil organic carbon content in mineral soils, ground ice content, and the geothermal heat flux) and atmospheric climate (air temperature, precipitation, solar radiation, vapor pressure, and wind speed). Climate data from 1901 to 2002 were from Mitchell and Jones (2005). Six climate scenarios were selected for the 21st century, generated by six general circulation models (GCMs): NCAR, CGCM, CSIROM, GFDL, HadCM, and ECHAM. These six scenarios covered most of the possible range of GCM projected scenarios for Canada (Zhang et al. 2008b). A

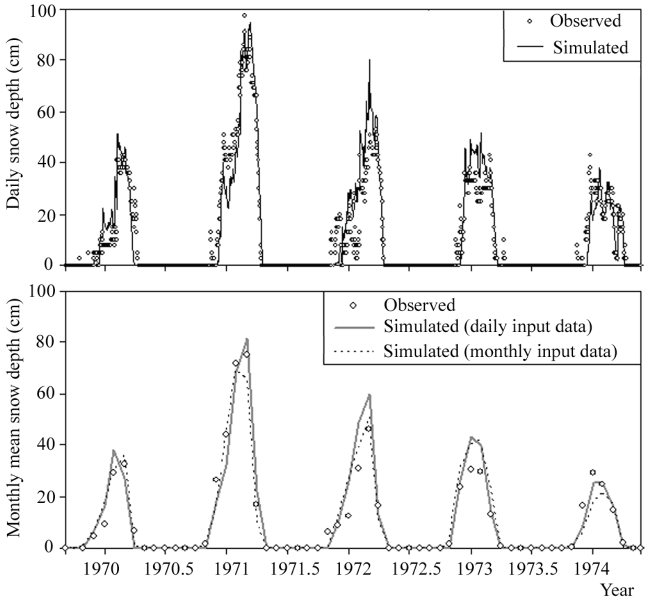

Figure 2. Comparisons between the measured and simulated snow depth at Ottawa climate station. a) comparing daily snow depth between the measured (circles) and the simulated (curves) using daily climate data as input. b) comparing monthly mean snow depth between the measured (circles) and the simulated using daily climate data as input (gray curves) and using month climate data as input (dash curves).

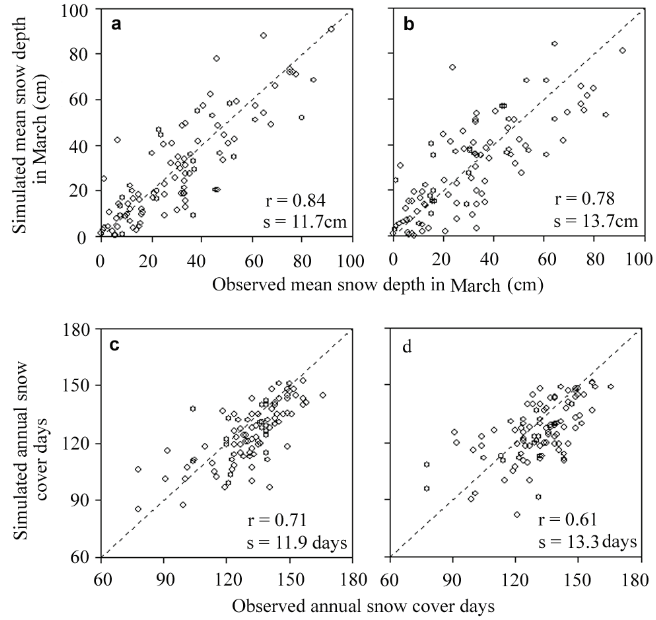

Figure 3. Comparisons between the simulated and the measured mean snow depth in March (a and b) and snow-cover days in a year (c and d) for Ottawa climate station from 1901 to 1999. The left panels (a and c) were simulated using daily climate data as input, and the right panels (b and d) were simulated using monthly climate data as input. *r* is correlation coefficient, and *s* is standard deviation.

detailed description of the vegetation and ground input data were provided by Zhang et al. (2006, 2008b). Several studies indicate that the current climate warming in Canada began largely from the end of the Little Ice Age (circa 1850) (Overpeck et al. 1997). Therefore, we initialized the model in 1850 assuming the ground thermal regime was in equilibrium with the atmospheric climate. We then simulated continuously from 1850 to 2002, and then from 2002 to 2100 under six climate change scenarios. Climate for 1850–1900 was extrapolated linearly from the data during 1901–1990. During the simulation, the monthly climate data were down-scaled to half-hourly to accommodate the short time-step requirement of the NEST model (Chen et al. 2003).

We validated the model using measured snow depth at climate stations. First, we validated the model by comparing measured daily snow depth with the simulated using daily climate data as input. We then ran the model using monthly climate data as input (derived from the daily observations and then down-scaled to half hourly in the model) and compared the simulated monthly snow depth with the observations. We selected the Ottawa climate station (45.4°N, 75.7°W) since this station has a long and continuous record of snow depth and other climate variables. Finally, we compared the nationwide simulation results with observations at 1670 climate stations which have at least 20 years of measurements. The daily and monthly climate station data were from Environment Canada (1999, 2000).

Result and Analysis

Comparing with measurements

Using daily climate data as input, the model was able to capture the observed patterns of snow-depth variation (Fig. 2a). The major difference was usually caused by the errors in defining precipitation as rainfall or snowfall. For dates on which daily measurements of snow depth were available from the snow database (Jan. 1, 1961, to Dec. 31, 1999; only monthly data were available in the database before 1961), the correlation coefficient between measured and simulated daily snow depth was 0.88 (n = 14149, standard deviation was 5.7 cm). A similar positive validation was presented for the Whitehorse climate station (60.9°N, 135.7°W) and for two boreal forest sites in Canada (Zhang et al. 2003).

Snow usually reaches the maximum depth in March in most of Canada. Figure 3a shows a comparison between measured and simulated mean snow depth in March using daily climate data as input (data from 1901 to 1999). It shows that the model can well capture the long-term variation patterns. Figure 3c shows a comparison between observed and simulated snow-cover days (days with snow depth >0 cm) in a year using daily climate data as input.

Using monthly climate data as input, the model could still capture seasonal patterns of snow dynamics (Fig. 2b). Monthly mean snow depths simulated using monthly and daily climate data as inputs were similar, and both are comparable to the observed monthly mean snow depth. The model could also capture the long-term (from 1901 to 1999) pattern of the snow depth in March using monthly data as

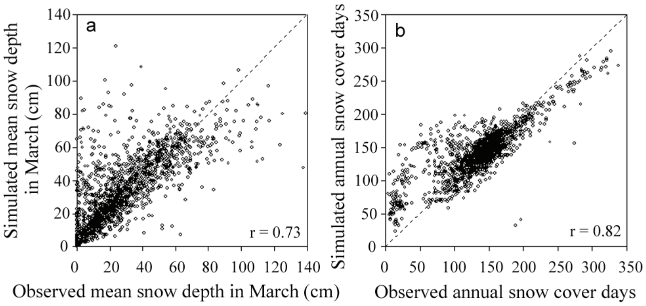

Figure 4. Comparisons between the simulated and observed mean snow depth in March (a) and mean annual snow-cover days (b) for 1670 climate stations in Canada. Each dot represents a climate station comparing between the observed and the simulated using the grid climate coving this station. The data for each station were averaged for all the observational years.

input (Fig. 3b), although the modeling skill was less than using daily climate data as input. Similarly, the simulated annual snow-cover duration and its long-term change using monthly climate data as input were also comparable with the measurements, although the relationship was not as good as when using daily climate data as input (Fig. 3d).

Figure 4 compares simulated and measured mean snow depth in March and the annual snow-cover days (averaged for all years with measurements) at about 1670 climate stations across Canada. The simulation was conducted using gridded monthly climate data as input. These results show that the simulated spatial distributions of snow-depth and snow-cover days were generally comparable with station measurements, although there were differences for some stations, especially in the province of British Columbia, where the terrain is complex and mountainous. This is mainly due to the differences between station and grid climate data. Local conditions could have significant effects on precipitation and snow conditions, while the model results were for average conditions in grid cells.

Changes in snow conditions in Canada over 1850-–2100

Figure 5 shows the spatial distributions of changes in mean snow depth in March and annual snow-cover days from the 1850s to the 1990s and from the 1850s to the 2090s simulated using the HadCM and CSIROM scenarios, in which the simulated difference between changes in soil and air temperatures were smallest and biggest, respectively (and the simulated snow conditions are near the extremes of the six GCMs). Snow depth in northern and eastern Canada would be thinner by the end of the 21st century, while becoming thicker in some regions in the western and southwestern regions. The annual snow-cover duration would be shorter almost everywhere in Canada by the end of the 21st century. On average for the major permafrost regions of Canada (latitude higher than 55°N), the mean snow depth in March shows a general decline over 1850–2100. The annual snow-cover duration shows a more consistent decline, with a more significant reduction during the 21st century (Fig. 6). These changes in thickness and duration of snow cover would affect the soil thermal conditions and permafrost.

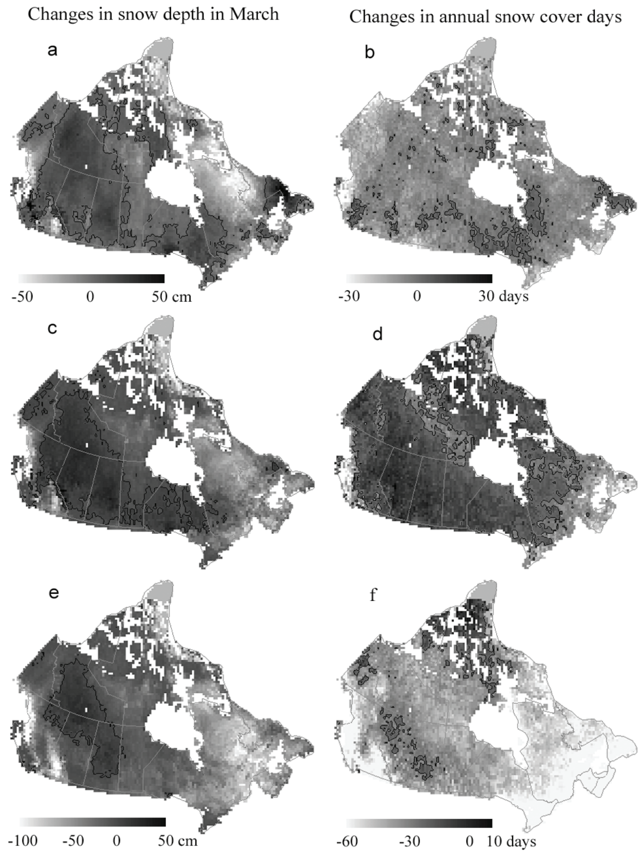

Figure 5. Simulated spatial distributions of changes in mean snow depth in March (the left panels) and annual snow-cover days (the right panels) from the 1850s to the 1990s (a, b), and from the 1850s to the 2090s (c–f) simulated using the scenarios of HadCM (c, d) and CSIROM (e, f). The uniform grey area at the top is glacier, which was not simulated.

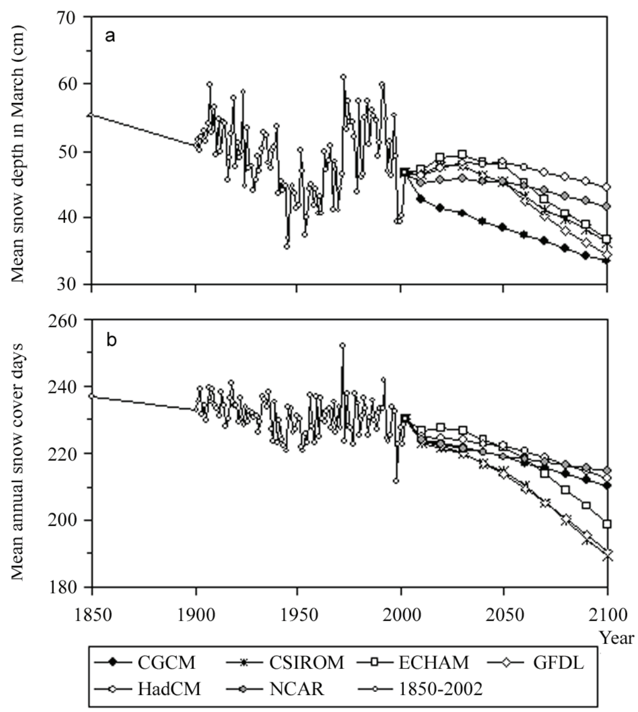

Figure 6. Simulated changes in mean snow depth in March and mean snow-cover days in a year in Canada with latitude higher than 55°N.

Effects of snow change on soil temperature and permafrost

Annual mean soil temperature near the ground surface generally responded strongly to the changes in air temperature, but they were not exactly in parallel. From 1850 to 2100, the rate of the increase in soil temperature near the ground surface was 1°C–2°C smaller than that of the air temperature, and the difference mainly occurred during the 21st century when warming was more significant (Figs. 7a, 7b).

Rates of change in air and soil temperatures were not significantly different in the summer months (Figs. 7c, 7d). The difference mainly occurred in winter months, with a much smaller increase in soil temperature than in air temperature (Figs. 7e, 7f), due mainly to the changes in snow conditions (snow depth and annual snow-cover days). As a result, the amount and the rate of permafrost degradation would be smaller than the estimates based on air temperature alone, although the influence of this seasonal differentiation would have little effect on the summer thaw depth. As for the possible effects on the southern boundary of permafrost under equilibrium conditions, a difference of 1°C–2°C in annual mean temperature is equivalent to about 100–200 km distance in latitudinal direction (the typical latitudinal air temperature gradient in Canada is about 0.01°C/km).

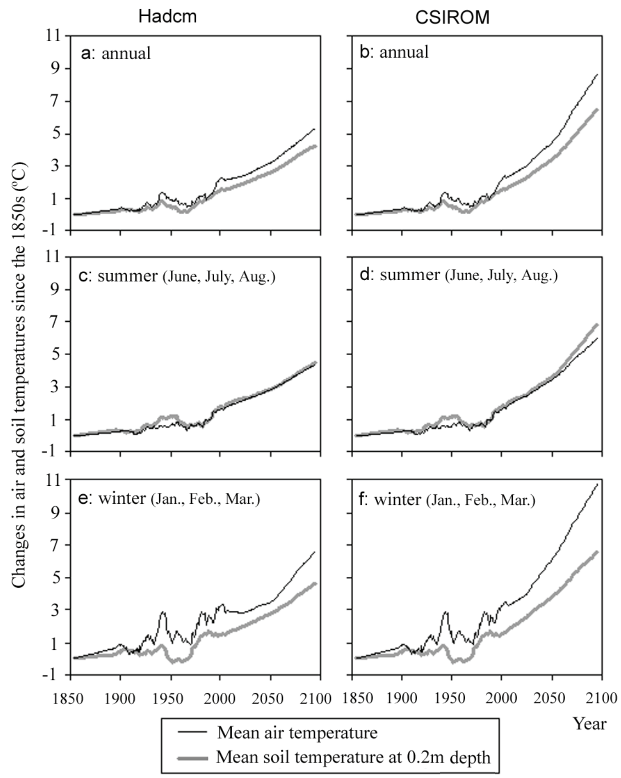

Figure 7. Changes in mean air and soil temperatures since the 1850s in Canada with latitude higher than 55°N. The values are calculated as 10-year running averages minus the averages in the 1850s.

Discussion

Climate station measurements in Canada from 1946 to 1995 show that snow cover and snow depth in spring are decreasing, especially in March (Brown & Braaten 1998). Earlier ablation of snow in spring would mean shorter annual snow-cover duration, which is in agreement with the simulated trend of this study. A shorter snow season was also simulated by GCMs for the 21st century (Räisänen 2007). The simulated decrease pattern of snow depth during the 21st century is generally consistent with GCM projections reported by Christensen et al. (2007). Räisänen (2007) found that SWE generally increases in coldest areas but decreases in other places during the 21st century, with the -20°C isotherm broadly defining the borderline. Our results show a more complex pattern in Canada, with a reduction in northern and eastern regions. The simulated changes in snow-cover days were stronger and more consistent than the simulated changes in snow depth during the 21st century, probably because the former is more dependent on temperature, while the latter is more directly affected by precipitation, which was projected to increase in most high latitudes during the 21st century. Statistical analysis also shows that temperature variations and trends play a significant role in variability and trends of snow-cover area in the Northern Hemisphere in the 20th century (Lemke et al. 2007). Our simulation shows that average snow-cover days in a year could be reduced by 13 to 37 days during the 21st century, which is comparable to the projected increase of 20–50 days in growing season length in the high latitudes (Wrona et al. 2005).

Field measurements and modeling studies have shown that the mean annual soil temperature near the ground surface can be several degrees warmer than the mean annual air temperature in permafrost regions, mainly due to snow-cover, which could last for about half of a year in these cold regions (Goodrich 1982, Zhang, 2005, Zhang et al. 2005). Reduction in the depth and duration of snow cover would reduce the insulating effects of snow, thereby reducing the difference between the annual means of soil and air temperatures. In other words, the increase in annual mean soil temperature in these cold regions would be smaller than that of the air temperature with climate warming (Zhang et al. 2005). On average for all the landmass of Canada with latitudes higher than 55°N, the mean annual soil temperature in the 1850s was about 3°C warmer than the annual mean air temperature. With a 1°C–2°C smaller increase in annual mean ground temperature than the air temperature over 1850–2100, the annual mean ground temperature on average for Canada would be only 1°C–2°C warmer than the annual mean air temperature by the end of the 21st century.

We used the general patterns of climate scenarios without considering the interannual variations for the 21st century. The large fluctuation during 1901–2002, when observations were available, shows that the actual variation pattern of snow depth in the 21st century could be different from the simulated general patterns because of the year by year fluctuations of climate. In addition, climate stations are sparser and the years of observations shorter in higher latitudes. This would induce errors in input data and the simulation results. In the current model, we did not consider snow drift by wind and the changes in vegetation conditions from year to year. For a more realistic simulation, especially at fine spatial resolutions, these features will need to be considered.

Conclusions

This study shows that it is necessary and possible to integrate the dynamics of snow when simulating the long-term impacts of climate warming on ground thermal regimes and permafrost. Comparisons with climate station measurements showed that the model not only could simulate snow dynamics using daily climate data as input, but also captured the seasonal patterns and long-term changes of snow using monthly climate data. Driven by monthly grid climate data, the simulated spatial distribution of snow in Canada was comparable with the measurements at climate stations.

This long-term simulation shows that snow depth would be thinner in northern and eastern Canada and annual snow-cover duration would be shorter almost everywhere in Canada by the end of the 21st century. These decreasing trends in snow-cover days and in snow depth were mainly due to the increase in air temperature. The simulated increase in annual mean ground temperature was 1°C–2°C less than that of the annual mean air temperature, due mainly to the concurrent change in snow conditions. This study shows that the interaction between air temperature and snow conditions would reduce permafrost degradation by a noticeable amount in response to climate warming.

Abstract

Recent progress in research about permafrost changes induced by climatic warming in Central Asia is summarized in this paper. Most permafrost in Central Asia is located on the Qinghai-Tibet Plateau in China, the Tien Shan Mountain regions in China, Kazakhstan, and Kyrgyzstan, Pamir and mountain regions in Tajikistan and Mongolia. Monitoring of the permafrost thermal regime has been carried out in all these regions in the past several decades. Accompanying climate warming, the thermal regime of permafrost changed greatly in all the permafrost regions in central Asia. Permafrost in the Tibetan Plateau is widespread, and occupies about 1.5 million square kilometers. In the continuous permafrost regions on the plateau, the annual mean temperature has risen by 0.1–0.2°C, while in the discontinuous permafrost regions the annual mean temperature has risen by 0.2–0.5°C from 1995 to 2002. The thickness of the active layer has increased by 0.15 to 0.50 m between 1996 and 2001 and residual thaw layers recently. The average rate of increase in mean annual permafrost temperatures is from 0.2°C to 0.4°C per decade in Hovsgol Mountains of Mongolia. Permafrost has been degrading more intensively during the last 15 years (since 1990s) than during the previous 15–20 years (1970s and 1980s). Permafrost occupies about 0.16 million square kilometers in the Tien Shan Mountain regions. Geothermal observations during the last 30 yr indicate an increase in permafrost temperatures from 0.3°C up to 0.6°C. During the same period, average active-layer thickness increased by 23% in comparison to the early 1970s.

Introduction

The most recent report of the Intergovernmental Panel on Climate Change (IPCC) provided a comprehensive assessment of the climatic changes that have occurred during the last 100 years. The report indicated that the global average surface temperature has increased dramatically, especially since about 1950 (IPCC 2007). Permafrost was identified as one of the key indicators of climate change (WMO 1997). Permafrost measurements are particularly important for determining the long-term terrestrial responses to surface climate change. Climate warming during the 20th century has a great influence on the contemporary thermal state of permafrost. Recent changes in permafrost conditions related to climate warming have been documented in Alaska, Canada, Europe, Siberia, and the high mountains of Central Asia (Jorgenson et al. 2001, Walker 2007, Osterkamp 2007, Camill 2005, Isaksen et al. 2007, Oberman & Mazhitova 2001, Cheng & Wu 2007, Marchenko et al. 2007, Sharkhuu et al. 2007).

Changes in the permafrost thermal regime can have significant impacts on local hydrology, land surface energy and moisture balances, carbon exchange between the land and the atmosphere, and ecosystems, as well as engineering infrastructure in cold regions (Cheng & Zhao 2000, Nelson et al. 2001, Zhang et al. 2005, Zimov et al. 2006a, b). It is, therefore, of great importance to study the permafrost dynamics of past decades. This paper summarizes recent response of permafrost to climatic changes in Central Asian regions, primarily on the Qinghai-Tibet Plateau, the mountain permafrost regions of Mongolia, and in the Tien Shan Mountains.

Study Region and Methods

The Central Asian region is the largest area underlain by alpine permafrost in the world, and includes the territories of southern Siberia, Mongolia, China, Kazakhstan, and adjacent countries (Fig. 1) (Brown et al. 2001). The mountain permafrost area of Central Asia is estimated to be 3.5×10^6 km^2, about 15% of the total areal extent of permafrost in the Northern Hemisphere (UNEP/GRID-Arendal 2007). Under climatic warming and increasing human activities in this region, the permafrost has been undergoing great changes. Here, we present a historical overview of recent permafrost investigations on the Qinghai-Tibet Plateau, Tien Shan Mountains, and Mongolia.

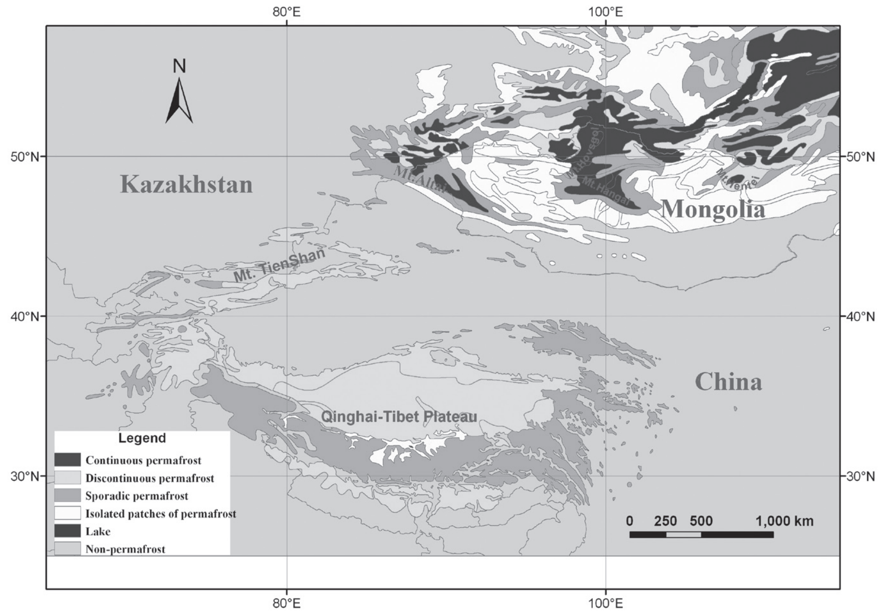

Figure 1. Permafrost distribution in the Central Asian regions (Brown et al. 2001).

Qinghai-Tibet Plateau in China

Systematic permafrost investigations on the Qinghai-Tibet Plateau began in 1954 when the Qinghai-Tibet Highway from Golmud to Lhasa was paved. In the early 1960s, intensive field investigations were conducted along the Qinghai-Tibet Highway to assess geological engineering conditions related to permafrost. Zhou and Du (1963) described permafrost characteristics, distribution, temperature, ground ice distribution, and related periglacial phenomena in detail along the highway. In 1974, a more systematic survey of permafrost was conducted by several research institutions and universities to solve the challenging problems involved in constructing a gas pipeline and the Qinghai-Tibet Railway in permafrost regions. After this survey, the work team summarized knowledge about permafrost distribution and characteristics, thermal and physical properties of frozen ground on the plateau, the thermal regime of permafrost and calculations related to permafrost, and the application of geophysical methods in permafrost studies (Tong & Li 1983). Permafrost on the Qinghai-Tibet Plateau was classified as predominantly continuous permafrost (continuity from 70% to 90%), widespread island permafrost (continuity from 30% to 70%), and sparse island permafrost (continuity less than 30%) (Zhou et al. 2000). During the 1980s, geocryologists and engineers made great progress involving the regularity of permafrost distribution, mechanisms of ground-ice formation, moisture and salt migration during the freezing and thawing process of frozen ground, and application of remote sensing techniques in periglacial geomorphic studies (Cheng 1982). After many field surveys and much analysis, the regularities of altitudinal, latitudinal, and continental mountain permafrost zonation based on the mean annual ground temperature (MAGT) of permafrost and mean annual air temperature (MAAT) were summarized and subsequently applied by the international permafrost community (Cheng and Wang 1982, Cheng and Dramis, 1992, King et al. 1992). In 1989, the Cryosphere Research Station on the Qinghai-Tibet Plateau was established in Golmud, Qinghai Province to perform long-term and continuous observations on permafrost temperatures and related climatic factors. To satisfy the needs for solving engineering problems in cold regions, further understanding the regularities of permafrost formation and evolution, and assessing the environmental significance of permafrost regions, the State Key Laboratory of Frozen Soil Engineering affiliated to Chinese Academy of Sciences was established in 1991. In the 1990s, permafrost studies on the plateau were improved to create a more detailed and comprehensive science that includes mapping of permafrost and seasonally frozen ground, conducting long-term programs of monitoring the thermal regime of permafrost and the active layer, exploring the thermal, physical and mechanical properties of frozen ground, investigating cold region hydrology and engineering, and especially assessing the impacts and feedbacks of permafrost degradation on engineering infrastructures, the climate system, and related aspects of the environment. Zhang (2005) summarized the historical development of permafrost studies from the 1950s to the present on the Qinghai-Tibet Plateau. A permafrost monitoring network along the Qinghai-Tibet Highway (Fig. 2) has been established, and includes 18 boreholes with depths from 20 to 127 m, 13 sets of active layer measurements systems, 4 automatic weather stations, and 2 eddy covariance systems to collect related data (Cheng & Wu 2007).

Mongolia

Permafrost regions occupy about two-thirds of the territory of Mongolia, predominantly in Altai, Hovsgol, Khangai, and Khentei mountainous regions, which are located in the southern reaches of the Siberian permafrost regions (Fig.

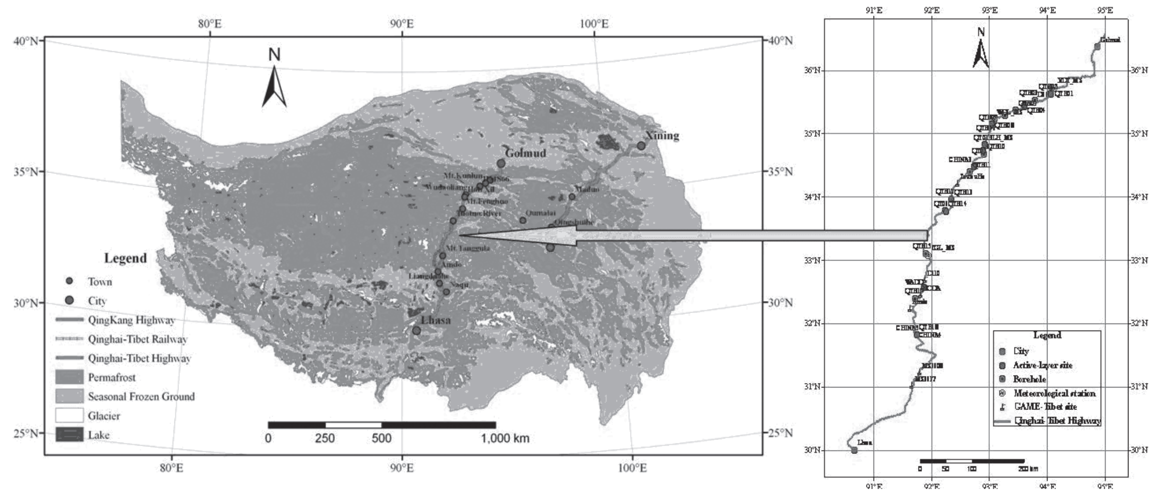

Figure 2. Permafrost monitoring network along the Qinghai-Tibet Highway.

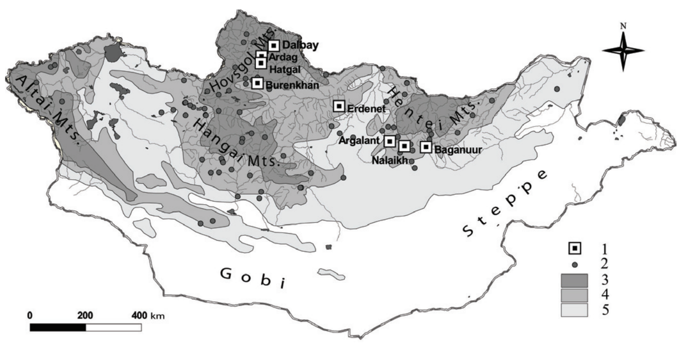

Figure 3. Permafrost distribution and the monitoring network in Mongolia (Sharkhuu et al. 2007).

3). Generally, permafrost temperatures in most regions of Mongolia are close to 0°C, and are thus very sensitive to climatic changes (Sharkhuu et al. 2006). In order to assess the responses of permafrost to recent climatic warming and human activities, Mongolian scientists began systematic observations of permafrost in 1996. The observation sites belong to the Circumpolar Active Layer Monitoring (CALM) and Global Terrestrial Network for Permafrost (GTN-P) programs. Furthermore, some cryogenic processes and phenomena are observed at different sites. Active layer depth and mean annual soil temperature at different levels are measured on the same dates of each year. Temperature data loggers and thaw tubes have been installed in some of the boreholes.

At present, there are fourteen sites for permafrost observations in Mongolia. Five of the sites are in Khentei (Baganuur, Nalaikh, Argalant, Terelj, and Gurvanturuu), two in Khangai (Terkh and Chuluut), six in Hovsgol (Sharga, Burenkhan, Hatgal, Ardag, Hovsgol Project, and Darhad), another site (Tsengel) is in the Altai mountains (Fig. 3). The depth of six boreholes ranges from 50 m to 80 m. So far, there are 37 boreholes belonging to the CALM network and the GTN-P program in Mongolia. Observations on periglacial processes, including thermokarst lakes, frost heaving, and icings, have been carried out seven sites in Hovsgol, Khangai, and Khentei mountains.

Tien Shan Mountains in Kazakhstan

The alpine permafrost region in the Tien Shan Mountains belongs to the Asian high-mountain permafrost area (Marchenko et al. 2007). It is estimated that permafrost in the Tien Shan Mountains formed about 1.6 million years ago due to its high elevation (Aubekerov and Gorbunov 1999). The permafrost in the Tien Shan Mountains has undergone repeated aggradation and degradation since the Holocene. Relict permafrost is found in many places in this region (Gorbunov 1996). Furthermore, mountain permafrost and associated periglacial landforms contain a large amount of ground ice. Moraines, rock glaciers, and other coarse blocky material have especially high ice content (40% to 90% by volume). Preliminary evaluation indicates that the total volume of ground ice is about 320 km^3 (Gorbunov and Ermolin 1981). Water derived from thawing permafrost could, therefore, become an important source of water for vegetation in this region.

The earliest reference to the occurrence of permafrost in the Tien Shan Mountains was in a Russian report in 1914 (Bezsonov 1914). Systematic investigations of mountain permafrost in the Tien Shan Mountains began in the mid-1950s (Gurbonov 1967, Gurbonov 1970). Traditionally, the alpine permafrost area of the Tien Shan Mountains is divided into altitudinal sub-zones of continuous, discontinuous, and sporadic permafrost (Gurbonov 1978, Gurbonov 1988). The earliest permafrost temperature measurements in the Northern Tien Shan began in 1973. Many methods have been used to observe permafrost temperatures, including measuring the active layer's thermal regime and thickness and spring water temperatures and DC resistivity soundings (Gurbonov & Nemov 1978, Zeng et al. 1993, Gorbunov et al. 1996). Permafrost investigations in the Inner Tien Shan were conducted from 1985 to 1992. Ground temperature measurements were conducted in 20 boreholes in the Ak-Shiyrak massif, and in more than 25 boreholes in the Kumtor valley. Thermistor sensors MMT-4 with a sensitivity 0.02°C and an accuracy less than 0.05°C were used during the observations (Ermolin et al. 1989, Marchenko et al. 2007).

Recent Climatic Changes in Central Asia

In Central Asia, including the Qinghai-Tibet Plateau, the air temperature is strongly affected by changes in the winter and spring snow cover. It is predicted that the area-averaged annual mean warming would be about 3°C in the decade of the 2050s over the land regions of Asia as a result of future increases in atmospheric concentration of greenhouse gases (IPCC 2007). Recent atmospheric warming particularly affects terrestrial systems where surface and sub-surface ice are involved. The retreat of glaciers and changes in permafrost in the central Asia in recent years is unprecedented as a consequence of climate warming. Kharlamova and Revyakin (2006) considered the oldest weather station in Asia, the Barnaul station as a benchmark for central Asia with 166 years measurement of air temperature. The statistical analysis showed that the MAAT has increased by 2.8°C over the 166-year period (1.8°C/100yr). The climatic warming in Central Asia is rather noticeable. The trend of MAAT from 1838 to 1958 amounts to 0.015°C/yr and 0.034 °C/yr from 1959 to 2003. During the last 166 years, the MAAT of the warm season (from April to October) has increased by 2.3°C (1.4°C/100yr) and of 3.4°C (2.2°C/100yr) warming found in the cold season (November to March). The most pronounced warming occurred in January (4.8°C), March (4.4°C), and April (4.5°C). The fourth IPCC assessment report (IPCC 2007) also documented that all of Asia is very likely to warm during this century and that the warming is likely to be well above the global mean in Central Asia. The long-term observation results in precipitation amount showed a significant increase in Central Asia from 1900 to 2005 (IPCC 2007).

Many previous studies have demonstrated that dramatic climatic warming has occurred on the Qinghai-Tibet Plateau (Liu and Hou 1998, Yao et al. 2000, Liu and Chen 2000, Duan et al. 2006, Wang et al. 2007). Liu & Chen (2000) collected monthly surface air temperature data from 97 meteorological stations above 2000 m a.s.l. on the plateau. Analysis of the temperature series indicated that most of the territory of the Qinghai-Tibet Plateau has undergone significant warming since the mid-1950s. The statistically significant warming trends in MAAT ranging from 0.016°C/yr to 0.032 °C/yr were found between 1955 and 1996. There is also a tendency for the warming trend to increase more in the high-elevation regions than in the surrounding low-elevation regions. It is evident that the Qinghai-Tibet Plateau region is among the most sensitive to global climatic changes. Wu (2005) analyzed inter-decadal changes of MAAT from 101 meteorological stations on the Qinghai-Tibet Plateau over the 1961–2000 period. Their statistical results indicate that there are 94 stations where the NAAT has increased. The MAAT has increased by about 0.70°C with a trend of 0.017°C/yr over the entire plateau during the last 40 years, which is much greater than the mean value in China (0.005°C/yr).

Based on systematic observations at 25 meteorological stations established beginning in 1936 in Mongolia, Batima and Dagvadorj (2000) it appears that the annual air temperature in Mongolia has increased by 1.56°C (0.026°C/yr) during the last 60 years. Winter temperature has increased by 3.61°C and the spring-autumn temperature by 1.4°C to 1.5°C. Furthermore, winter warming is more pronounced in high mountains and in open valleys (Batima et al. 2005). In the Altai Mountains, the MAAT has increased with a trend of 0.03°C/yr during the last 50 years. Summer precipitation has increased by 11% while spring precipitation has decreased by 17% from 1940 to 1998. The mean annual precipitation in Mongolia has displayed little increasing trend during the past 50 years.

Aizen et al. (1997) analyzed climatic data from 110 sites in the Tien Shan Mountains from 1940 to 1991. Their results show that the MAAT increased by an average rate of 0.01ºC/yr over the entire Tien Shan Mountains and by 0.006ºC/yr in the northern Tien Shan Mountains below 2000 m. The rise in air temperature was greater, especially in the central Tien Shan Mountains (0.012°C/yr) and in the high altitudes of the peripheral northern and western regions. Mean annual precipitation has increased 100 mm, or about 12-14%, during the past 52 years. Research also indicates that the average trend of MAAT ranges from 0.006°C/yr to 0.032°C/yr in different parts of the Tien Shan Mountains during the last 70 years (Dikih 1997, Marchenko et al. 2007).

Permafrost Changes

Qinghai-Tibet Plateau

The results outlined above indicate that extensive permafrost degradation has occurred during the past several decades on the Qinghai-Tibet Plateau. Evidence includes the thickened active layer, thinned permafrost, increased permafrost temperatures, talik formation, and disappearance of permafrost islands (Cheng & Wu 2007). In areas of discontinuous permafrost, the MAGT has increased by 0.1°C to 0.3°C (Wang et al. 2000, Cheng & Wu 2007) and active-layer thickness has increased during the 1980s and 1990s by several centimeters to 1 m, even 2 m at some sites (Wang & Zhao 1997). Observations of ground temperature at the Kunlun Pass site and Mt. Fenghuo site showed a warming trend in permafrost from 1996 to 2002 (Fig. 4). In undisturbed permafrost regions, the permafrost surface temperature has increased by about 0.1°C to 0.7°C from 1996 to 2001 and the thickness of the active layer has increased by 10–40 cm (Wu & Liu 2004, Yang et al. 2004). Temperature at the permafrost surface and at the depth of 6 m rose at different rates from 1996 to 2001 (Table 1) (Wu et al. 2005). The change in cold (<-1.5°C) permafrost is greater than that in warm (>-1.5°C) permafrost under the effect of climate warming. However, warm permafrost is very susceptible to climatic warming and the thermal regime of warm permafrost will be impacted more directly and immediately by surrounding warming (Wu et al. 2007).

In the sporadic permafrost regions, ground temperature measurements at Xidatan, located in the vicinity of the northern altitudinal lower limit of permafrost (i.e., the zone above which permafrost occurs), indicate that the MAGT at 20 m depth increased by 0.2–0.3°C in the same period and

Table 1 Permafrost observation from 7 sites on the plateau (Wu et al. 2005).

Site	ALT* (m)		TTOP (°C)		TP_6* (°C)

TP6* denotes permafrost temperature taken at 6 m depth. ALT is the abbreviation of Active Layer Thickness.

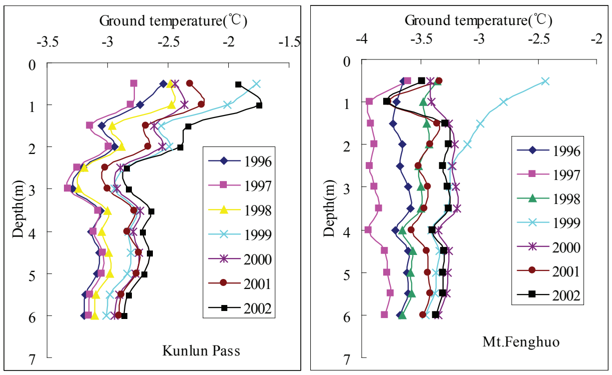

Figure 4. Variations of permafrost temperatures in the Kunlun Pass and the Mt. Fenghuo from 1996 to 2002.

permafrost has disappeared at some locations. The base of permafrost rose by about 4 m from 1983 to the end of the 1990s. A borehole was drilled in 1983 to a depth of 30 m at the Cryosphere Research Station on the Qinghai-Tibet Plateau (CRSQTP) site (35°43′N, 94°05′E) to monitor changes in permafrost temperature. The measurements indicate that ground temperatures at depths of 12–20 m have risen by 0.15–0.36°C and soil temperatures at depths from 5 to 10 m increased by about 0.2°C between 2001 and 2003. The permafrost base monitored from a borehole profile at the Jingxiangu Valley (10 km south of the CRSQTP site) has risen by 10–15 m and the MAGT has increased by 0.5–0.8°C over the last 20 years.

The Amdo-Liangdaohe section of the Qinghai-Tibet Highway is located in the vicinity of the southern lower altitudinal limit of permafrost and is underlain by sporadic permafrost. Permafrost has decreased in area by 35.6% and the lower altitudinal limit of permafrost has risen by 50-80 m. The southern boundary of permafrost has been displaced northward by 1.0–2.0 km over the past 30 years (Wang and Zhao 1997). A 19.53 m borehole was drilled near Amdo in July 1975 to monitor permafrost change. Drilling records indicate that the permafrost table was at a depth of 3.5 m and that the thickness of permafrost was 6.5 m. However, temperature measurements made in July 1989 demonstrate that the MAGT had increased by 0.1–0.2°C and no frozen layer was detected. Another borehole was drilled in June of 1975 to the south of the Highway Maintenance Squad (HMS) 124. Records show that the permafrost table was at a depth

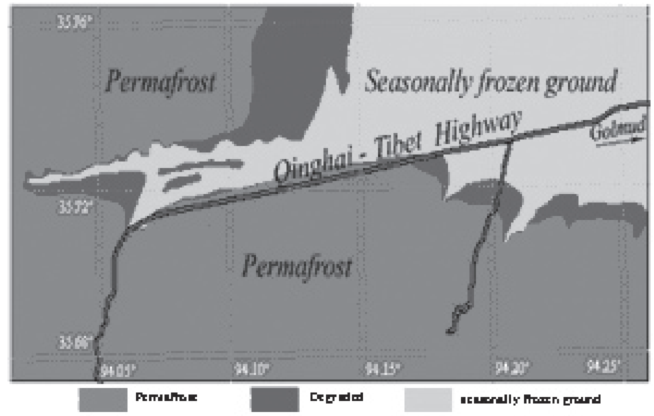

Figure 5. Permafrost change in Xidatan during the last 30 years.

of 3 m and the thickness of permafrost was 5.5 m. However, ground temperature records taken in 1989 indicate that the MAGT had increased by 0.2–0.3°C and permafrost had completely disappeared (Cheng & Wu 2007). The Qinghai-Kang (West Sichuan) Highway travels through the hilly terrain of eastern Qinghai-Tibet Plateau, which is underlain by sporadic and discontinuous permafrost. Approximately 300 km of the Qinghai-Kang Highway is over permafrost. Recent studies reveal that permafrost along the highway in the eastern part of the plateau is undergoing degradation. Taliks have developed at Madoi, Qingshuihe, and the Huashixia Permafrost Station. To the east of Huashixia, a 2.2 m test pit was dug in a marsh at an elevation of 4230 m in June 1992. At that time, soil was thawed to a depth of 0.60 m; ice was found from 0.60 to 1.20 m. A thawed layer was located between 1.20 and 1.60 m; soil was frozen below. A 7 m borehole was drilled near Qingshuihe in May 1995. The borehole records indicate that the ground was frozen to a depth of 1.5 m and a talik was located between 1.5 and 3.0 m. The layer below was frozen from 3 to 7 m. Another borehole, 154.88 m deep, was drilled in 1990 at Qingshuihe. The drilling records indicate that a talik was located between 1.50 and 15.34 m and the layer below was frozen from 15.34 to 37.32 m. A number of boreholes and test pits were drilled or dug to map the distribution of permafrost along the Qinghai-Kang Highway in the 1960s and 1990s. It appears that the lower altitudinal limit of permafrost along the highway rose by approximately 50-100 m over a 30-year period. Ground Penetrating Radar investigations in the northern plateau indicated that the lower altitudinal limit of permafrost has risen by 25 m and permafrost shrank in area considerably over the last 30 years (Fig. 5) (Wu et al. 2005).

Based upon field observations of permafrost temperatures, Wu (2005) discovered that the annual rate of increase in MAGT is 0.042 to 0.065°C/yr for stable permafrost (MAGT <-3°C), 0.016 to 0.098°C/yr for quasi-stable permafrost (MAGT between -0.5 and -3°C), and 0.011 to 0.041°C/yr for unstable permafrost (MAGT >-0.5°C), respectively. It is estimated that the base of permafrost rose at a rate of 0.1 to 0.2 m per decade on average during the last four decades throughout the plateau (Zhao et al. 2003). This trend is expected to continue under the current climate conditions.

Mongolia

The preliminary results of observation indicated that permafrost is degrading to a different extent depending on the regional and local changes in climate and human activities. The change of permafrost condition in bedrock is greater than that in unconsolidated sediments, in ice-poor substrates greater than that in ice-rich ones, on south-facing slopes greater than that on north-facing slopes, and at sites influenced by human activities greater than those undisturbed ones. In generally, permafrost degradation during the last 15-20 years (from 1990s to 2000s) was more intensive than that during the 1970s to 1990s. Spatially, permafrost in the Hovsgol Mountains changed more intensively than that in the Khentei, Khangai Mountains (Sharkhuu et al. 2006).

The Hovsgol Mountain region of northern Mongolia is located at the southern fringe of the Siberian continuous permafrost zone. Monitoring results obtained through measuring ground temperatures and active layer thickness in boreholes indicate that the average rate of increase in mean annual permafrost temperatures is from 0.02°C/yr to 0.04°C/yr. The observation results from selected Sharga, Hatgal, Tsagaan-nuur, and Burenkhan long-term monitoring sites (Fig. 3) showed an apparent trend of increase in mean annual permafrost temperatures at a depth of 10–15 m during the measurement period, ranging between 0.026 and 0.045°C/yr (Fig. 6). The highest rate, 0.042°C/yr with an increasing trend (r^2=0.91, P<0.0001) in permafrost temperatures during the last 11 years, is observed in the Burenkhan 1 borehole on a mountain slope composed of high thermal conductivity bedrock. Moreover, MAGTs in the Burenkhan mountain area have increased by 0.027°C/yr on south-facing slope, while 0.019°C/yr on north-facing slope, 0.023°C/yr in the upper watershed and 0.011°C/yr in the valley bottom (Sharkhuu et al. 2007).

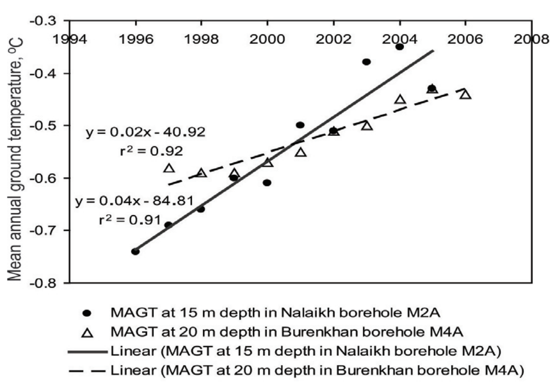

Figure 6. Trend of mean annual permafrost temperatures.

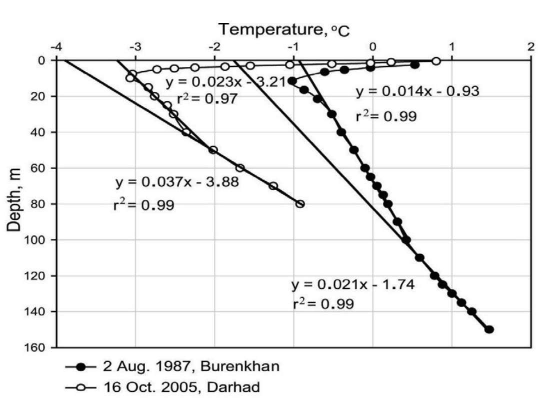

Figure 7. Change in permafrost temperature gradients with depth.

Increasing temperature gradients in the Dahard and Burenkhan 2 deep boreholes (Fig. 7) support the hypothesis that the observed change in thermal gradient with depth in addition to lithological factors might be associated with a warming temperature pulse. The Darhad site would be considered as a benchmark of warming trend in the early 1980s, while the Burenkhan site would be considered as a benchmark of warming trend in the early 1960s. Estimated trends of the increase in mean annual permafrost temperatures over 20–30 years in Mongolia are 0.01–0.02°C/yr in the Hangai and Hentei region, and 0.02–0.04°C/yr in the Hovsgol region (Sharkhuu et al. 2006).

Observation of thermokarst processes at Chuluut (in Khangai Mountain region) and Nalaikh (in Khentei Mountain region) during the last 30 years showed that subsidence of 3–10 cm/yr has taken place in the land surface. The maximum subsidence of land surface amounts to 20 to 40 cm/yr during the formation of a thermokarst pond at the Chuluut site. Until late August of 2004, active layer thickness on 5-meter-high pingo in Nalaikh has deepened to 1.50 m from 1.35 m in 1998, and the southeastern side of the pingo has subsided. The subsiding trend of the ice-rich lacustrine clays by the Chuluut River bank is estimated to be 15-30 cm/yr (Sharkhuu et al. 2006).

Tien Shan Mountains

There is some evidence indicating that climatic changes in the 20th century have exerted a significant impact on the thermal condition of mountain permafrost in the Tien Shan Mountains. The geothermal observations during 1974–1977 and 1990–2004 indicate that permafrost has been warming during the last 30 years (Fig. 8). Ground temperatures increased by 0.2–0.3°C at undisturbed sites, and up to 0.6°C at those influenced by human activities. In the northern Tien Shan Mountains, average active layer thickness has increased from 3.2 to 3.4 m in the 1970s to a maximum of 5.2 m in 1992 and to 5.0 m in 2001 and 2004 (Fig. 8),

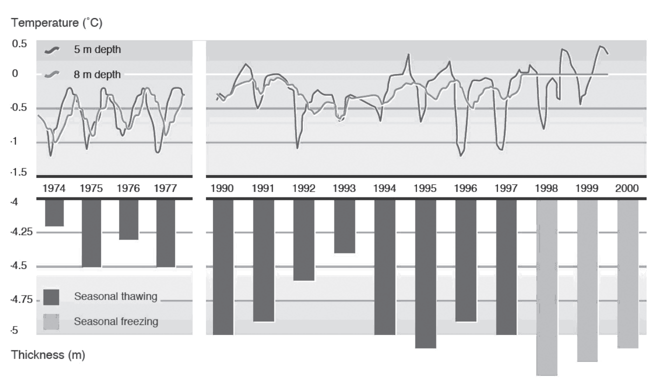

Figure 8. Permafrost temperatures and active layer thickness variations during 1974-1977 and 1990-2000 measured in Borehole K1, 3328 a.s.l., northern Tien Shan Mountain (Marchenko et al., 2007).

a major increase from the early 1970s (Marchenko et al. 2004). As a result of a deep ground thawing, a talik between 5 and 8 m in depth at different sites has formed. Permafrost temperatures in the Inner Tien Shan Mountains have also increased by 0.1°C over 1986-1993 both in the valley and on the mountain slopes (Marchenko et al. 2007).

Summary

Extensive climatic warming has taken place in Central Asia. MAAT has increased with a trend of 0.017°C/yr on the Qinghai-Tibet Plateau during the last 40 years, 0.026°C/yr in Mongolia in the past 60 years, and 0.01°C/yr over the entire Tien Shan Mountains over the 1940–1991 period. The climatic changes occurring in Central Asia have had a pronounced influence on the thermal condition of permafrost. In the different permafrost regions in Central Asia, permafrost degradation has occurred as shown by increasing ground temperatures, thickening of the active layer disappearance of permafrost patches, formation of taliks and development of thermokarst terrain. Permafrost degradation will impact engineering infrastructure, surface and subsurface hydrology, ecosystems, and will even feedback to climatic changes by means of emission of stored carbon from permafrost. In the high-mountains regions of Central Asia, the further near-surface permafrost degradation will probably accompany a transformation in environmental conditions and may lead to slope instability and permafrost-related hazards such as landslides, thermakarst, and glacial lake outburst causing mudflows.

Acknowledgments

We express our gratitude to Dr. Jerry Brown, the president of the International Permafrost Association, for all his help. This paper would not have been possible without his kindly help. Thanks for all the suggestions from Dr. Frederick E. Nelson, Dr. Douglas Kane, and other anonymous reviewers. Thanks for the support from the Chinese Key Basic Research development Project (973 Project: No. 2005CB422003), the Chinese National Science Foundation (No. 40471026), and the Innovation Project of the Chinese Academy of Science (KZCX3-SW-345, KZCX3-SW-351).

Monitoring Permafrost Changes on the Qinghai-Tibet Plateau

Lin Zhao, Tonghua Wu, Yongjian Ding, Changwei Xie
Cryosphere Research Station on the Qinghai-Tibet Plateau, Cold and Arid Regions Environmental and Engineering Research Institute, Chinese Academy of Sciences

Abstract

This paper summarizes recent research conducted on permafrost changes on the Qinghai-Tibet Plateau. Long-term temperature data were collected and analyzed for assessing the variations of permafrost thermal regimes. The field investigations indicated that the lower altitudinal limit of permafrost has moved up by 50 to 100 m over the plateau during the last 20 years. Research also indicated that the thinning and disappearance of permafrost has taken place in the southern and northern limit of the plateau. The mean annual temperature of permafrost has risen in the continuous permafrost regions, as well as in the discontinuous permafrost regions with different annual rate of increase in mean annual soil temperatures. Permafrost degradation has significant influence on greenhouse gas emission, local hydrology, and ecology on the plateau. The extensively occurring climatic warming on the plateau could be responsible for the permafrost degradation during the past decades.

Keywords: climatic warming; environmental significance; permafrost degradation; Qinghai-Tibet Plateau.

Introduction

Recently more and more attention has been paid to permafrost degradation all around the world under scenarios of climatic warming. A large amount of research based on long-term continuous temperature observations indicates that the permafrost on the Earth is undergoing extensive warming (Osterkamp 2007, Isaksen et al. 2007, Cheng & Wu 2007, Walker 2007). Variations in the permafrost thermal regime in cold regions have exerted profound impacts on the local hydrology, the surface energy and moisture balance, carbon emission, engineering constructions, as well as on the whole ecosystem (Cheng & Zhao 2000, Nelson et al. 2001, Zhang et al. 2005, Zimov et al. 2006).

The permafrost area in the Qinghai-Tibet Plateau covers about 1.50 x 10^6 km^2 and is the largest mid-latitude permafrost zone in the world. This permafrost was formed during the late Pleistocene (Fig. 1). Research has shown that the permafrost has been degrading and shrinking in areal extent with a general tendency of warming during the Holocene (Jin et al. 2007). In this paper, we have summarized some recent observation results about the evolution of permafrost on the plateau.

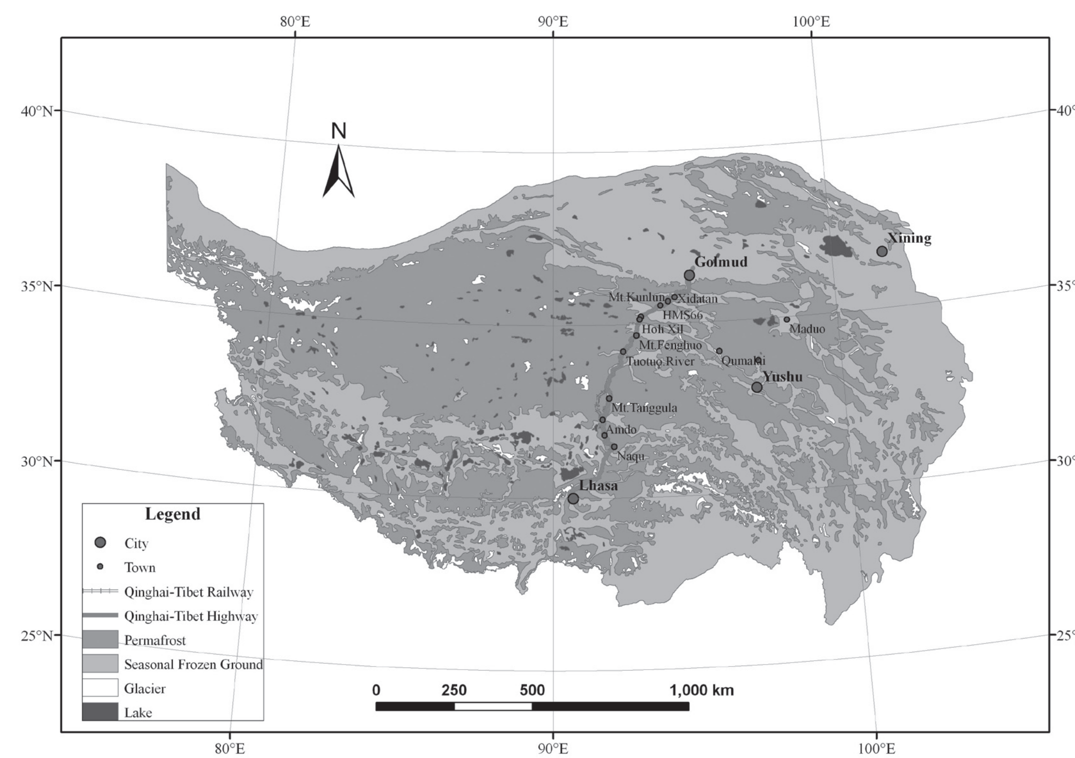

Figure 1. Permafrost distribution and the locations of study sites on the Qinghai-Tibet Plateau.

Site Conditions and Methods

Over the last 40 years Chinese researchers and engineers have established a permafrost monitoring network along the Qinghai-Tibet Highway (Fig 2). Eighteen boreholes, whose depths range from 20 to 127 m, have been drilled along the Qinghai-Tibet Highway to monitor the thermal regime of permafrost. Calibrated thermistor thermometer sensors were installed on cables at certain depth intervals and were put into these boreholes. Initially, soil temperatures at different levels were measured manually three times per month and then averaged over a year. The precision of the temperature data was estimated to be within 0.01°C. In 1998 automatic temperature data loggers were installed to collect temperature data at different depths. Since then the temperature readings have been automatically recorded 12 times per day at 2-hour intervals. We selected those sites whose measurements are continuous to be analyzed and discussed in this paper.

Furthermore, thirteen integrated monitoring sites were installed to collect soil temperature, moisture content, and heat flux data within the active layer. Some of these sites are close to the above-mentioned boreholes. Four automated weather stations and two eddy covariance systems were set up to measure parameters including air temperature, soil temperature and moisture content, precipitation, wind speed and direction, surface evaporation, radiation and CO_2 fluxes. All sites are in undisturbed natural conditions and represent the predominant types of landscape on the plateau. This paper focuses on the recent research carried out on the Qinghai-Tibet Plateau on permafrost warming and its environmental implications.

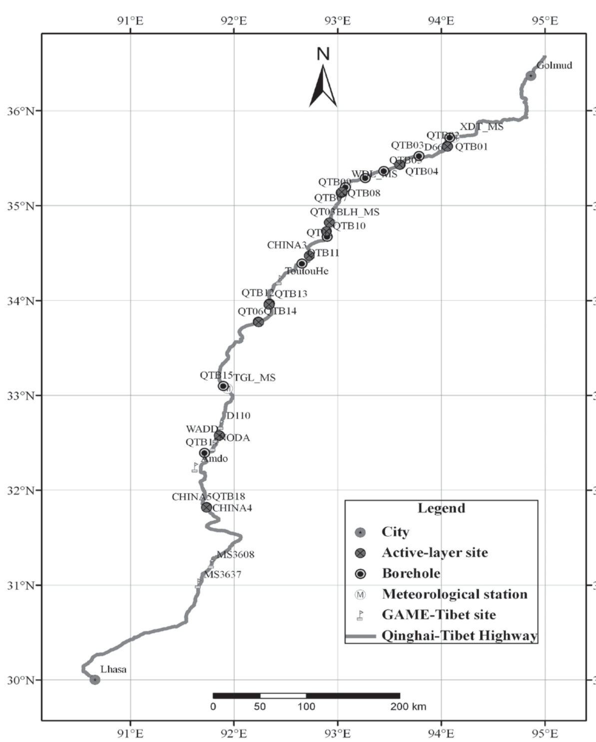

Figure 2. Permafrost monitoring network along the Qinghai-Tibet Highway.

Results and Analysis

It is apparent that permafrost on the Qinghai-Tibet Plateau has undergone severe degradation during the past decades. Various observation data indicates that the mean annual ground temperature has increased and that the active-layer has thickened; talik and thermokarst development and disappearance of sporadic permafrost has occurred in some regions.

Borehole drillings and testpit excavations on the plateau in the 1970s and 1990s indicated that the lower altitudinal limit of permafrost has uplifted by 50 to 100 m (Wang et al. 1997) (Table 1). Ground-penetrating radar investigations at the northern limit of the continuous permafrost zone on the plateau also showed an uplift of 25 m for the lower altitudinal limit in the past 20 years (Wu et al. 2005). In the 1960s ground temperature data taken from a borehole drilled in Xidatan, which is the northern lower limit of permafrost on the plateau, suggested the existence of permafrost at depths between 11.4 m and 16.0 m; but no frozen layer was observed at the same site in 1975 (Wang et al. 1996). The Amdo-Liangdaohe section of the Qinghai-Tibet Highway is located in the vicinity of the southern lower limit of the continuous permafrost zone on the plateau. The temperature observations from a 19.53 m deep borehole drilled in 1975 indicated that the permafrost table was at a depth of 3.5 m and that the permafrost thickness was about 6.5 m. However, temperature measurements in 1989 showed that the permafrost has disappeared (Zhao et al. 2004).

Observed ground temperature changes in the discontinuous permafrost regions on the plateau

The Xidatan site is located in the transitional area from the discontinuous permafrost zone to the continuous permafrost zone. Another 30 m deep borehole was drilled in 1998 as a long-term observation site. The borehole site is situated at a down-faulted basin in the west section of the Kunlun Mountains. The surficial geology consists of fluvial sands and gravel. The available meteorological data in 1976 showed that the mean annual air temperature was -2.9°C. We installed the thermistor thermometers (precision was

Table 1. Changes in the lower altitudinal limit of permafrost on the Qinghai-Tibet Plateau.

Site	Latitude	Lower altitudinal limit (m)		Uplift of altitude (m)
		1960s	1990s	
North slope of southern Mt. Qinghai	36°25′N	3650-3700	3700-3800	50-100
North slope of Mt. Heka'nanshan	35°49′N	3800-3840	3860-3900	60
North slope of Mt. Ngola	35°25′N	3850	3900	50
Southwest slope of Mt. Animaqing	34°35′N	4180	4250	70

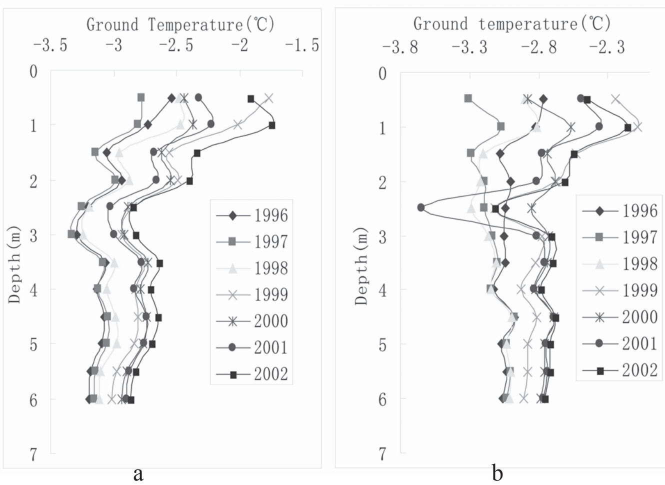

Figure 4. The changes of MAST at the Mt. Kunlun sites.

0.01°C) in the borehole. The available observation results in November of 2001 to 2003 indicated that the permafrost temperature had increased by 0.04~0.10°C on average (Fig. 3). The change in ground temperatures at a depth of 5 m to 8 m was estimated to be more than 0.10°C during the 3 years.

Observed ground temperature changes in the continuous permafrost regions on the plateau

Mt. Kunlun sites

In 1995 two boreholes were drilled to a depth of 6 m in 1995 in an undisturbed plain. The observation results indicated that the upper ground temperatures of permafrost were between -3.5°C and -2.0°C. The mean annual soil temperatures (MAST) in one borehole had increased by 0.50°C in the 7 years, which annual rate of increase in mean annual soil temperatures amounts to 0.086°C/yr. The MAST at a depth of 1 m had risen by 0.98°C. The ground temperatures at different levels showed a clear warming trend although there was some fluctuation (Fig. 4a). The MAST in the other borehole had increased by 0.34°C on average at an annual increase rate of 0.072°C/yr from 1996 to 2002 (Fig. 4b). The MAST at a depth of 1 m had risen by 0.66°C. We think the sudden decrease in the value of soil temperature at a depth of

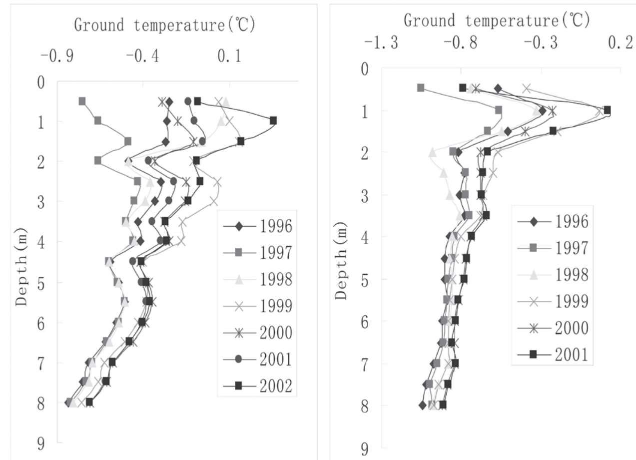

Figure 5. The changes of MAST at the HMS 66 sites.

2.5 m results from the un-recalibration or malfunction of the sensor. And the soil temperatures at both sites had increased greatly at depths of 0.5 m to 2.0 m.

HMS 66 sites

The HMS (Highway Maintenance Squad) 66 site is located in a plain near the Xieshui stream, a branch of the Chumaer River. The ground surface is covered by sand and gravel, and sand dunes can be found in this region. The observation records showed that the mean annual ground temperature in the borehole was approximately -0.6°C to -0.7°C. The mean annual soil temperatures in this site also displayed a warming tendency from 1996 to 2001. The collected observation data from two 8 m deep boreholes also showed that the soil temperatures in 7 years had increased by 0.11°C with an annual increasing rate of 0.030°C/yr at one borehole, and by 0.22°C with an annual increasing rate of 0.041°C/yr at the other borehole (Fig. 5). The mean annual soil temperatures were mostly higher than -1.0°C, which was delimited as high-temperature permafrost. From Figure 5 we can conclude that permafrost warming has taken place from 1996 to 2001.

Hoh Xil site

An 8 m deep borehole was drilled in 1995 to measure the ground temperatures at this site. The results showed that the MAST is between -1.3°C and -2.2°C. The ground temperatures had increased by 0.26°C ~ 0.89°C in the 7 years; the annual increase rate amounted to 0.098°C/yr. The MAST above 5 m depth had increased by 0.67°C, while the MAST between the 5 m to 8 m levels by 0.34°C during the 7 years. Soil temperatures at different levels showed a clear warming trend (Fig. 6).

Wudaoliang site and Mt.Fenghuo site

The Wudaoliang site is located in hilly land with an elevation of about 4735 m a.s.l. The soil profiles are composed of eolian and solifluction deposits. The permafrost table is located between 1.5 m to 1.8 m in this site, and the vegetation is alpine meadow with the coverage of about 50%

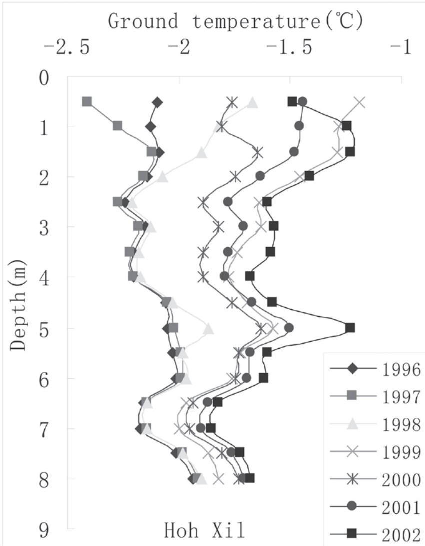

Figure 6. The changes of MAST at the HMS 66 sites.

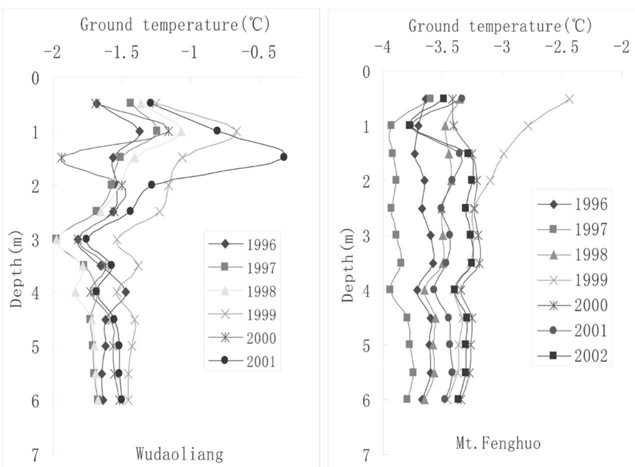

Figure 7. The changes of MAST at the Wudaoliang site and the Mt. Fenghuo site.

(Zhao et al. 2000). Observation results from the 6 m deep borehole at theWudaoliang site indicated that the MAST has increased by 0.07~0.57°C, from 1996 to 2001 with an annual increasing rate of 0.047°C/yr (Fig. 7). The drastic fluctuation in the value of soil temperature at a depth of 1.5 m in 2000 and 2001 results from the malfunction or the un-recalibration of the sensor.

The Mt. Fenghuo site is located in the hinterland of the Qinghai-Tibet Plateau. The permafrost temperatures at the Mt. Fenghuo site were lower than -3.5°C, which were delimited as low-temperature permafrost. The MAST at the Mt. Fenghuo site has increased by 0.32°C on average with an annual increasing rate of 0.065°C/yr (Fig. 7).

Mt.Tanggula sites

There are two boreholes whose ground temperatures were very close to 0°C drilled to the south of Tanggula Mountain. The observation results from a 10.8 m deep borehole indicated that the MAST had increased by 0.01°C~0.07°C from 1999

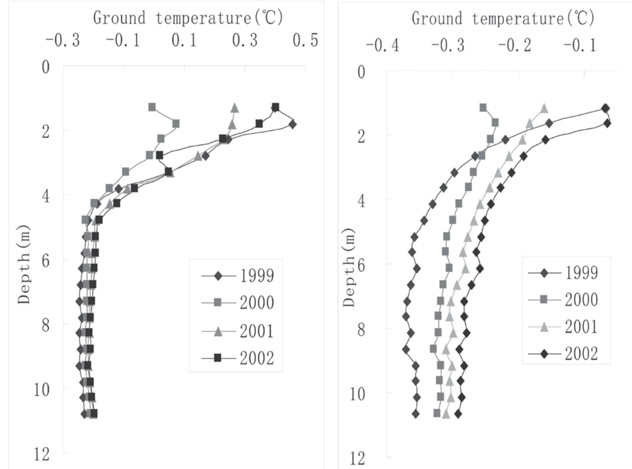

Figure 8. The changes of MAST at the Mt.Tanggula sites.

to 2002. The observation results from another 10.65 m deep borehole indicated that the MAST had increased by 0.06~0.10°C over the 4 years. The annual increasing rates of MAST were 0.011°C/yr and 0.027°C/yr respectively (Fig. 8). At both boreholes, mean annual temperatures of the lower layer of permafrost have changed steadily, and permafrost will disappear if the warming continues.

The environmental implications of permafrost degradation on the plateau

The experiments to measure the emission of CH_4 and CO_2 from the permafrost regions of the plateau indicated that the CO_2 exchange between the ground and atmosphere is characterized by emission, while the CH_4 exchange is characterized by absorption (Lin et al. 1996). Jin et al. (1999) estimate that methane emission from the wetland on the plateau amounts to 0.7–1.0 Tg per year.

Permafrost degradation closely interacts with hydrological and thermal processes near the ground surface, as well as with other components of the ecosystem. Permafrost degradation also results in the lowering of local water tables and lake water levels and the shrinking of wetlands and grazing grasslands (Cheng & Zhao 2000). Cao et al. (2006) concluded that the deterioration of marshy meadows at the source area of the Yellow River results from the lowering supra-permafrost water table.

Climatic Change on the Qinghai-Tibet Plateau

Using mean monthly air temperature data for 1961–2000 at 101 weather stations located all over the plateau and adjacent regions (Fig. 9), we analyzed the decadal changes of mean annual air temperature in the study regions during these 40 years. The results indicated that there are 19 stations where the mean annual air temperature has increased by more than 1.0°C, 50 stations where it increased by 0.5°C–1.0°C, and 25 stations where the mean annual air temperature had increased by 0.0°C–0.5°C (Fig. 9).

Among the above-mentioned 101 weather stations, we analyzed the data of 4 stations located in permafrost regions

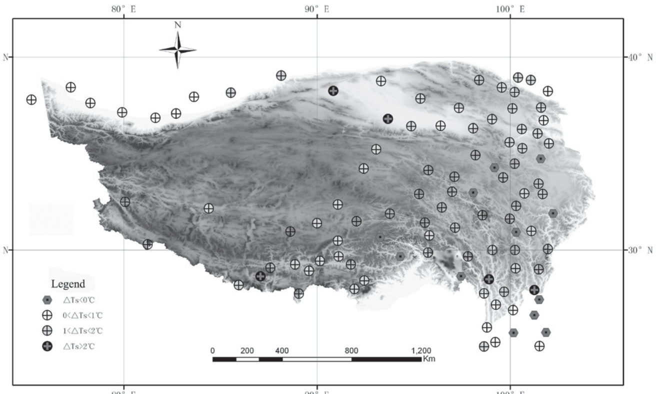

Figure 9. Location of the 101 weather stations with mean monthly air temperature observations on the Qinghai-Tibet Plateau and adjacent regions.

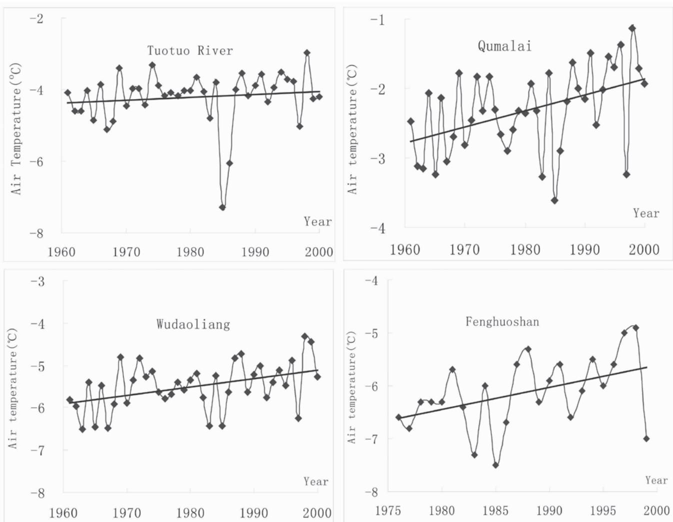

Figure 10. The changes of mean annual air temperature during the last several decades at the stations located in permafrost regions.

to reveal the climate changes occurring in permafrost zones. The results showed the mean annual air temperature in Tuotuo River increased by 0.46°C, 0.79°C in Qumalai, 0.68°C in Wudaoliang from 1961 to 2000, and 0.65°C in Mt. Fenghuo from 1975 to 2000 (Fig. 10). The climatic warming has occurred predominantly in winter. The mean annual increasing rates of air temperature at those 4 stations amounted to 0.022°C/yr. The dramatic increase of air temperature in winter decreased the seasonally frozen depth and deepened the active layer, which finally led to the permafrost degradation. With no doubt the extensively occurring climatic warming during the last decades is one of the principal factors leading to permafrost degradation on the plateau.

Conclusions

Observation results from most sites on the Qinghai-Tibet Plateau indicate that extensive permafrost degradation has taken place during the last years. In the northern and southern lower limits of the discontinuous permafrost regions, permafrost has thinned and disappeared in some areas, and the lower limit of permafrost has risen in altitude. In the hinterland of the plateau where continuous permafrost regions predominate, the ground temperatures have displayed an obvious warming tendency in recent years. In general, the annual rate of increase in MAST is 0.042°C to 0.065°C/yr for low-temperature permafrost (mean annual ground temperature is lower than -3.0°C), 0.016°C to 0.098°C/yr for the permafrost whose mean annual ground temperature is between -0.5°C and -3.0°C, and 0.011°C to 0.041°C/yr for high-temperature permafrost (mean annual ground temperature is higher than -0.5°C). Previous studies indicated that freezing and thawing processes have great impacts on carbon absorption and emission on the plateau. In the mean time, the regional lowering of ground water tables triggered by degrading permafrost is likely mainly responsible for the deteriorating environment on the plateau, as evidenced by dropping lake water levels, shrinking wetlands, and degenerating grasslands.

Based on the analysis of the decadal changes of mean annual air temperature, we revealed that extensive climatic warming has occurred on the plateau during the last decades. Records from weather stations in permafrost regions also indicated that mean annual air temperature has increased especially in winter. The observed climatic warming could be responsible for permafrost degradation.

Acknowledgments

We would like to express our gratitude to the Cryosphere Research Station on the Qinghai-Tibet Plateau, Chinese Academy of Sciences for the observation data collection and logistic support. Especially we thank Dr. Stephen Robinson and another anonymous reviewer for their constructive comments and suggestions to improve this manuscript. This work was supported by a grant from the Major State Basic Research Development Program of China (973 Program, No.2007CB411506) and the Knowledge Innovation Project of the Chinese Academy of Sciences (No. KZCX3-SW-345 and KZCX3-SW-351).

Abstract

A group of tests were conducted to study the impact of freezing on the re-distribution of water and on dry density in silty clay soil samples. Tests determined that freezing has nearly no influence on dry density. Tests also show that, in those standard samples with evenly distributed water content initially, the water content will be re-distributed following freezing. The extent of water re-distribution in a sample is determined by the soil type, the state of saturation, and the freezing method. For water-unsaturated Lanzhou Loess samples, a great amount of water appears to have migrated during radial freezing or axial freezing, and the maximum range of water content in one specimen reaches 4.46%. For water-saturated Lanzhou Loess and water-unsaturated Beiluhe Soil frozen by the axial method or the radial method, and for water-saturated Beiluhe Soil specimens frozen by the axial freezing method, water migration is minor and the range of water content in each specimen is less than 2%.

Keywords: axial freezing; radial freezing; silty clay; water migration; water-saturated; water-unsaturated.

Introduction

Laboratory mechanical experiments are usually performed to evaluate mechanical properties of frozen soil for geotechnical engineering as well, as to obtain a variety of parameters for the modeling of constitutive relationship. Standard cylindrical soil samples with a diameter and a length being twice the diameter are usually used in laboratory mechanical experiments. The soil samples include two types: undisturbed samples which are drilled in-situ directly, and remoulded samples which are made and frozen under artificial cryogenic environment indoors. A large number of studies show that water migration toward freezing front will occur during the soil freezing process (Solomatin & Xu 1994, Butler et al. 1996, Spaans & Baker 1996, Newman & Wilson 1997, Zhao et al. 1997, Stahli et al. 1999, Dawson et al. 1999, Brouchkov 2000, Brouchkov 2002, Iwata & Hirota 2005, Qi et al. 2006). Even if rapidly freezing method and close system are applied to making remoulded frozen soil samples, there still exists slight moisture migration. The effect caused by this migration might be possibly ignored if the results of mechanical tests on remoulded frozen soil samples are used in engineering. However, in theoretic modeling which assumes an ideally evenly moisture distribution throughout soil sample, a more precise measurement is required. In this context moisture migration should be taken into account. This paper will be dedicated to the study of moisture redistribution in remoulded frozen silty clay samples in association with a specific specimen-preparing method and varying freezing approaches.

Table 1. The physical properties of test soils.

	Liquid limit	Plastic limit	Plastic index
Lanzhou Loess	29.36	14.92	14.44
Beiluhe Soil	32.88	17.50	15.38

Test Preparation

Materials

The materials used in this investigation are remoulded silty clay from the Donggang town of Lanzhou City, termed *"Lanzhou Loess"* in this paper, and from the Beiluhe area of the Qinghai-Tibet plateau, referred to here as "*Beiluhe Soil*." Their physical properties and particle distribution curves are shown in Table 1 and Figure 1, respectively. Both of them are classified as CL based on the Unified Soil Classification System.

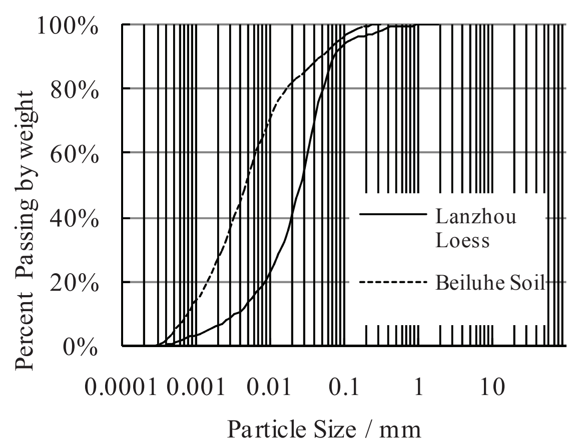

Figure 1. The particle distribution curves of test soils.

Testing apparatus

All samples were prepared using the Standard Specimen Instrument (Fig. 2a) designed by Zhao (1998) consisting of mainframe, control system, mould, and drain system. Press-poles and press-caps of various sizes are assembled with high precision load sensors. The maximum loading capacity is up to 180 kN. In this test, a press-pole with a loading capacity of 30 kN was used. The nominal size of the soil specimen is 61.8 mm in diameter by 125 mm long.

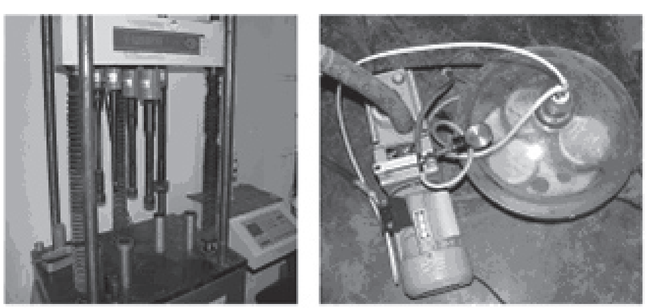
Moulding

Our earlier tests (Zheng et al. in press) found that the dry-density distribution in samples prepared by the pressure method was better than that in samples prepared by the layered-bumping method which has been widely adopted in literature (Zhu & David 1987, Zhao et al. 1998, Yang et al. 2000). In this paper the pressure method is used to make soil samples.

First, raw soil samples were air-dried, ground and sifted with a 2 mm sieve. Second, distilled water was added to dry soil to form a moist soil with the equired water content. After storage overnight to allow for moisture equilibration, the moist soil was carefully put into the mould. Third, the press-pole was descended to compact the moist soil, with the descending velocity adjusted through the control system. A higher velocity was used at the very beginning, and then at a constant but lower velocity after the press cap touches soil sample. The pressing lasted a certain time, after which the sample was turned over and pressed with the same lower speed. The overall pressing time periods are 8 h and 4 h, respectively, for Lanzhou Loess and Beiluhe Soil. In this way, water-unsaturated specimens can be obtained.

After compaction, partial specimens were deaerated under a vacuum of 73 mm Hg and then water saturated with distilled water for more than 12 h. The set-up for Water-saturation is shown in Figure 2b.

Both water-unsaturated and water-saturated specimens were put into special moulds. The moulds were then placed into a freezing cabinet and quickly frozen in a close system (without water supply) with an upper boundary temperature of lower than -30°C. Two freezing approaches were used: axial freezing and radial freezing. The axial freezing approach is to use a heat-insulated sponge to pack peripheral and bottom parts of the moulds so that specimens are frozen downwards. The radial freezing approach places plastic caps to both ends of a specimen, causing the specimen to be frozen from the exterior to the center. After freezing more than 24 h, the specimens were removed from the moulds.



(a) (b)

Figure 2. Standard specimen instrument and set-up for water-saturation.

Testing procedure

Each specimen was partitioned vertically into four layers to test the dry density. The inner part (symbolized as part A in Fig. 3) and outer part (symbolized as part B in Fig. 3) of each layer were detached to test water content. For each specimen, four dry density values and eight water content values can be obtained.

Test Results

The dry density distribution in specimens

To study the dry density distribution, the mean value (ME), standard deviation (SD) and range (R) for each specimen were calculated and shown in Tables 2 and 3.

Tables 2 and 3 show a similar change trend of dry density in Lanzhou Loess and Beiluhe Soil from the unfrozen to frozen states. The standard deviations observed in all specimens are small. Moreover, there are minor variations in standard deviation for each group of specimens (unfreezing, axial and radial freezing), which proves that the freezing process has nearly no influence on dry density distribution.

The water content distribution in specimens

To analyze the water content distribution, the mean value (ME), standard deviation (SD) and range (R) were calculated and are shown in Tables 4 and 5.

		Water unsaturated				Water saturated			
Specimen no.		1	2	3	4	1	2	3	4
Un-freezing	ME	16.29	14.30	14.15	14.49	21.79	21.75	21.68	
	SD	0.35	0.15	0.17	0.05	0.54	0.66	0.72	
	R	0.95	0.47	0.54	0.19	1.57	2.11	2.40	
Radial freezing	ME	15.56	15.68			20.34	20.87	21.65	21.37
	SD	1.31	1.56			0.45	0.43	0.39	0.42
	R	3.20	3.48			1.4	1.49	1.19	1.44
Axial freezing	ME	15.34	15.65	15.33	14.98	20.67	20.52		
	SD	1.54	1.73	1.28	1.52	0.27	0.49		
	R	3.91	4.46	3.33	3.61	0.77	1.41		

Table 4 shows that in the water-unsaturated Lanzhou Loess samples, the initial water content distributes evenly, and R of water content for each sample is less than 1%. In the process of freezing, a significant amount of water migration was observed with both the radial and axial freezing approaches. The maximum difference of water content between different positions of a specimen can reach up to 4.46%. This difference will make sense, especially when we study the impact of water content on frozen soil mechanical or thermal characteristics through indoor experiments. Therefore, in such a case, we should take into account water content variations inside a specimen rather than using simple mean water content.

Table 4 also suggests that the amounts of SD and R in the water-saturated state are larger than those in water-unsaturated for Lanzhou Loess. However, after axial or radial freezing, SD and R of water content will decrease. Each R for samples of frozen water-saturated Lanzhou Loess is less than 1.5%, indicating to some degree that moisture in frozen water-saturated Lanzhou Loess is evenly distributed. These results are in accordance with the conclusion of Liu et al. (2002).

Table 5 shows the initially even water content distribution in water-unsaturated Beiluhe Soil, with R of water content for each sample being less than 1%. Only minimal water migration was observed during the axial or radial freezing process. The R of water content for each sample is still under 1% after freezing.

Table 5. The water content (%) distribution in Beiluhe Soil.

		Water unsaturated				Water saturated			
Specimen no.		1	2	3	4	1	2	3	4

Table 6. The mean value and range of water content (%) for the inner and outer parts of Lanzhou Loess.

	Specimen no.		Unfreezing		Radial freezing		Axial freezing	
			ME	R	ME	R	ME	R
Water unsaturated	1	Inner	16.47	0.88	14.31	0.60	14.03	2.80
		Outer	16.10	0.48	16.81	1.33	16.65	0.93
	2	Inner	14.33	0.35	14.13	0.24	14.21	3.18
		Outer	14.27	0.41	17.23	0.59	17.10	1.31
	3	Inner	15.22	0.47			14.22	2.07
		Outer	15.06	0.29			16.45	0.99
	4	Inner	14.51	0.13			13.75	2.84
		Outer	14.47	0.12			16.22	0.78
Water saturated	1	Inner	21.93	1.37	20.29	0.95	20.70	0.74
		Outer	21.65	1.44	20.39	1.40	20.68	0.59
	2	Inner	21.94	1.30	20.80	0.57	20.54	1.18
		Outer	21.55	1.97	20.95	1.49	20.50	1.34
	3	Inner	21.95	1.32	21.68	0.99		
		Outer	21.40	2.19	21.62	1.15		
	4	Inner			21.08	0.69		
		Outer			21.65	0.95		

Table 5 also shows that SD and R for water-saturated Beiluhe Soil samples are larger than those for water-unsaturated samples. The SD and R of water content will increase after radial freezing, but decrease after axial freezing. The R for water-saturated Beiluhe Soil samples frozen by the axial freezing approach is less than 2%.

The water migration in specimens

To study the direction of water migration, the water content of the inner part and outer parts were collected. The mean value (ME) and range (R) were then calculated, and results are shown in Tables 6 and 7.

A number of similar change trends in water content can be found for these two types of soils in Tables 6 and 7. First, for unfrozen water-unsaturated samples, there is small variation of the mean water content between inner and outer positions of a specimen. Meanwhile, the R of water content in both inner and outer parts is rather small. After water-saturating, a similarly small variation of mean value of water content

Table 7. The mean value and range of water content (%) for the inner and outer parts of Beiluhe Soil.

	Specimen no.		Unfreezing		Radial freezing		Axial freezing	
			ME	R	ME	R	ME	R
Water unsaturated	1	Inner	16.05	0.51	15.07	0.16	15.57	0.7
		Outer	15.95	0.71	15.53	0.13	16.07	0.39
	2	Inner	16.37	0.30	15.28	0.14	15.59	0.53
		Outer	16.19	0.22	15.73	0.12	16.05	0.23
	3	Inner	16.42	0.19				
		Outer	16.25	0.32				
	4	Inner	16.28	0.46				
		Outer	15.95	0.38				
Water saturated	1	Inner	18.74	1.84	18.06	0.43	18.33	0.84
		Outer	18.35	1.97	19.32	0.93	19.46	0.69
	2	Inner	18.81	0.31	18.37	0.22	18.02	0.34
		Outer	18.45	0.26	19.66	0.68	19.07	0.61
	3	Inner	20.41	1.4	18.70	0.52	18.02	0.74
		Outer	19.52	0.13	20.52	1.81	18.87	0.64
	4	Inner	19.58	1.13	18.44	0.83	18.34	0.31
		Outer	19.44	0.79	19.93	1.38	19.02	0.77

between inner and outer parts was preserved. But a larger R of water content at either the inner or outer parts appears, proving that the degree of water supply at different position along the axial direction differs. Secondly, for all unfrozen samples, the mean value for the central inner part is slightly larger than that for the outer part, while for all frozen samples, the mean value for the outer part is larger than that for the inner part, implying that water moves outwards during the freezing process.

Table 6 shows that when the water-unsaturated Lanzhou Loess samples were radial frozen, there is a distinguishing difference between mean water content in the inner and outer parts of a same specimen, along with invariant R statistics in those parts. This observation indicates water has migrated outwards along the radial direction. When the water-unsaturated samples were axially frozen, not only was there is great difference between ME at inner and outer parts, but also R at both parts are large, proving water has migrated along radial and axial direction at the same time.

Table 6 also shows that, when water-saturated Lanzhou Loess samples were frozen by the radial or axial freezing approach, there is still little difference between the ME of the inner and outer parts; moreover, R in both parts decreases. These results prove that water moves mainly along the axial direction and makes the water content distribution more uniform.

Table 7 shows that, when the water-unsaturated Beiluhe Soil samples were frozen by radial or axial freezing, there is still little variation between the ME in the inner and outer parts, and that R in both parts is still small. This proves that there is nearly no water migration during the freezing process.

Table 7 also shows that when the water-saturated Beiluhe Soil samples were frozen by radial freezing, the difference between the mean value of water content of the inner and outer parts clearly increase, while R in both parts is still as much as that for unfrozen water-saturated samples. This proves that the water moves mainly along the radial direction.

Furthermore, the following result can also be observed in Table 7. When water-saturated Beiluhe Soil samples were frozen by axial freezing, the variation between the mean value of the water content in the inner and outer parts increases slightly, and R in both parts decrease.

The influence of soil type on water migration

If specimens are prepared by the pressure method, the longer the pressing time, the more uniform the samples will be. The pressing time is 8h and 4h for Lanzhou Loess and Beiluhe Soil, respectively, which proves that it is easier to obtain uniform specimens with Beiluhe Soil.

For water-unsaturated samples, there is obvious water migration in Lanzhou Loess, and there is nearly no water migration in Beiluhe Soil. The main reason can be expressed as follow. The particle-size analysis results show that silty particles and clay particles account for 77.73% and 13.55% by weight in Lanzhou Loess, while accounting for 40.79% and 52.78% in Beiluhe Soil. Lanzhou Loess mainly consists of silty particle, which can form better channel for water migration. In Beiluhe Soil, the percentage of silty grain and clay grain both occupy higher proportions. The grain gradation is good; it is therefore difficult to form channels for water migration.

For water-saturated samples, water migration in Beiluhe Soil is more obvious than that in Lanzhou Loess. Beiluhe Soil contains more fine grains with lower thermal conductivity, so the freezing front penetrates more slowly during freezing and there is enough time for water migration.

If those samples with water content R of less than 2% can be considered as feasible, then, both water-saturated Lanzhou Loess and water-unsaturated Beiluhe Soil--frozen by the axial or radial freezing approach--can meet this requirement. The water-saturated Beiluhe Soil specimens frozen by the axial freezing approach also meets this requirement. However, for the water-unsaturated Lanzhou Loess, the internal unevenness of water content must be considered.

Conclusions

To summarize the test results, the following conclusion can be drawn.

The water content distribution in specimens prepared by the pressure method is uniform. The degree of water supply at different position along the axial direction differs during the water- saturating process.

For all unfrozen samples, the mean value of water content for the inner part is slightly larger than that for the outer part, while for all frozen samples, the mean value for the outer part is larger than that for the inner part, implying that water moves outward during the freezing process.

The freezing process has nearly no influence on dry density distribution.

For water-unsaturated Lanzhou Loess samples, in the process of freezing a significant amount of water migration was observed with both the radial and axial freezing approaches. The maximum difference in water content between different positions of a specimen can be up to 4.46%. This difference will make sense, especially when we study the impact of water content on frozen soil mechanical or thermal characteristics, through indoor experiments. Therefore, in such cases, we should take into account internal water content variation rather than simple average water content of a specimen.

For water-saturated Lanzhou Loess and water-unsaturated Beiluhe Soil, proper specimens can be obtained by the axial or radial freezing approaches. The water-saturated Beiluhe Soil specimens frozen by the axial freezing method also meets the requirement.

Abstract

CO_2 concentrations from 0 to 180 cm in active layer soil were measured by static dark enclosed chamber technique from January in 2006 to January in 2007 in alpine grassland located on the Qinghai-Tibet Plateau. Results revealed: (1) CO_2 concentrations increasing gradually from 0 cm to 140 cm depth, and feebly decreasing from 140 cm to 180 cm. The ranges of CO_2 concentrations changed successively from 1138 to 3162 ppm. (2)Seasonal variations from 0 to 100 cm depth showed the highest concentrations occurring in the active layer thawing period and lowest occurring in the frozen period. The CO_2 concentration's seasonal changing ranges at deeper layers were all significantly higher than those at surface layers, but the deeper (100–180 cm) layers did not show clear trends. The variations of CO_2 concentrations in the soil were hardly explained by soil temperature at any depth. A significant correlation was found between CO_2 concentrations and active layer unfrozen-water content.

Keywords: active layer; alpine grasslands soil; CO_2 concentrations; Qinghai-Tibet Plateau; variation.

Introduction

Global warming has been of great concern, and the accumulation of greenhouse gases in soils is assumed to be responsible for the rise in mean global temperatures (Crowley 2000). As one of the most effective greenhouse gases, carbon dioxide (CO_2) is a maximum atmospheric trace gas and responsible for almost 63.7% (Rodhe 1990) of anticipated annual global warming undergoing an atmospheric concentration exceeding 367 ppm (IPCC 2001). Some evidence from the literature indicated that the elevated atmospheric CO_2 could affect many belowground processes of grassland such as grassland types, root respiration, and soil microbes (Pietikainen et al. 1999).

There are many sources of CO_2, but the most important natural source of atmospheric CO_2 is assumed to be microbial activities in environments like soil and water (Andersen et al. 2001). The partial pressure of CO_2 in the soil may differ greatly from that in the atmosphere. Due to the respiratory activity of plant roots and soil biota, the higher CO_2 concentration can be measured compared to that in the atmosphere. Several studies have shown that a high spatial variation of the CO_2 efflux from the soil can be efficiently explained by fine root and microbial biomass distribution, and by physical and chemical soil properties (Pangle & Seiler 2002, Maestre & Cortina 2003). Much of that heterogeneity occurs within short distances (Stoyan et al. 2000) and is especially high in areas where the distribution of ecological factors and organisms is markedly patchy (Maestre & Cortina 2003).

In comparison to data on atmospheric CO_2 enrichment, surprisingly, less is known about soil CO_2. To our knowledge, however, there is no study on temporal and spatial variation in permafrost soil on Qinghai-Tibet Plateau.

The mean altitude of the plateau is more than 4000 m above sea level with an area about 2,500,000 km^2. Great uplift of the plateau since the Late Cenozoic has been strongly affecting the physical environment of the plateau itself and its neighboring regions. Meanwhile, the plateau is also a sensitive trigger of climate change in Asian monsoon region, which is closely related to the global change (Zheng and Zhu 2000). Due to the topographic features and the characteristics of the atmospheric circulation, typical alpine zones of forests, meadows, grasslands, and deserts appear in succession from southeast to northwest in the plateau. Alpine grassland is one of the most important ecosystems on the Qinghai-Tibet Plateau because of its large area. Besides, the area is special for its lack of human activity. It provides an ideal scientific field for understanding on CO_2 exchanges in a soil-plant-atmosphere profile.

Freeze–thawing fluctuations are common characters in cold areas. Their effects on soil biogeochemical processes are a subject of major ecological interest, because it is often suggested that freeze–thawing events may be a major factor contributing to the microbial release of C in plant available form (Lipson et al. 1999, Grogan & Jonasson 2003). Furthermore, since plant productivity is often strongly limited by nutrient availability (Vitousek et al. 1991), freeze–thawing effects on soil nutrient transformations may substantially influence the C balance of cold ecosystems. Freezing and subsequent thawing of soils often results in an initial flush of microbial respiration and CO_2 effluxes (Muller et al. 2002). Laboratory incubation studies indicate that freeze–thawing cycles can lyse a substantial proportion of microbial cells, resulting in C releases into the surrounding soil, that may be immobilized by surviving microbes as they consume the enhanced supply of C substrate (Skogland et al. 1988). Thus, the extent and biogeochemical significance of freeze–thawing processes to overall ecosystem C cycling remains unclear, and may vary substantially depending on the character of the plants and temperature the freeze–thawing process is largely uninvestigated. Most of the above conclusions have been based on studies of soils without freeze–thawing process on the Qinghai-Tibet Plateau. CO_2 fluxes responses to freeze–thawing are clearly important, since soils in cold ecosystems generally contain large CO_2 concentrations (Zhao et al. 2005). Therefore, studies on the variations of CO_2 concentrations in active layer are necessary to fully evaluate freeze–thawing processes effects on whole ecosystem C cycles.

Materials and Methods

Site description

The experimental site is at Beiluhe Experimental Station, Cold and Arid Regions Environmental and Engineering Research Institute, Chinese Academy of Sciences (34°51.24′N, 92°56.39′E, 4628 m a.s.l.). The station is located in continuous permafrost area with cold and dry climate condition, and top soil is frozen from September to April of the next year. The annual average temperature is -5.2°C with the lowest temperature of -37.7°C and the highest of 23.2°C.

The sampling site is located in an area near the station. The soil, under typical vegetation type (alpine grassland) was collected, and its basic chemical and physical properties were analyzed.

The sampling site is at a river bank where the vegetation type was alpine grassland under which Cab-Gel-Sandic Entisols had developed (Chinese Soil Taxonomy, Gong et al. 1999). About 70% of the ground was covered by the dominant plants such as *Avena fatua, Kobresia pygmea, Aster asteroids, Astragalus melilotoides, and Saussurea arenaria*. The parent material of the soil at 0–100 cm was aeolian sand and at the 100–140 cm depth, alluvial sand over red residual of the Tertiary at 140–180 cm. The contents of $CaCO_3$ and clay along the profile illustrated $CaCO_3$ moved downward slightly, but the clay did not, reflecting unintensive soil water movement. The high clay content at the 140–160 cm layer should be ascribed to the parent material. There was no groundwater at the 0–180 cm depth when soil sampling.

Experimental design

CO_2 concentrations at different layers in the soil were examined thrice (1 d) a month from January 2006 to January 2007. On each sampling day, CO_2 concentrations were measured between 10:00 and 16:00. At each depth, three samples were taken by sampling pipes. All gas samples were taken with polypropylene syringes equipped with three-way stopcocks into 12 mL polyethylene vacuum vials for CO_2 concentration analyses (Maljanen et al. 2001). The samples were transported to the lab frozen, and were analyzed using gas chromatography.

We gathered the soil gas samples at the depths of 0.1, 0.2, 0.4, 0.6, 0.8, 1.0, 1.2, 1.4, 1.6, and 1.8 m from the soil through soil gas samplers, which were similar to Burton's facilities (Burton & Beauchamp 1994). Our gas samplers were made of stainless steel tubes. The outside tube has an exterior diameter of 16 mm, and the diameter of the inside pipes was 8 mm. The tops of the inside pipes were tightened by three-way stopcocks, thereby separating the inner soil gases from the outer atmosphere. The sampling plots were selected on typical plant community and coverage of the study area, and the example wells were dug on January 2006. Samplers were put in each well osculated to the soil profiles in order to get the exact CO_2 concentrations at different soil layers. Gas samples were gathered from each of the airtight pipes with polypropylene syringes into 12 mL polyethylene vacuum vials. Furthermore, the soil temperature and moisture content were also measured using temperature and moisture content probes during the experimental time.

Sample analyses

The Total Soil Organic Carbon (TOC) was analyzed using a Shimazu 5000A, and its standard analytical procedure for TOC was adopted. The Microbial Biomass Carbon (MB-C) was measured by extracting 20 g of defrosted soil with 40 ml K_2SO_4 solution for 1 h under shaking at 200 rpm. After extraction, the soil suspensions were filtered. MB-C was measured by directly determining TOC using the Shimazu 5000A at 680°C. The Water Dissolved Organic Carbon (WDOC) was measured by the method described by Wu et al. (2003). CO_2 concentrations were analyzed within 30 days by a gas chromatography (GC) (Type: Hewlett-Packard 6890), which was equipped with a flame-ionization detector (FID).

Results and Discussion

Soil carbon characteristics

Soil moisture increased gradually with depth from values of about 3.61% at the surface to 13.75% at 1.5 m. The root system here was stronger than the plain area due to the frigid climate.

The TOC content in the soil profiles decreased as the depth increased, and the trends could be described as exponential processes. It decreased dramatically in the 0–60 cm depths and then slowly in the lower layers with the depth increasing.

The TOC mass (0–180 cm) in the soil was 69.64 Mg C ha^{-1}, of which 66.11 Mg C ha^{-1} was in the 0–100 cm depth. About 94.4% of TOC in the solum was in the upper 0–100 cm layers and only a little below the layers. Even though the solum of this site was composed of loam or sandy loam which favor water percolation, the soil moisture in the layers below

100 cm were saturant the whole year and it was near saturant in the 50–100 cm layers most of a year, due to the permafrost layer beneath 180 cm (Zhao et al. 2000). The excess water prohibited root growth, and thus nearly all of the TOC was located in the upper 60 cm layer. The distribution of root residual along the profile was both a reflection of the soil water regime and an explanation of the TOC distribution in the layers: totally 9.23 Mg C ha^{-1} as root residual and all of it was in the 0–40 cm layers. Beside the soil water regime, the high content of pebble or particles larger than 2 mm in the layers below 40 cm definitely influenced the root growth and therefore the TOC distribution along the profile.

The WDOC contents declined dramatically with depth increasing, and it was significantly higher in the 0–40 cm layers than the lower layers. Also, in the soils MB-C was detected only in the 0–20 cm layers, and it was much higher in the 0–10 cm layer than the 10–20 cm layer.

CO_2 concentration in soil profile

Soil CO_2 concentrations increased gradually with depth, and the highest CO_2 concentration was found at the depth of 150 cm; the lowest CO_2 concentration occurred at the 10 cm, which is similar to the researches at the agriculture (Burton & Beauchamp 1994). In general, the mean concentrations in the atmosphere were all much lower than the CO_2 concentrations in the soil, which introduced a CO_2 emission from the alpine grassland soil to the atmosphere in our study area. Furthermore, the standard deviations of CO_2 concentrations in the atmosphere were all much lower than those in the soil. The ranges of CO_2 concentrations changed successively from 1138 to 3162 ppm in soil, which are less than the range in Chinese Loutu soil and the soil under alpine grassland in the Wudaoliang region of the Tibetan Plateau, and is less than the range in soil of farmland and grassland that has been reported.

The particle size distribution of soil has been described as the dominant independent variable determining CO_2 concentrations. It has been clearly demonstrated that CO_2 in soils is produced by microbe processes. But things are more complex than this, because the amount of CO_2 produced by either transfer processes or the activity and amount of microbe depends on the prevailing oxygen conditions; maximum yields of the gas occur only in a narrow range of low oxygen concentrations (Bange 2000). Some previous studies suggested that higher CO_2 concentrations were caused by increased CO_2 production from aerobic conditions rather than by increased production from anaerobic conditions in soils (Dowrick 1999). At the same time, the soil aperture, which is produced by particle size heterogeneity, controls the amount of CO_2 in soil.

Temporal variations of CO_2 concentrations

Over the one-year measurement period, concentrations tended to be positively correlated with the active layer freezing-thawing processes, with highest CO_2 levels occurring in thawing conditions, and lowest values in frozen, soil temperature also exerted an important control.

Soil CO_2 concentrations varied significantly during the study period, both temporally and with depth. Seasonal variation of CO_2 concentrations in the soil during the sampling period were the greatest at superstratum depths (Fig. 2). This was quite different and provided an interesting contrast to some previous studies (Bouton & Beauchamp 1994). Their experiments were carried out in the areas with strong human impacts. Production of CO_2 at topper soil changed widely with human activities including fertilizer application, farming, and land-use changes (Hadietal. 2000, Pathak & Nedwell 2001). But our study site was located at a remote plateau with little human activities. CO_2 concentrations in the surface layers kept a more stable state than those in the deeper layers, whereas the diffusion of CO_2 in deeper layers was lacking efficient pathways. The seasonal variation of CO_2 concentrations in soil showed a very clear pattern, with the higher CO_2 concentration occurring at the thawing period (from summer mid-autumn to the mid-autumn) and the lower concentrations during the frozen period (spring and winter). During the experimental period, variations of

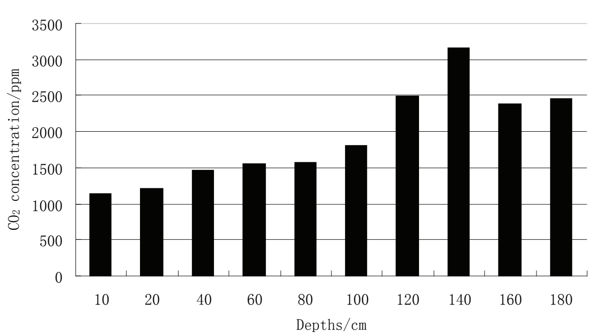

Figure 1. The average CO_2 concentration in soil depths.

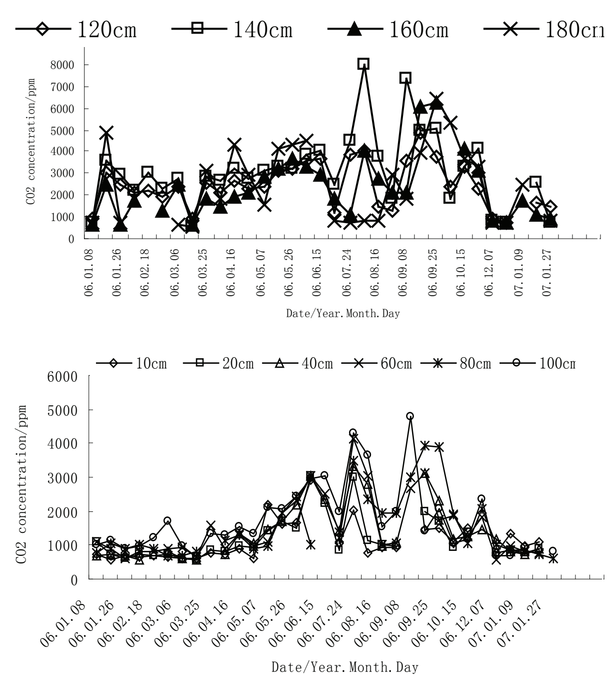

Figure 2. Variation of CO_2 concentrations at different depths in the soil.

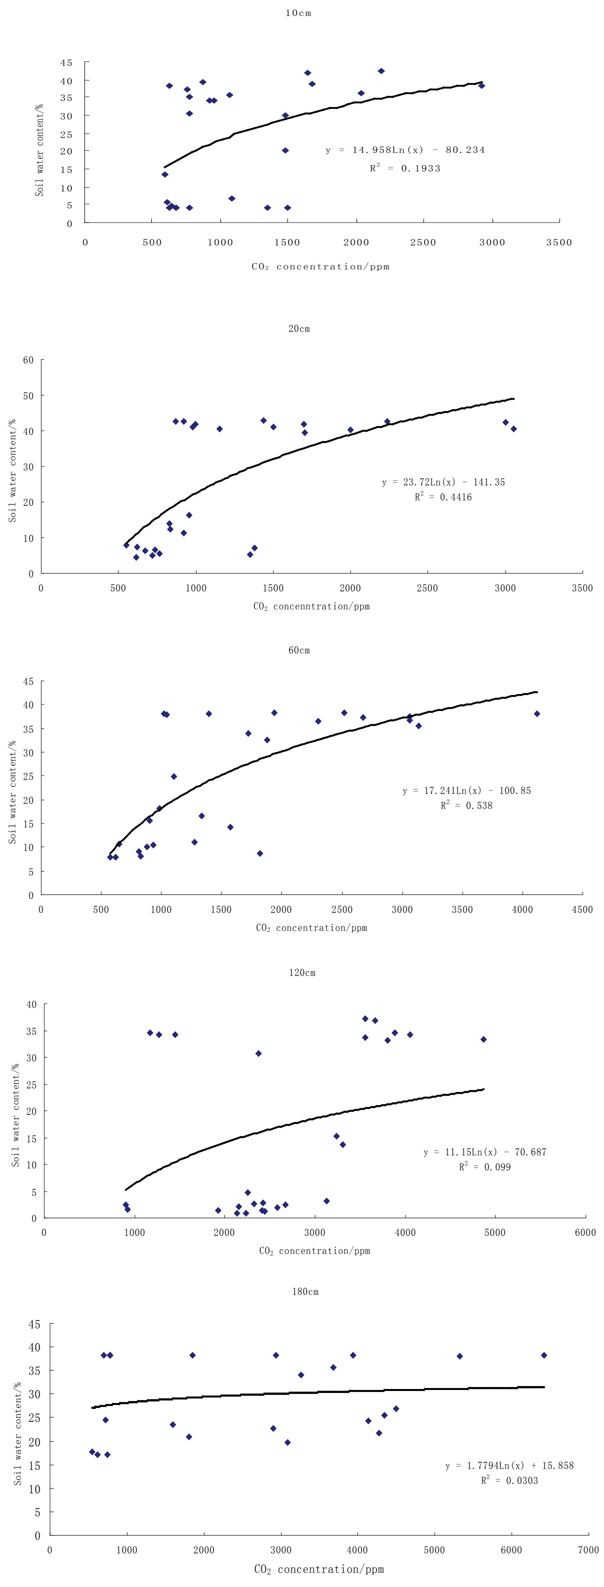

Figure 3. Correlations between CO_2 concentrations and soil water content at different depths in the soil.

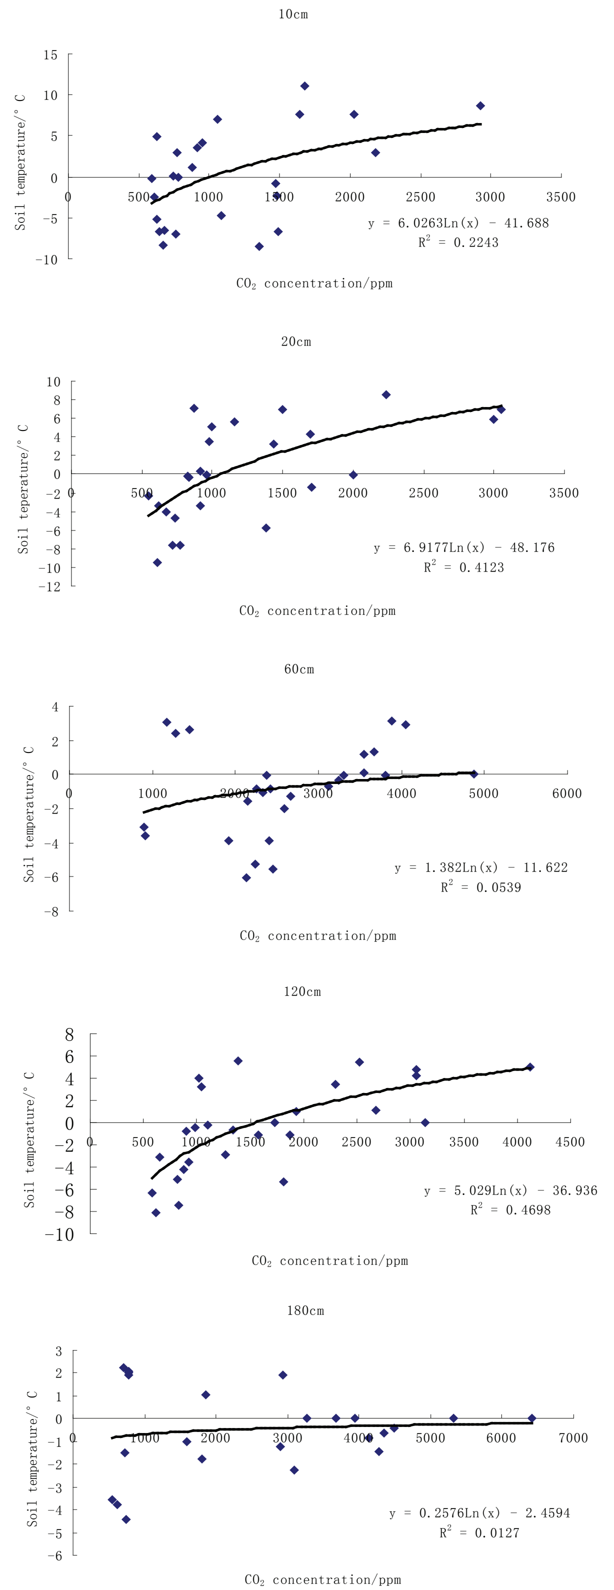

Figure 4. Correlations between CO_2 concentrations and soil temperature at different depths in the soil.

CO_2 concentrations in soil showed different ranges at all depths: the ranges of deeper layers (120–180 cm) larger than which in topper soils (10–100 cm). It may be caused by the variations of particle size distribution and unfrozen-water content in the bottom of active layers. The highest ranges occurred in the 140 cm depth layer, which was the pebble layer in the soil. It is well known that CO_2 concentrations in soil was the direct lie on the CO_2 producing processes and the storage conditions, so the CO_2 concentrations and its variability in the pebble layer were large.

Although mean CO_2 concentrations varied widely with depth in the soil, the seasonal variations of concentrations showed significant correlation between soil water contents in surface soil (10–60 cm).The most interesting result is the correlation between CO_2 concentrations at surface layers increased with depth, and the most significant correlation (R^2=0.54, P<0.01) (Fig. 3) was found at 60 cm depth layers where the greater mass of WDOC was measured. The WDOC, which have effect on CO_2 production and transportation procedures, were easily disturbed by the soil water contents at soil surface; on the contrary, the soil water contents showed more stable state at deeper layers relatively because of unfrozen-water content was near saturation.

Furthermore, the soil temperature has influences on CO_2 concentrations at the soil surface layers, but we can find influences 1.2 m deep in the soil. The situation in the surface layers in soil is relatively simpler than the soil deeper layers, so the CO_2 procedures here were only dominated by the temperature. That is the reason why the correlation between CO_2 concentration variations at surface layers was more significant than that at bottom layers. A significant correlation (R^2= 0.47, P<0.01) was also found between CO_2 concentrations and soil temperature at 1.2 m in depth during the study period (Fig. 4). This implied that the variation of CO_2 concentrations in the layer was the most direct driving force of soil particle size distribution (sandy loam). It is known that the terrestrial C cycles are driven by the activities of microorganisms. The frozen water in the form of an ice layer represents a diffusion barrier which reduces CO_2 supply to the microorganisms and partly prevents the release of the CO_2.

Conclusions

CO_2 concentrations increase gradually from 0 to 140 cm depth in soil, and feebly decrease from 140 cm to 180 cm. The ranges changed successively from 1138 to 3162 ppm. Seasonal variations in the 0 to 100 cm depth soil showed almost the same seasonal pattern, with the highest concentrations occurring in the active layer thawing period and lowest concentrations occurring in the active layer thawing period. The seasonal variations of CO_2 concentrations in the 100–180 cm layers did not show clear trends, but it can be explained by temperature and unfrozen-water content in soil. There was a significant correlation between CO_2 concentrations changing and active layer unfrozen-water content.

Acknowledgments

This study is financially supported by the projects of National Foundation for Sciences (40701033) and (40471025). The efforts of Mr. Zhixue Ma and Mr. Zesheng Gao are appreciated for their help in locating study sites. Ms. Yuemei Li and Ms. Donghui Wang are appreciated for their assistance in laboratory analyses. Dr. Guojun Sun is sincerely appreciated for his efforts in identification of plant species. This study was conducted at the Beiluhe Experimental Station and Germud Experimental Station of Chinese Academy of Sciences.

Cost Impact of Climate Change-Induced Permafrost Degradation on Building Foundations in Inuvik, Northwest Territories

F. Zhou, A. Zhang
Canada Centre for Remote Sensing, Enhancing Resilience in a Changing Climate Program, Natural Resources of Canada, Ottawa, Canada

E. Hoeve
EBA Engineering Consultants Ltd., Yellowknife, Canada

Abstract

Permafrost degradation due to climate warming can impact buildings supported on permafrost. This paper describes a methodology used to evaluate impacts and costs for adaptation, considering soil profile, geothermal response, foundation type, mode of deformation, and building age, type, and service life to determine if and when foundation adaptation would be warranted, and at what likely cost. As Inuvik is predicted to experience the largest impact in the Northwest Territories, with 40 to 75% of existing buildings potentially impacted during their remaining service life, this case is described. The estimated cost without adaptation ranges from \$52M, under a moderate climate warming scenario, to \$121M, under an aggressive climate warming scenario. "Informed adaptation" (where the costs of remedial measures are considered in the context of the remaining service life and value of the building) was the most economical approach, reducing the cost impacts to about two-thirds of these costs.

Keywords: climate change; cost assessment; foundations; permafrost degradation.

Introduction

The stability of building foundations in many northern communities relies on the strength of the underlying permafrost. The Intergovernmental Panel on Climate Change (IPCC) projected that by 2100, air temperature will likely increase globally by 2.0°C to 4.5°C, based on a range of greenhouse gas emission scenarios (Solomon et al. 2007). Temperature increases in the north are predicted to be higher than the global average. Air temperature increases can be expected to bring about permafrost degradation, thereby impacting foundation systems in northern communities.

The impact of climate warming on foundation systems was recognized as a community issue in the Canadian north, and a lack of specific information was identified as a concern (Eamer et al. 2003). Studies of the climate change impacts on community housing, especially quantitative assessments, have been very limited and adaptation cost estimates are rare.

In Canada, the only previous studies (Robinson et al. 2001, Couture et al. 2002) dealt with the compilation and documentation of the infrastructure, geotechnical, and borehole data for two of the 32 communities in the Northwest Territories (Norman Wells, Tuktoyaktuk). While these studies identified permafrost degradation to have potential negative impacts on the foundation systems of these communities, no follow-up investigations or analyses were undertaken.

Khrustalev (2000, 2001) indicated that temperature increases could result in a significant decrease in the service life and potential failure of foundations. Nelson et al. (2001, 2002) mapped the hazard potential associated with thawing permafrost under global warming. The maps were created using a dimensionless thaw-settlement index, computed using the projected percentage change in active-layer thickness and the ground ice content. The resulting maps depicted areas of "low," "moderate," and "high" hazard potential. They then superimposed the locations of existing infrastructure on the hazard map to obtain a general assessment of the susceptibility of engineered works to thaw-induced damage. However, the spatial resolution of this mapping was rather coarse (0.5° by 0.5°), thus producing only a macro-view, which could not be used for foundation impact assessment at the community level.

This paper summarizes an approach to obtain quantitative estimates of the potential physical and cost impacts of climate change, and the associated timeframe, on existing building foundations in the Northwest Territories, using Inuvik as an example. This represents a portion of a broader project by Natural Resources Canada, which developed similar estimates for five communities. The overall objective of the study summarized in this paper was to take science and engineering-based information and put it into a form that could be considered at the planning and policy level to assist in determining the resources to be expended towards mitigation.

Methodology

A multiple accounts analysis (MAA) of the 32 communities in the Northwest Territories was used to rank the sensitivity of building foundation infrastructure in these communities to climate change. MAA is well suited to situations where a variety of factors affect an outcome, and it provides an overall framework in which such factors, described quantitatively or qualitatively, may be taken into account. MAA has been previously used fully or in part to identify most acceptable options in various development projects (e.g., Robertson & Shaw 2004).

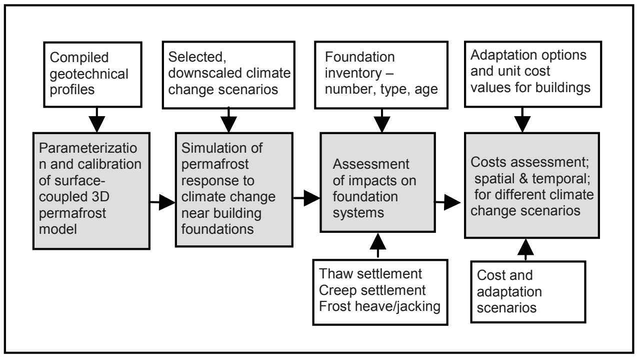

Figure 1. Methodology for foundation impact assessment.

In this case, thermal, physical, and infrastructure sensitivities were considered. The Inuvik region in general, and the community of Inuvik in particular, were determined to have the highest overall sensitivities (EBA 2005, Hoeve 2005).

Based on the MAA assessment, five representative communities were selected among the 32 for a more detailed analysis: Inuvik, Tuktoyaktuk, and Paulatuk in the continuous permafrost zone and Norman Wells and Tulita in the extensive, discontinuous permafrost zone. The selection was designed to represent a range of sensitivities, geographic regions, and population sizes. Only the results from Inuvik are summarized in this paper.

Figure 1 illustrates the methodological framework of the overall study leading to the cost assessment for the selected case communities.

Geotechnical profiles

Generalized geotechnical profiles were compiled to represent areas within which the subsurface was assumed to have geotechnical properties, such as soil texture, hydraulic and thermal properties, water/ice content, and the thickness of each layer, that are horizontally uniform or vary within only a narrow range. The impacts of permafrost degradation were assessed for each sub-area, considering the temporal and spatial distribution of foundation systems.

Climate change scenarios selection and downscaling

From among the many scenarios produced with the aid of General Circulation Models (GCMs) (IPCC 2001), three were chosen (CGCM 1 GHG + aerosol, HadCM3 SRES A2 and B2) that roughly represent an upper, a middle, and a lower level of the impact of greenhouse gases emissions on future air temperature trends. Thus, with these scenarios, the simulated geothermal dynamics should accordingly have an upper and lower bound as well as a middle range.

In this study, the selected GCMs were downscaled by using the Statistical Downscaling Model (SDSM) tool (Wilby & Dawson 2004). Six climatic variables were downscaled—air temperature, precipitation, solar shortwave and longwave radiation, wind speed, and water vapour pressure—for input into the model.

Surface-coupled three-dimensional geothermal model

A physical, process-based, surface-coupled, three-dimensional finite-element geothermal model (SC3D) was developed. Driven by climate variables, and constrained by ground surface condition, geothermal gradient, and geotechnical profile characteristics, the model transforms the changes in climate variables into ground surface temperature dynamics by computing surface energy and water balance including snow. The model mimics the three-dimensional flux of heat and water that occurs around and underneath the building. The model also represents the building's effects on these processes through dynamically differentiating the solar radiation, precipitation, and snow cover received by the ground surface at different locations underneath and around the building, and it reflects the modification of the natural geothermal regime by the building. Zhou et al. (2006) provides a detailed description of the model, the required input data, and results of its validation.

Modeling of permafrost changes

The modeling space was specified as a cube, 22 m by 18 m in plan and 100 m deep. The "building" was specified as a typical residential house, with an enclosed area of 14 m by 10 m, and a height of 5 m with a 0.5 m high air space under the floor.

The finite-element mesh was uniform in both X and Y directions, on a 2 m grid. To capture the details of heat and water transfer near the ground surface and to achieve computational efficiency, the vertical cell size was 10 cm for upper layers, and it increased downward to 4 m at the bottom of the modeling space.

Following the protocol recommended in IPCC-TGIA (1999), the period of 1961–1990, with actual data, served as a benchmark, and the projected period 2010–2069 was used to assess the changes due to climate warming with respect to the benchmark. The IPCC recommended three assessment periods: 2010–2039, 2040–2069, and 2070–2099. The period of 2010–2069, representing two of these recommended periods, was chosen because it covers the expected service life of all the existing buildings (constructed before 2005).

The simulation employed a daily time step. From recorded vertical temperature profiles, two indices of permafrost condition were computed: mean annual ground temperature and active layer thickness.

Impact of permafrost degradation on building foundations

The rate of permafrost degradation determines the degree of soil deformation in response to climate change. In this study, three types of terrain instability due to permafrost degradation were taken into account in the estimation of the impacts: thaw settlement and creep settlement, and frost-jacking. The rate of permafrost degradation was quantified through increasing mean annual ground temperature and deepening active layer thickness. The former was considered mainly in creep settlement analysis, and the latter is used for the calculation of thaw settlement and frost-jacking.

For pile foundations, the assessment took into account all the three types of terrain instability. Only thaw and creep settlements were involved in estimating the impact on shallow foundations, which would include surface footings or buried spread footings.

Differential settlements were obtained as a result of the varying geothermal response below various portions of the building. The ground below the centre of the building was coldest and the ground at the south corners/side was the warmest.

A critical part of the physical impact assessment concerns the thresholds at which damage to building systems is considered to occur. The maximum allowable total settlement of a building was set at 30 mm, and allowable differential settlement between adjacent foundation supports at 10 mm over a 3 m span during the service life of the building (CFEM 1992). Thus, if settlement of a building is 30 mm or higher or if differential creep settlement is more than 10 mm over the horizontal distance of 3 m, the building was regarded to be at risk.

For pile foundations, the frost-jacking and resisting forces were evaluated. If at any location under the building, the frost-jacking force exceeded the resisting force (sum of pile resistance and dead load), the building was considered at risk of frost-jacking.

Cost assessment

Typical building sizes, foundation configurations and unit costs for the most appropriate rehabilitation technique applicable to each foundation type were determined (EBA 2006, Hoeve et al. 2006).

Foundation inventories were prepared to characterize individual buildings within each geotechnical profile area by age (grouped at 5-year intervals), replacement cost and present value. A depreciation factor of 5% per year was used to determine present value. The age distribution was determined by examination of historical air photos. It should be noted that the compilation of inventories was office-based, incorporating assumptions based on experience and judgment, and not including site visits, except as documented by Robinson et al. (2001) and Couture et al. (2002) for Tuktoyaktuk and Norman Wells.

Commercial/institutional buildings were considered to have a longer service life (65 years) than residential buildings (50 years). If the age of a building reached these thresholds, the building was considered to retire "maturely." If a younger building was assessed at risk due to permafrost degradation, it would either be forced to retire prematurely or to undergo an adaptation.

The cost study considered three responses (Fig. 2):

Response 1 – mature retirement: a building will reach the end of its service life without detrimental impact induced by climate warming. In this scenario, no action will be needed and no cost will be incurred. As no cost would occur in Response 1, it is not considered further.

Response 2 – no action: a building is assessed to be at risk, but no action will be taken. The building will be forced to retire early and cost of the premature retirement would be incurred, equal to the residual value of the building. Therefore, the cost will be the total asset value of all impacted buildings at the age when the buildings would be assessed at risk.

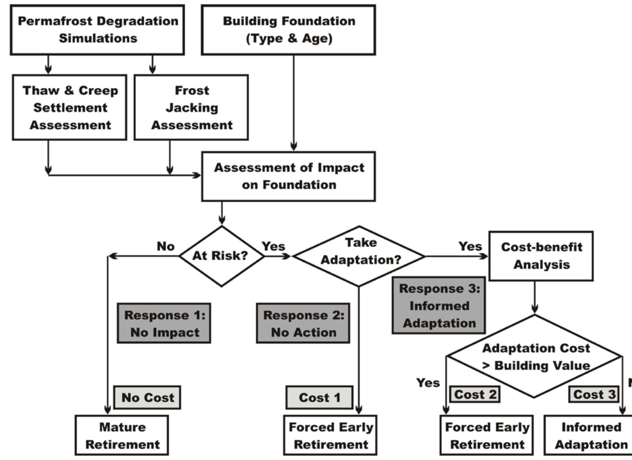

Figure 2. Procedures for impact and cost assessment.

Response 3 – informed-adaptation: when a building is assessed to be at risk, a cost-benefit analysis is conducted to determine what actions should be taken and when. The cost-benefit analysis thus compares the adaptation cost and asset value of the building under consideration when it is assessed at risk.

If a building at risk is approaching the end of its service life, the cost of the impact (forced premature retirement) would be relatively low. Conversely, if a building is at risk in its early service life, the cost of the impact would be relatively high and adaptation may be warranted. The cost-benefit analysis thus aims to minimize total costs of the climate change impacts, i.e., the sum of Cost 2 and Cost 3 is less than Cost 1.

The foregoing procedure was applied to each category of building/foundation type in each geotechnical profile, over each time increment and for each case community. Details are presented in Zhou et al. (2007).

Assessment Results for Inuvik

Inuvik is located on the East Channel of Mackenzie Delta, approximately 100 km from the Arctic Ocean, at latitude 68°19′N and longitude 133°29′W. In 2003, it had a population of 3688.

Typical geotechnical profiles

Geotechnical data from 17 evaluations was reviewed to develop typical subsurface soil profiles in the Inuvik area. The community was divided into two sub-areas of generally similar subsurface stratigraphy. The extent of Profiles 1 and 2 within the community are shown on Figure 3. Profile 3 was developed for the area located west of town along the Dempster Highway out to and including the Inuvik airport.

The soil profiles and associated thermal properties were described in EBA (2004) and are summarized in Figure 4.

Figure 3. Location of geotechnical profiles for Inuvik.

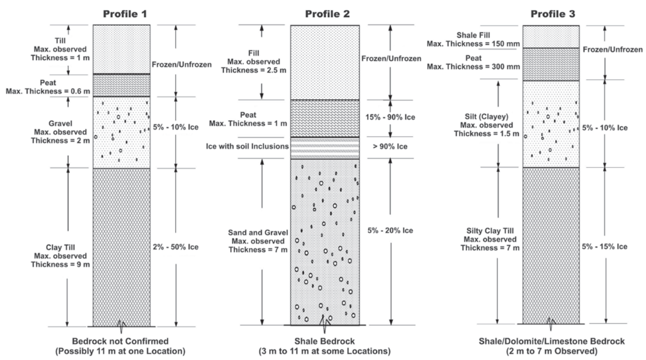

Figure 4. Geotechnical profiles for Inuvik.

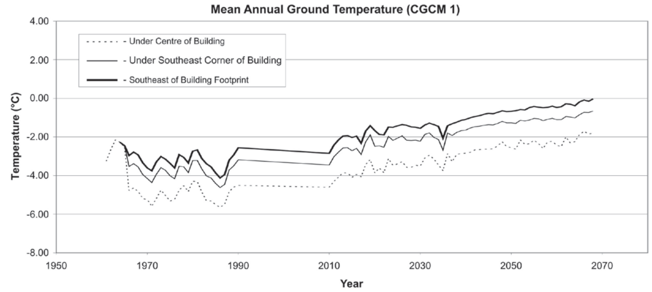

Figure 5. Mean annual ground temperatures for Inuvik, Profile 1.

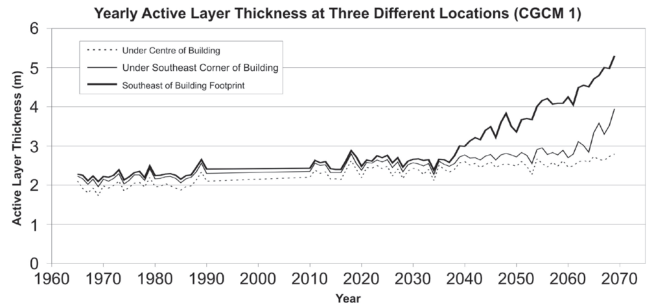

Figure 6. Active layer thickness response for Inuvik, Profile 1.

Building age distribution

The temporal distribution of buildings over about 5-year increments were compiled by examining air photos. The majority of the buildings are located in the Profile 1 and Profile 2 areas. The area of Profile 1 has about 600 residential and 60 commercial buildings and encompasses the newer development areas. Profile 2 is in a mature area of the community and the number of buildings has remained stable since the late 1970s, with about 400 residential and 40 commercial/institutional buildings. The area of soil Profile 3 has exhibited growth, but only has about 30 commercial/institutional buildings and negligible residential buildings.

Ground temperature trends under climate change scenarios

The model was calibrated with ground temperature data from a power station in Inuvik, a site within the Profile 2 area. Cables were installed in 1995, extending under the building, at the perimeter of the building and away from the building (EBA 1996). Regular data were available for four years, with sporadic data available for another six years. The model was initialized and run from 1961 through the period where measurements were available.

Permafrost simulations were conducted for the baseline period (1961–1990) and two projected periods (2010–2039, 2040–2069). The simulations through the baseline period were driven by actual climate data, and the simulations during the projected periods were driven by the downscaled GCM data.

The intervening period, 1991–2009, was not modeled, because it was not called for in the IPCC-TGIA (1999) protocol and because the input data, either actual or projected, were not complete.

Figure 5 shows the mean annual ground temperature response (average for depths 1 m to 10 m) at three locations, derived from the CGCM 1 scenario, which is the most severe. The locations for which results are plotted range from the maximum mean annual ground temperature at a point outside the building footprint to the minimum mean annual ground temperature under the centre of the building. The intermediate point represents the warmest under the building, with the southeast and southwest corners being approximately the same.

The simulation began in 1961, and the building effect was introduced in 1965. The building caused an immediate and substantial change in the temperature regime, and this effect was strongest underneath in the centre of the building. Figure 5 also suggests that the temperature differential did not increase over time. Once the thermal regime stabilized, the building exerted an approximately constant additional effect on the near-surface temperature profile.

Figure 6 shows the change in active layer thickness derived from the CGCM 1 scenario. It indicates that the projected active layer thickness did not change substantially between 2010 and 2040 for all the locations. However, the active layer thickness became deeper at a faster rate away from the building after about 2040, at the south corner around 2065, and there was little change under the centre of the building during the modeling period.

The results in Figure 6 seem to suggest that the shading effect of a building, on solar radiation and snow cover, has a more dominant effect on active layer thickness than increasing air temperature.

The analyses indicate that, over the long term, ground temperature changes more or less in step with air temperature but changes in the active layer lag behind changes in ground temperature. This is attributable to the latent heat that must be overcome for an active layer response in ice-rich soil.

Table 1. Summary of impacted buildings in Inuvik.

	Profile 1		Profile 2		Profile 3		Inuvik Overall	
Total Buildings	659		448		34		1141	
Scenario	Buildings Impacted							
	#	%	#	%	#	%	#	%

HadCM3 A2	5	1	441	98	5	14	451	40
HadCM3 B2	5	1	441	98	14	42	460	40

Table 2. Cost impacts in Inuvik for three climate scenarios.

Climate Change Scenario	Response 3 (2005 C$M)					Response 2 (2005 C$M) (Cost 1)
	Premature Retirement (Cost 2)		Adaptation (Cost 3)		Total	
	Res.	Com.	Res.	Com.		
CGCM1	15.3	5.4	4.0	55.3	80.0	121.3
HadCM3 A2	9.0	4.1	1.3	21.5	36.0	52.3
HadCM3 B2	9.0	4.9	1.3	24.5	40.0	56.3

Impacts on building foundations

Table 1 summarizes the number of buildings impacted for the three climate change scenarios and within the three geotechnical profiles. Among the 1141 buildings in Inuvik (as of 2005), 659 buildings are located in Profile 1, 448 in Profile 2, and 34 in Profile 3. The buildings in Profile 2 are most severely affected. This is because the baseline (1961–1990) active layer in Profile 2 is deeper, at about 3 m, compared to about 2.5 m and 1.5 m for Profiles 1 and 3.

The fraction of buildings in Profiles 1 and 3 that would be affected ranged from around 15% (Profile 3 with HadCM3 A2) to 60% (Profile 1 with CGCM1 GHG+aerosol). Buildings in Profile 3 would be the least impacted due to a shallower active layer and lower mean annual ground temperature. These results reflect the importance of the geotechnical conditions on the susceptibility of building foundations, the impact being modulated by the climate change scenario employed.

The differences between climate change scenarios (CGCM1 GHG+aerosol and HadCM3 A2 or HadCM3 B2) are rather strong: about 74% of all buildings would be impacted under CGCM1 scenario, compared to approximately 40% for the two HadCM3 scenarios. This difference represents about 400 buildings, mostly located in Profile 1.

Cost impacts

Table 2 summarizes the distribution of costs to community buildings for the three climate scenarios. Results of Responses 2 and 3 are shown. Based on the Response 3 (informed adaptation, Fig. 2), cost-benefit analysis was used to determine whether or not adaptation measures were warranted for each impacted building. The results show that CGCM1 scenario would bring about the highest cost of approximately C$80M, and HadCM3 A2 and HadCM3 B2 would result in the cost about C$36M and C$40M, respectively. The costs were also broken down to the costs due to premature retirement (Cost 2) or costs for adaptation (Cost 3). The results show that, under CGCM1 scenario, about 74% of the total cost would be for adaptation. Under climate change scenarios HadCM3 A2 and HadCM3 B2, about 64% of the total cost would be due to adaptation.

Under all climate change scenarios, the higher adaptation costs are associated with commercial/institutional buildings. The highest premature retirement costs are associated with residential buildings. This is partially attributable to the longer service life of commercial/institutional buildings, but is also a result of the magnitude of adaptation costs relative to residential building value. Commercial/institutional buildings are more likely to warrant adaptation than residential buildings.

The table also lists the costs of the no action scenario in which impacted buildings are assumed to retire prematurely with no attempt at adaptation (Cost 1, Response 2). Although the total number of impacted buildings in Responses 2 and 3 are the same, the total cost of informed adaptation ($80M) is only about two-thirds of the no-adaptation scenario ($121M) under CGCM 1 scenario. This relationship held true for the HadCM3 A2 and B2 scenarios.

To help put these costs into perspective, the total replacement cost of the building infrastructure in Inuvik was calculated to be about $1.2 billion and the present value of the buildings was calculated to be about $250 million, in 2005 dollars.

The analysis shows that "informed adaptation" is the preferable management response to dealing with impacts of climate change on building foundations in Inuvik.

Acknowledgments

The authors are grateful to Josef Cihlar for his advice on the study and for his guidance. Thanks also go to Yu Zhang and Fred Wright for advice on permafrost modeling and Richard Fernandes' research group for providing climate data; the NWT Housing Corporation, the Government of the NWT, and Departments of Public Works and Services and Municipal and Community Affairs who contributed community infrastructure data. Abstract

Five exposures on two arctic islands in southern Lena Delta, Russia, were investigated in order to determine the development of iron-oxides under different pedogenic conditions in permafrost-affected paleosols and to prove their application for describing environmental conditions during pedogenesis of buried soils and the predominant paleoclimate during their development. The samples were collected from the active layer on Samoylov Island as well as from Late Pleistocene and Holocene paleosols on Kurungnakh Island. The amounts of iron extractable by dithionite (Fe_d) and by oxalate (Fe_o) were determined for all samples. The extracts were conducted to determine the forming conditions of paleosols and their iron-oxide contents and to compare them with modern permafrost-affected soils. The iron-oxide amounts characterize well the sedimentation conditions and the paleoclimate of the investigated paleosols. As contributing factors, the organic matter content and the inundation were identified. Additionally, in modern soils, translocation processes within the polygon affect the conditions of the different Fe-fractions.

Keywords: environmental and climate change; Gelisols; iron-oxides; Lena Delta; paleosols; Siberia.

Introduction

Permafrost-affected soils (Gelisols or Cryosols) cover nearly one-fourth of the terrestrial surface in the northern hemisphere. Staudies have been conducted for more than 100 years (Goryachkin et al. 2004). The first studies were exploratory in nature in order to find land for agriculture. Pedoscientists study permafrost-affected soils to learn more of their active physico-chemical processes (Tarnocai 2004). Spatial distribution, genesis and properties of different Cryosols are presented in details by Kimble 2004. However, this does not imply that these soils have been sufficiently investigated.

Pedogenesis in permafrost regions takes place in the active layer above the permafrost table only during the short summer period. On one hand, the cold conditions hinder strong pedogenesis; on the other hand, permafrost preserves records of former soil conditions.

Spatial distribution and genesis of soils in the southern Lena Delta provide a basis for evaluation of the impact of environmental and climate change on permafrost landscapes.

The objective of this study was to prove if crystallized iron-oxides are a useful criterion for estimating environmental conditions of pedogenesis of buried soils and paleoclimate during their development.

Morphological and analytical data are taken into account to understand both properties and genesis of buried soils in ice rich permafrost sediments (so called ice complex) and modern soils in the southern Lena Delta.

Identifying different forms of iron-oxides helps to understand the environment in which active pedogenesis took place. In general paleosols are often characterized by their iron-oxides fractions, and this data facilitates an estimate of the relative age of a given soil-sequence (Arduino et al. 1984, Arduino et al. 1986, Bäumler 2001).

During expeditions to the Lena Delta in 2002 and 2007 investigation of several soil profiles were carried out to determine the development of iron-oxides under different pedogenic conditions in permafrost-affected paleosols and to prove their application for description of environmental conditions of pedogenesis of buried soils and predominant paleoclimate during their development. For understanding the processes of modern pedogenesis, from the active layer of young soils were investigated.

Investigation Area

The study sites are located on Samoylov Island (72°22′N, 126°28′E) and Kurungnakh Island (72°20′N, 126°18′E). The islands are situated at one of the main Lena River channels, the Olenyokskaya Channel in the southern part of Lena Delta (Fig. 1). The Lena Delta is located in northeastern Siberia, where the Lena River cuts through the Verkhoyansk

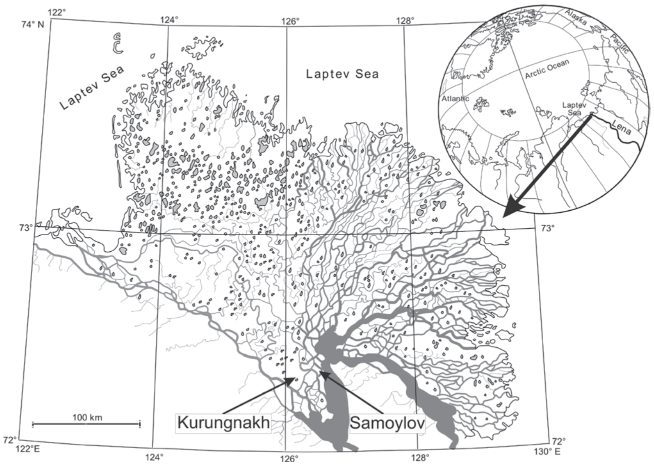

Figure 1. Map of the Lena Delta with study sites.

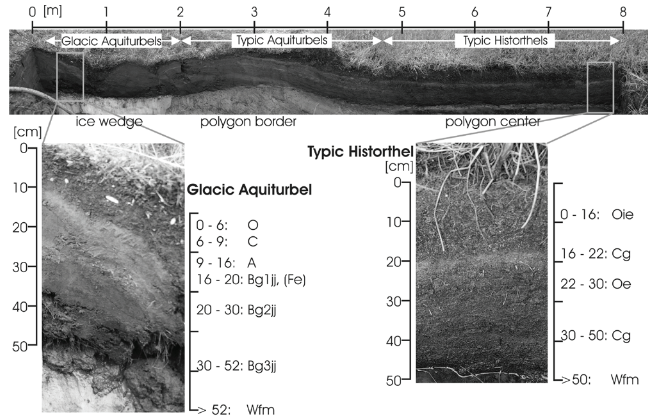

Figure 2. Soil-cross-section of a half of a low-centered polygon on Samoylov Island with the soil-complex of Glacic Aquiturbel and Typic Historthel, according to U.S. Soil Taxonomy.

Mountains Ridge and discharges into the Laptev Sea, which is part of the Arctic Ocean.

Samoylov Island can be divided into two major geomorphological units (Akhmadeeva et al. 1999): the relative young floodplain (0 to 4 m a.r.l. [about river level]) in the western part which is flooded annually in spring, and the higher-elevated (1 to 12 m a.r.l.) river terrace of Late Holocene age, the "first" terrace in the eastern part (Pavlova & Dorozhkina 1999). The first terrace is flooded only during extreme high-water events (Kutzbach 2005).

Kurungnakh Island belongs to the third river terrace complex (up to 55 m a.r.l.) of the Lena Delta. The third terrace is the oldest terrace in the delta. It was formed in Middle and Late Pleistocene (Schwamborn et al. 2002, Kuzmina et al. 2003). This terrace forms autonomous islands along the Olenyokskaya and Bykovskaya Channels. The Kurungnakh Island is located at the southeastern part of Olenyokskaya Channel (Schwamborn et al. 2002).

The climate in the Lena Delta is high-arctic with continental influence and characterized by low temperatures and low precipitation. The mean annual air temperature, measured by the meteorological station in Tiksi located about 110 km (68 stat. mi.) to the southeast directly at the coast of the Laptev Sea, was -13.6°C (7.5°F) during the 30-year period 1961–1990; the mean annual precipitation in the same period was 319 mm. The average temperatures of the warmest month August and the coldest month January were 7.1°C (44.8°F) and -32.4°C (-26.3°F), respectively (ROSHYDROMET 2007), demonstrating the extreme climatic contrasts between polar day and polar night for continental Polar Regions.

Material and Methods

The main soil unit of the first terrace above the floodplains of Samoylov Island is covered mainly by polygonal wet sedge tundra with soil-plant-complexes which consist of ice rich ground, wet and cryoturbated Gelisols (Glacic Aquiturbels) and very wet organic rich Gelisols (Typic Historthels). Typic Historthels are Gelisols that have more than 40%, by volume, organic materials from the surface to a depth of 50 cm (Soil Survey Staff 2006). According the WRB-Classification the Gelisols were classified as Glacic Turbic Cryosols and Haplic Histic Cryosols (Food and Agriculture Organisation, 2006). Typic Historthels were formed in depressed centers of low-centered ice-wedge polygons characterized by high water saturation to the soil surface and high organic matter accumulation due to anaerobic conditions.

Glacic Aquiturbels formed at the elevated borders of the polygons are characterized by prolonged inundation but with less organic matter accumulation and pronounced cryoturbation. Thus Glacic Aquiturbels are Gelisols that have one or more horizons showing cryoturbation in the form of irregular, broken or distorted horizon boundaries, involutions, and accumulation of organic matter on top of the permafrost and ice wedges. They have within 50 cm of the mineral soil surface redox depletions and also aquic conditions during normal years and a glacic layer with its upper boundary within 100 cm of the mineral soil surface (Soil Survey Staff 2006).

Beside these wet and organic rich soils various sandy soil complexes such as Psammorthels and Psammoturbels are typical along the eroded cliffs. They are drier than the Aquiturbels and Historthels (Pfeiffer et al. 1999, Pfeiffer et al. 2000, Pfeiffer et al. 2002). Psammorthels and Psammoturbels are soils that have less than 35%, by volume, rock fragments and a texture of loamy fine sand or coarser in all layers within the particle-size control section (Soil Survey Staff 2006). In the erosional cliff area thermal erosion results in formation of high-centred polygons which are often covered with eolian sands.

Glacic Aquiturbels and Aquic Histurbels are common on Kurungnakh Island as on Samoylov Island. These modern soils are compared with paleosols such as Histels of different degree of decomposition, iron-rich Aquorthels and Aquiturbels of exposures on both islands.

For investigations of paleosols three exposures of 2.1, 2, and 1.2 m thickness were selected on the third terrace of Lena Delta on Kurungnakh Island. The samples were taken during the expedition "LENA 2002" (Kuzmina et al. 2003).

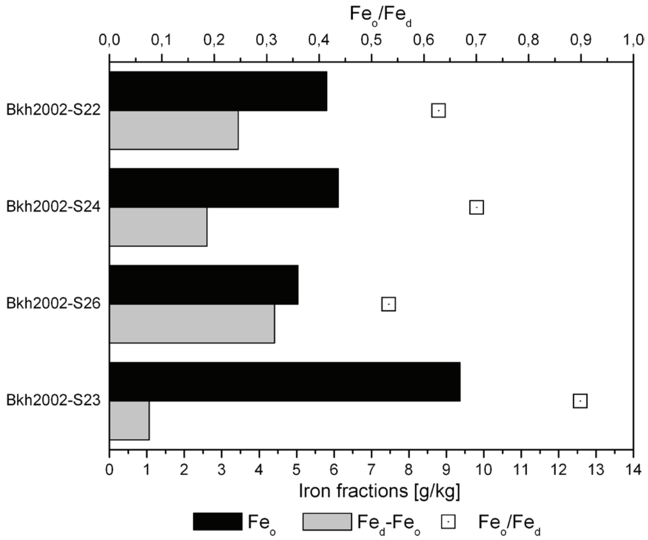

Figure 3. Values of Fe_o, Fe_d-Fe_o, and Fe_o/Fe_d in different soil horizons of profile Bkh2002-S22 to S26. Late Pleistocene paleosol, Kurungnakh Island.

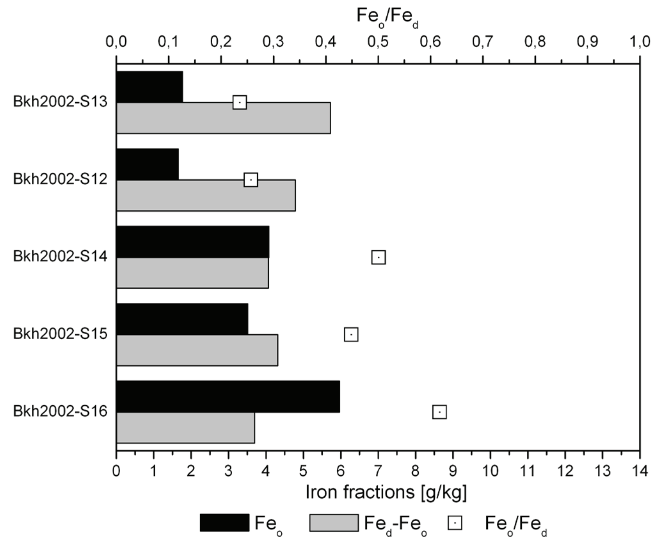

Figure 4. Values of Fe_o, Fe_d-Fe_o, and Fe_o/Fe_d in different soil horizons of profile Bkh2002-S12 to S16. Late Glacial paleosol, Kurungnakh Island.

The third terrace was formed in Middle and Late Pleistocene (Schwamborn et al. 2002). We collected samples of different ages from 5.8 to 40 ky BP (Schirrmeister et al. 2003, Wetterich et al. subm.).

Samples of modern soils have been taken on Samoylov Island during the expedition 'LENA – New Siberian Islands – 2007' in summer 2007 from the active layer of a low-centered polygon (Fig. 2).

Samples were collected from each layer of individual exposures. Pedological descriptions including Munsell soil color, fresh weight and other morphological remarks were made in the field. All analyses were done on the <2mm fraction and data are expressed on an oven-dry basis (105°C).

For pH determination a soil suspension with 0.01 M $CaCl_2$ was prepared and measured after an equilibration time of one hour with pH-Meter Schott CG820.

Total organic carbon (TOC) and nitrogen (N) were determined by VarioMax Elementaranalysator (Elementar Analyse Systeme GmbH).

A special consideration is given to different pedogenically formed iron-oxides to compare recently formed cryosols with paleosols of deeper sediment layers of both islands.

Oxalate-extractable iron (Fe_o) was determined by the method of Schwertmann (1964) at room temperature, in dark with acid ammonium oxalate at pH 3.25. Dithionite-extractable iron (Fe_d) was determined by the DCB method of Mehra & Jackson (1960) with dithionite-citrate buffered by bicarbonate at pH 7.3. Iron in all extracts was determined by Atomic-Absorption-Spectrometer.

To make an estimation of the degree of pedogenesis and relative age of a soil-horizon using analysis of different forms of Fe the following fractions were used: Fe_o as "active" Fe-oxides, probably ferrihydrite, (Fe_d - Fe_o) as Fe-oxides in less "active" well crystallized form, probably goethite and the ratio Fe_o/Fe_d as a degree of activity and pedogenesis.

Results and Discussion

Bkh2002-soil-sample series, Kurungnakh Island (Expedition 2002)

This sample collection represents the paleosols of the third terrace of Lena Delta. The lowest part of the third terrace consists of fluvial sands with low organic matter content (Schwamborn et al. 2002, Wetterich et al. subm.). The accumulation conditions were shallow water similar to the modern flood plains (Schirrmeister et al. 2003). The pedogenesis was characterized by hydromorphic conditions scarce vegetation and a cold dry climate. The unit was radiocarbon dated to >57 ky BP (Schirrmeister et al. 2003). The sand unit is covered by ice complex deposits (17 – 29.5 m a.r.l.). The profile Bkh2002-S22 to S26 (24 – 26.1 m a.r.l.) belongs to the ice complex sequence that was formed during the Late Pleistocene regression (Schwamborn et al. 2002). It is composed of fine grained poorly sorted sediments, thick peaty paleosols and large ice wedges (about 5 m wide and 20 m high). The thick peat layers were found in the lower part of the ice complex. They are thinner in the upper part where sand lenses were often observed. According to radiocarbon ages the entire ice complex sequence was formed between 44 and 17 ky BP in connection with niveo-eolian and slope processes (Schirrmeister et al. 2003, Wetterich et al. subm.). Pedogenesis during this time mirrors relatively warm and wet interstadial climate with tundra-steppe vegetation. Climate conditions with high production of organic matter are clearly recognizable in the extracted iron-oxide values that vary from 5 to 9.4 g/kg for active not crystallized oxides (Fe_o) and 1.1 to 4.4 g/kg for crystallized oxides (Fe_d-Fe_o) (Fig. 3).

High amounts of organic matter as they were found in the peaty paleosols with TOC values from 3.5 to 7.1% (Tab. 1) hinders the transformation of active iron-oxides to more crystallized oxides or even leads to formation of Fe-organic complexes (Cornell & Schwertmann 2004).

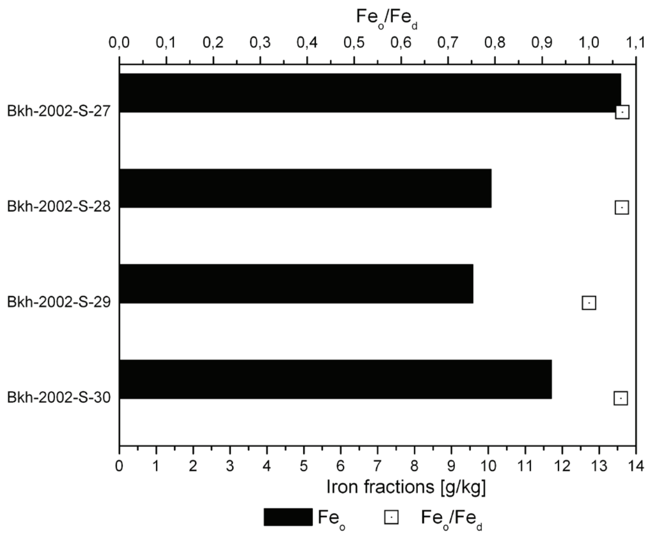

Figure 5. Values of Fe_o, and Fe_o/Fe_d in different soil horizons of profile Bkh2002-S27 to S30. Early Holocene paleosol, Kurungnakh Island.

According to the high amount of Fe_o-fraction the Fe_o/Fe_d ratio is relatively high with amounts from 0.5 to 0.9. The highest ratio was measured in the Bkh2002-S23 sample of a peat layer (TOC – 7.1%) that was formed during the wettest and warmest conditions that existed between ca. 44 and 38 ky BP (Schirrmeister et al. 2003).

The pH values vary from 6.9 to 5.5 whereby the moderate acid one was found in the peat horizon with the highest Fe_o/Fe_d ratio.

The ice complex is covered by two younger units dated to 17 – 8 ky BP and 6 – 3 ky BP respectively. The first one (29.5 – 33.5 m a.r.l.) was formed under very cold and dry climate with scarce steppe-like vegetation and dry soil conditions (Schirrmeister et al. 2003, Wetterich et al. subm.). It consists of poorly sorted silt deposits with low organic matter content. In this unit Bkh2002-S12 to S16 were sampled (29 – 31 m a.r.l.).

Values of the extracted iron-oxides vary from 1.7 to 6 g/kg and 3.7 to 5.7 g/kg for Fe_o-oxides and Fe_d-Fe_o-oxides respectively (Fig. 4). The Fe_o/Fe_d ratio is relatively low in the samples Bkh2002-S13 and S12 with 0.24 and 0.26. With increasing altitude the ratio decreases. The highest ratio of 0.62 was found in Bkh2002-S16 (29 m a.r.l.) sampled of a mixed horizon of sand and peat. Under dry and cold late glacial climate conditions with scarce vegetation and low organic matter content pedogenesis can progress but less intense well-expressed by relatively low iron activity ratio and high amounts of better crystallized iron-oxides indicating dry soil conditions with distinct iron-oxide crystallization.

The TOC values vary from 1.1 to 4.7% and pH values show low variability in the sandy horizons (7.4–7.3). In the mixed horizon there are weakly acid conditions (6.7) corresponding to higher content of organic matter (TOC–4.7%) similar to the last sample of the ice complex profile (Bkh2002-S23).

Samples of the last profile were taken from the youngest unit that was formed in Mid Holocene (6 ky BP). It was comprises of 4 samples (Bkh2002-S27 - S30) taken from

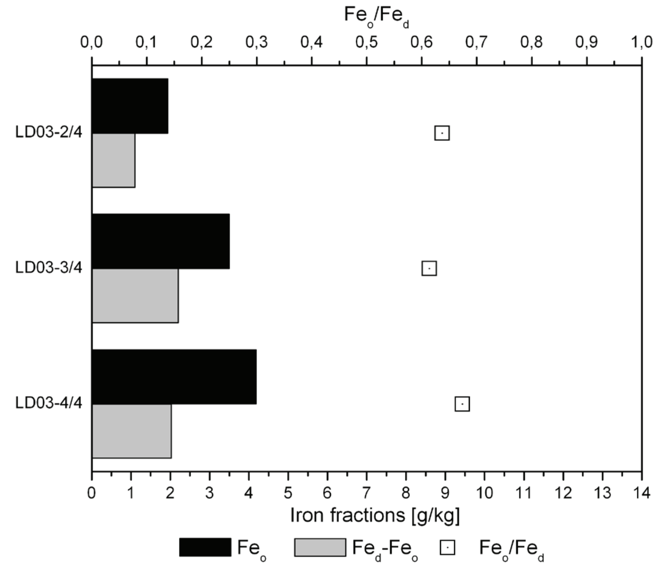

Figure 6. Values of Fe_o, Fe_d-Fe_o, and Fe_o/Fe_d in different soil horizons of profile LD03-2/4 to 4/4. Modern Gelisol Typic Historthel, Samoylov Island.

the 33.5 to 34.7 m a.r.l. The values of not crystallized active iron-oxides and Fe-organic complexes are very high and vary from 9.6 to 13.6 g/kg (Fig. 5). Crystallized iron-oxides were not verifiable, because of negative Fe_o-Fe_d values.

The Fe_o/Fe_d ratio is about 1 and the highest described in this paper. The pH values are acid (4.4 to 4.9) and correspond to the high organic matter content (TOC 3 to 4.6%) throughout the entire profile that consists of grey silt sediments with peat lenses. These sediments with high amounts of organic matter developed because of warmer climate, which caused a vegetation change to tundra-like. According to paleoenvironmental reconstructions (Wetterich et al. subm.) the pedogenesis took place under wet local conditions during this period.

LD-soil-sample series, Samoylov Island (Expedition 2007)

This sample collection which is composed of two active layer profiles represents recent pedogenesis on the first terrace of Lena Delta. The first terrace is of Holocene age and the young floodplains are assumed to represent the active part of Lena Delta. Maximum altitude is 12 m a.r.l. representing the oldest parts of the first terrace. The first terrace is formed by fluvial sediments that change from organic-rich sands at the bottom to silty-sandy peats towards the surface including several layers of eolian sands (Akhmadeeva et al. 1999, Schwamborn et al. 2002). This terrace is characterized by active ice wedge growth, low- and high-centered polygons, and thermokarst lakes.

The investigated profiles were sampled at a cross-section of a typical low-centered polygon (Fig. 2). These modern soils were classified by using U.S. Soil Taxonomy (Soil Survey Staff 2006).

In the polygon center a Typic Historthel (LD03-2/4 – 4/4) (11.85 – 11.5 m a.r.l.) and at polygon rim a Glacic

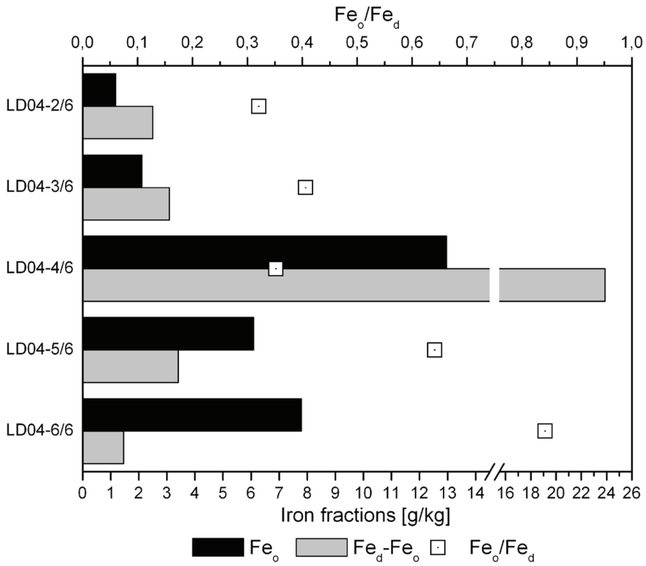

Figure 7. Values of Fe_o, Fe_d-Fe_o, and Fe_o/Fe_d in different soil horizons of profile LD04-2/6 to 6/6. Modern Gelisol Glacic Aquiturbel, Samoylov Island.

Aquiturbel (LD04-2/6–6/6) (11.95–11.5 m a.r.l.) were selected (Figs. 6, 7).

In the polygon center the values of the oxalate extractable iron-oxides (Fe_o) vary from 1.9 to 4.2 g/kg and for crystallized iron-oxides from 1.1 to 2.2 g/kg where the lowest values (Fe_o - 1.9 g/kg, Fe_d-Fe_o – 1.1 g/kg) were found in C-horizon (sample LD03-2/4) containing an eolian sand band at the altitude of 11.85 m a.r.l. (Fig. 6) with very slightly decomposed organic matter with C/N of 25. (Table 1). All horizons of this profile are rich in organic matter (TOC values from 1.8 to 5.5 %) and high C/N values from 23 to 25.2. Due to the organic matter the Fe_o/Fe_d ratio is relatively high. The pH values are strongly acid (4.5 – 4.8) and show low variability (Table 1).

The Fe_o values of the investigated Glacic Aquiturbel (LD04-2/6–6/6) vary from 1.18 to 12.96 g/kg and values of less active iron-oxides vary from 1.1 to 23.87 g/kg. The particularly high values were extracted from the Bg1jj-horizon (sample LD04-4/6) containing an iron band (Figs. 2, 7). This iron band can probably be considered as an enrichment horizon due to element redistribution among recent soil profiles by downward-translocation of mobile iron (Fiedler et al. 2004).

Relatively low values of iron-oxides in C- and A-horizon (samples LD04-2/6 and 3/6) support this hypothesis (Fig. 7) when they are regarded as eluvial horizons. The Fe_o/Fe_d ratio is low in the upper part of the profile. The value increases with increasing depth below ground surface. The upper horizons are first aerated during the slow process of thawing in spring and summer. This leads to the transformation of active iron-oxides to more crystallized oxides in the upper part. The pH values vary from 4.6 to 5.8 with strongly acid values in horizons Bg2jj and Bg3jj (samples LD04-5/6 and 6/6). The organic matter content (TOC) is lower than in the polygon center and shows values from 1.5 to 2.3% (Tab. 1).

Table 1. Analysis data of different soil horizons. Bkh2002: paleosol samples, Kurungnakh Island. LD: modern soil samples, Samoylov Island.

Soil sample	Altitude [m]	pH [$CaCl_2$]	TOC [%]	C/N
Bkh2002 - S27	34.70	4.9	4.6	18.1
Bkh2002 - S28	34.50	4.4	3.6	17.9
Bkh2002 - S29	34.00	4.6	3.8	19.7

LD04-5/6	11.80	4.7	1.9	14.0
LD04-6/6	11.70	4.8	1.5	15.4
LD03-2/4	11.85	4.5	1.8	25.2
LD03-3/4	11.80	4.8	5.5	24.5
LD03-4/4	11.70	4.8	4.2	23.0

Conclusions

The differences in values and ratios of extractable iron-oxides suggest that changes in forms of iron-oxides depend on the main soil material and water conditions. The influence of organic matter on iron-oxide transformation from young and active to more crystallized oxides is in evidence.

Paleosols show clear differentiation according to their stratigraphic position and paleoenvironmental conditions.

Soils that developed under relatively warm and wet interstadial climate (44–38 ky BP) and during the Early Holocene Climatic Optimum (8–6 ky BP) are characterized by relatively low values of well crystallized iron-oxides due to climatically caused high production of vegetation and the negative effect of the organic matter on the crystallization progress. Dry stadial climatic conditions as they were predominant at the end of Late Pleistocene (about 17 ky BP) associated with lower production of biomass and higher aeration of soil horizons principally lead to the formation of varying iron-oxides with relatively high values of the well crystallized fraction.

The results of the investigated modern soils from the active layer are comparable with those of the paleosols. The organic matter content and the seasonal inundation play a major role for Fe-transformation in modern soils. Further elements of modern soils are affected by translocation processes within the polygon. Detailed considerations of processes taking place in polygons during thawed periods have to be included in further investigations.

This approach promises to be more effective when applied to iron-oxides. The identification of texture and minerals and the radiocarbon dating of all samples will be finished. The analysis is still in progress.

Acknowledgments

This paper is based on the joint Russian-German science cooperation "System Laptev Sea" supported by the German Ministry of Education and Research. We thank the University of Hamburg and the Alfred Wegener Institute for Polar and Marine Research for financial support. We thank all Russian and German colleagues who helped us during fieldwork and laboratory studies. In addition, we thank Leon von Below for English language correction as well as two anonymous reviewers for their helpful comments.
